and

$$\frac{0.923}{14} = 0.066, \textit{ or } 6.6 \textit{ per cent. additional}$$

A similar calculation for the second case with a 26-inch vacuum and 80 per cent. humidity, with the engine using 15 pounds of steam per horsepower-hour, gives:

Air per minute =

$$\frac{15}{60} \times 184$$

Horsepower to fan =

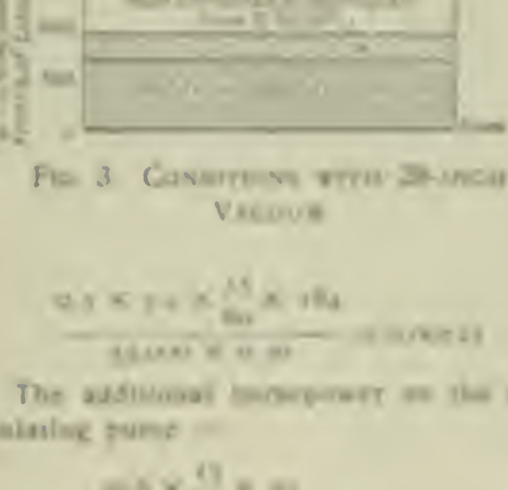

FIG. 3. CONDITIONS WITH 26-INCH VACUUM

$$\frac{0.3 \times 5.2 \times \frac{15}{60} \times 184}{33{,}000 \times 0.30} = 0.00724$$

The additional horsepower on the circulating pump =

$$\frac{20.6 \times \frac{15}{60} \times 30}{33{,}000} = 0.00468$$

If the fan engine and the circulating apparatus were steam driven, then using the same rate as before:

$$0.0072 \times 35 + 0.00468 = 0.443$$

and

$$\frac{0.443}{15} = 0.0295, \textit{ or about 3 per cent. additional}$$

If the cooling surface used in the tower offers much resistance to the free discharge of air from the fan through the tower, it may be necessary to run the fan at a higher velocity and this increases the work of driving.

Spray Nozzles

By spraying water into the air, cooling may be effected through the evaporation of a part of the water just as in the case of the cooling tower. The total exposed surface of the sprayed jet meets less air per pound than in the cooling tower, and on this account it is often advisable to spray 30 to 50 per cent. of the water a second time before sending it through the condenser.

Generally speaking, spray nozzles of the size known as 2 inches are the most economical. This size screws onto a 2-inch outlet, the opening in the nozzle tip being about 0.8 inch. As many nozzles should be provided as are needed to discharge the entire weight of condensing water under a pressure of not over 15 pounds gage at the nozzle.

The nozzles should be set from 8 to 10 feet apart if 2 inches; and a greater distance if over 2 inches. Where a number of nozzles are used, it is customary to have the water which is sprayed into the air fall back into an artificial pond one or two feet deep. Also, when a number of nozzles are in use the aspirator effect produced by the jets causes a current of air to flow along the surface of the pond from the edge toward the center and this current of air assists to some extent in the cooling.

In some few instances spray nozzles have been put along the edges of a narrow brook and the falling spray caught on board fences inclined 30 degrees with the ground and draining into the brook.

There are a few small plants where the cooling nozzles discharge onto the roof of the building. The extra head of water on the circulating pump makes this inadvisable, however.

Experiments on Schutte & Köerting nozzles of sizes known as 3, 2 and 1 inches have been carried on at the Massachusetts Institute of Technology since 1908; and at the present time two other types of nozzle are being tested. The nozzle under test is placed at the center of a flat roof about 44x40 feet, sloping 1 foot in 10 feet, and the water caught on the roof is drained into tanks and weighed. The discharge through the nozzle is figured from the pressure shown by a gage attached to a piezometer just beneath the nozzle, the coefficient for each nozzle having been determined by exhaustive tests made in the laboratory. From the tests on the Schutte & Köerting nozzles the following seem to hold true:

1. The temperature of the water after spraying is more dependent upon the temperature and humidity of the atmosphere and upon the fineness of the spray than upon the initial temperature of the water. Therefore, it is advisable to spray the water as hot as possible without excessive steaming.

2. At high humidities, say 80 or 90 per cent., the temperature of the water may be lowered to within 12 or 13 degrees Fahrenheit of the temperature of the air, with a total drop in temperature of 35 to 40 degrees Fahrenheit.

3. At low humidities, of 20 to 30 per cent., the temperature of the water after spraying may be as much as 8 degrees below the temperature of the air and the total drop in temperature 40 to 45 degrees Fahrenheit.

4. The loss of water by evaporation is approximately 0.15 pound per degree lowering of temperature per 100 pounds of water discharged, or a gross loss of about 6 per cent. for 40 degrees Fahrenheit lowering of temperature. In no case was the loss found to exceed 7 per cent.

The discharge from these nozzles was found to be as shown in the following:

DISCHARGE FROM NOZZLES UNDER TEST

Head in Feet at Base of Nozzle	Cubic Feet per Minute for 1-Inch Pipe. Diameter of Nozzle at Tip = 0.406 Inch	Cubic Feet per Minute for 2-inch Pipe. Diameter of Tip = 0.800 Inch	Cubic Feet per Minute for 3-inch Pipe. Diameter of Tip = 1.181 Inches
25	1.782	6.736	14.83
30	1.952	7.379	16.24
35	2.109	7.971	17.54
40	2.254	8.521	18.75
45	2.391	9.036	19.89
50	2.520	9.526	20.97
55	2.643	9.991	21.99
60	2.761	10.44	22.97
65	2.873	10.86	23.91

Cooling Ponds and Spray Nozzles

When there is a natural pond of moderate size adjacent to a power plant, sufficient cooling may be obtained by spraying all or a part of the condenser discharge, the cooling from the surface of the pond being of considerable assistance.

Cooling Ponds

Unless the pond is of considerable area the cooling from mere surface contact with the air is not usually sufficient to keep the temperature from rising, especially on hot damp days.

Bonom Steam Turbine

A brief description of a new development of the radial-flow turbine, showing the steps taken to secure a maximum number of expansions in a machine of comparatively small diameter and short length.

In the development of the steam turbine which has been more rapid than that of any other prime mover a great diversity of types has been evolved. In the axial flow in order to get the largest possible number of expansions it has been necessary to use designs involving rotors of either comparatively great length or of large diameter. In the radial flow the diameters have been large, and of comparatively low rotative speed. The Bonom turbine is a radial-flow machine of comparatively small diameter and short length and consequently capable of a high degree of rotative speed or of containing within a small space the number of stages necessary for efficiency at low speeds.

If the long rotor and case of an axial-flow turbine could be compressed accordion fashion into a series of rings of uniform diameter with deep recesses between, and with buckets or blades on the sides of the rings running between the redirecting buckets of the case it would in a way illustrate the Bonom idea of turbine construction.

The idea of the turbine is shown in the longitudinal and cross-sections, Figs. 1 and 2, the latter consisting of eight partial sections through the correspondingly numbered planes of Fig. 1.

At the left of the casing is the inlet chamber or steam chest extending entirely around the case furnishing steam to the ring of nozzles, which are opened and closed by a perforated ring valve under the control of the governor.

These nozzles are of the convergent-divergent type designed for a considerable initial fall of pressure with the production of a high jet velocity. They are shown in the section *I—I* of Fig. 2 which shows also the three rows of blades, the middle one stationary and the two others moving, through which this velocity is abstracted. The initial stage is thus of the double-velocity or Curtis type, expanding the steam to such a volume that even with full admission, that is, with steam admitted through the full circumference, the first blades may be of considerable size. This reduces the proportion of clearance to blade area, and the low pressure attained by expansion in the symmetrical nozzles reduces the tendency to leak by the blades in the later stages.

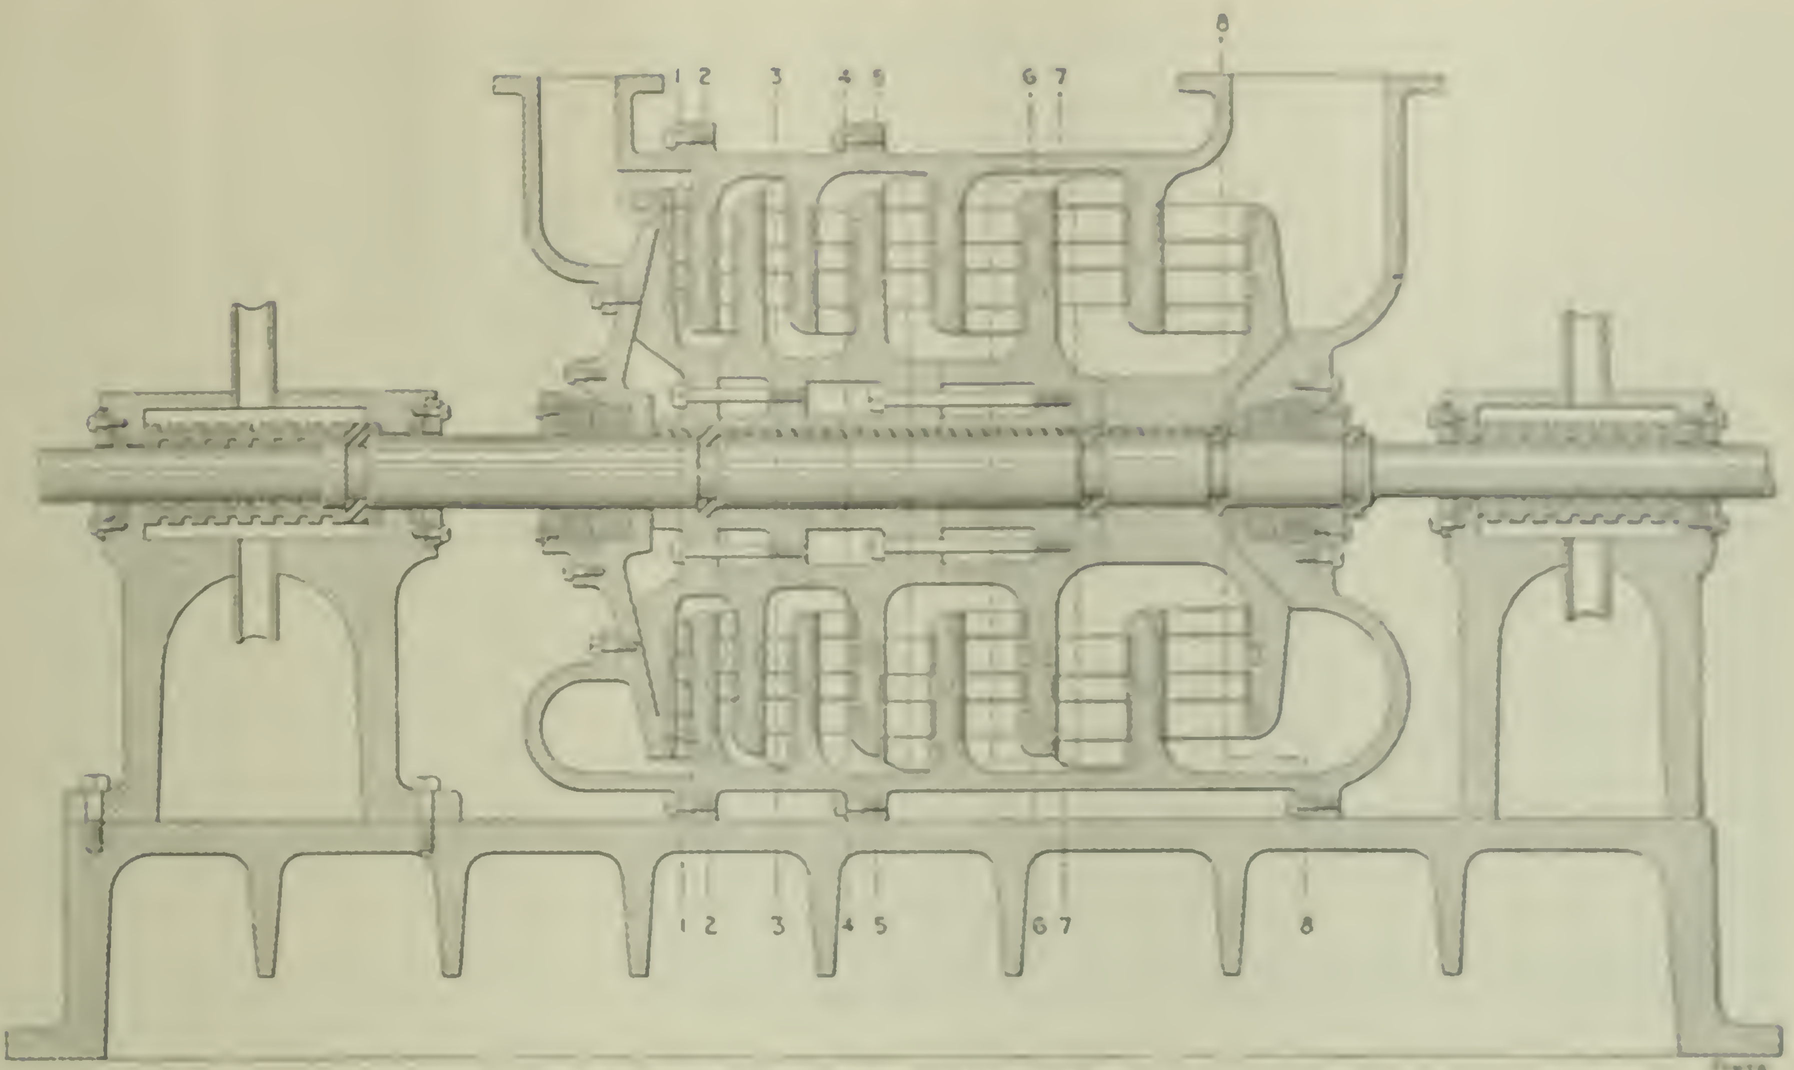

Fig. 1. Sectional View of Binom Steam Turbine

After the first stage the type becomes that of Parsons with continuous expansion through the constantly increasing passages of alternately rotating and fixed rows of blades. The peripheral velocity of the blades would be different, according as they were nearer to or farther from the shaft; but if the design favors those having the mean velocity it is suggested that a change in speed will improve the efficiency of those to one side of this line while diminishing that of those upon the other and thus permit a considerable change in speed with small variation in torque or efficiency.

Both the moving and stationary vanes are secured in dovetail grooves and are provided at the outer ends with lips which connect one to the next and form a complete shroud which except for the necessary mechanical clearance closely fits an annular groove at the opposite side of the chamber, making a smooth continuous path for the steam and preventing the in-

Fig. 2. Partial Cross-sections through Lines 1-1 to 8-8

Fig. 3. Blade and Method of Attachment

cape of steam around and over the ends. This is clearly seen in Fig. 1, while Fig. 3 shows the form of the buckets and their arrangement, both in the stationary and moving parts.

Fig. 4 shows the disassembled stator rings, and Fig. 5 the rotor rings reassembled on the shaft, giving a clear presentation of the progressive increase in the volume provided for the expansion of the steam as it gives up its energy in passing through the successive stages. In the stator ring at the right in Fig. 4 the first set of directing nozzles is plainly shown. Around the outside of this circle of nozzles there is another ring with perforations corresponding to the entrance openings of the nozzle which under the control of the governor is advanced or retrograded as the load demands, throttling the steam for light loads or giving a wide opening for heavy ones.

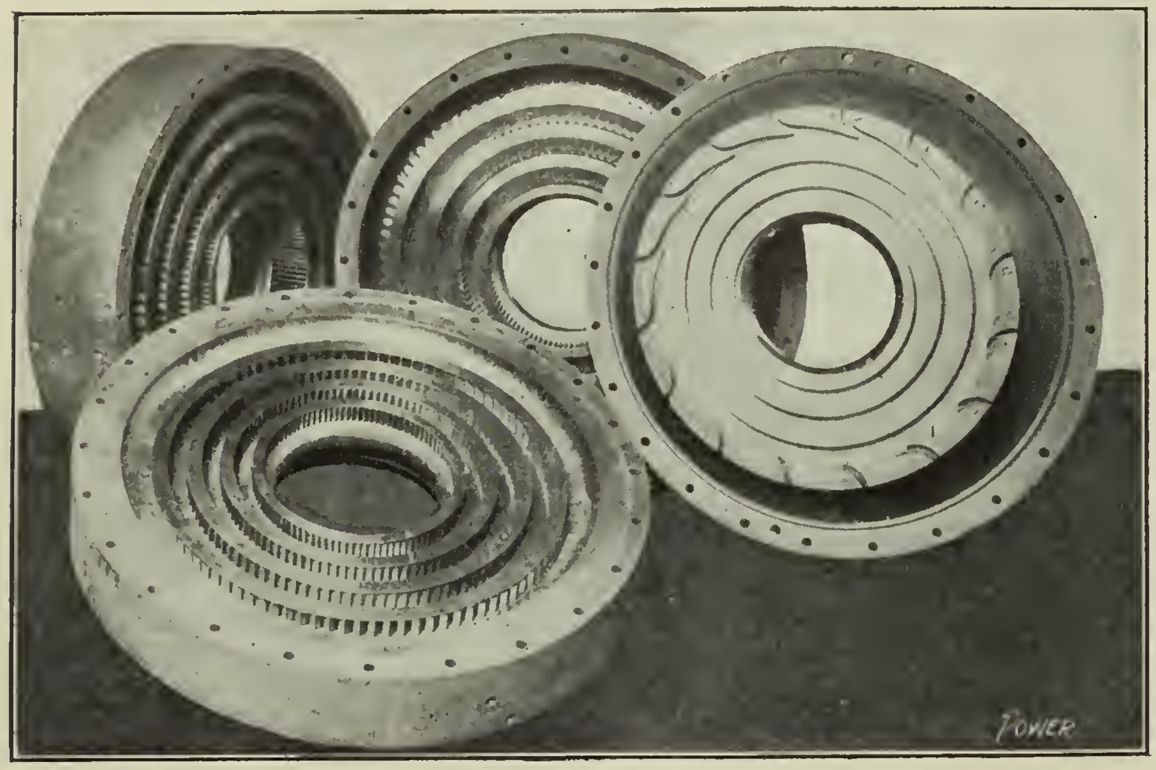

Fig. 4. Disassembled Stator Sections

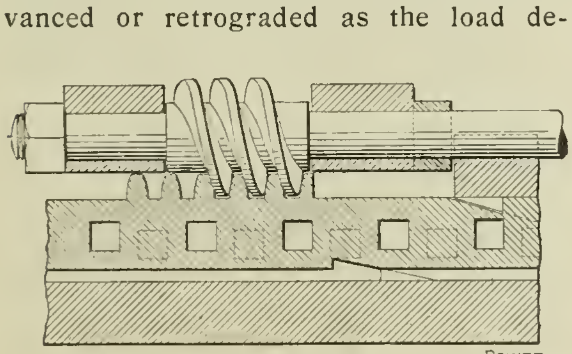

Fig. 6. Circumferential Valve

Fig. 6 is a short section, showing the construction and method of operating this admission ring which may be called the circumferential valve. This valve is moved circumferentially by the worm and is also guided in a sidewise direction by angle blocks which cause the openings through the valve to approach and pass over the entrance openings of the nozzle diagonally until full opening is obtained when the valve reaches full travel.

The drawings submitted do not show any provision for balancing the end thrust resulting from the differences of pressure on opposite sides of the rotating disks. This may be done by the use of a dummy piston which may be small on account of the absence of high-pressure steam in the bladed portion of the case; by reversing the flow and making the pressure act toward the nozzles in the later stages, or by splitting the turbine into a double-flow, a procedure favored by the original acceptance of the initial-velocity stage.

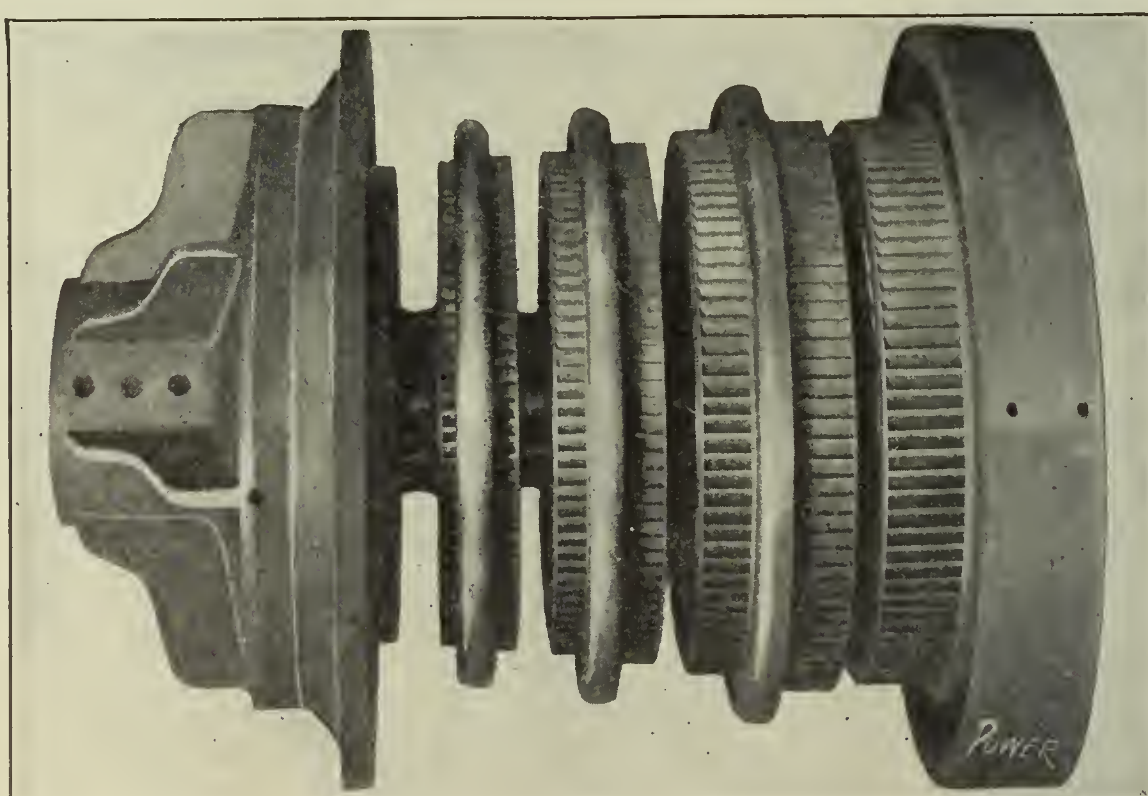

Fig. 5. Rotor Showing Progressive Increase in Width of Blades

It is intended to build these machines in convenient commercial sizes for all classes of work.

The inventor is Alfred Bonom and the turbine is handled by the Bonom Turbine Company, Central Bldg., Paterson, N. J.

The Value of the CO_2 Recorder

By H. S. Vassar

In a recent issue of Power there appeared a letter headed, "Economy in the Boiler Room," which called attention to the need of boiler-room records, especially in the case of electric-power plants. The article was a timely one, bringing out many points which certainly require watching if economies are sought.

I noticed, however, that more stress was laid on flue-gas analysis than on daily coal and water records. Personally, I am inclined to the opinion that without the latter, CO_2 records are of little use. Now, I have no quarrel with those who have so ingeniously devised automatic devices for flue-gas analysis as I fully believe that such instruments have a proper place in many boiler rooms. There are, though, other plants in which CO_2 apparatus has been installed with no facilities for daily coal and water weighing.

Such a condition reminds me of a hungry man who, neglecting the more substantial viands on the table, attempts to satisfy his appetite with pudding or pie. CO_2 enthusiasts often assume that a knowledge of the percentage of CO_2 carries with it something definite concerning the amount of air. While this is true of *excess* air it is not true of the converse, that is, CO_2 records tell nothing about an *insufficient* air supply, resulting in the formation of CO. Unfortunately, high CO_2 is frequently accompanied by a greater or less percentage of CO, the loss due to which sometimes more than offsets the gain due to the low excess-air volume indicated by the high CO_2. Therefore, while high efficiencies cannot be expected with low

CO_2 it does not necessarily follow that high CO_2 is accompanied by economical combustion. In other words, the indications of the automatic CO_2 machines appear to me to be largely negative.

After several years' experience with flue-gas analysis and boiler testing, I do not believe that CO_2 records are at all dependable as measures of furnace efficiency. In support of this contention Figs. 1 and 2 are submitted. These charts

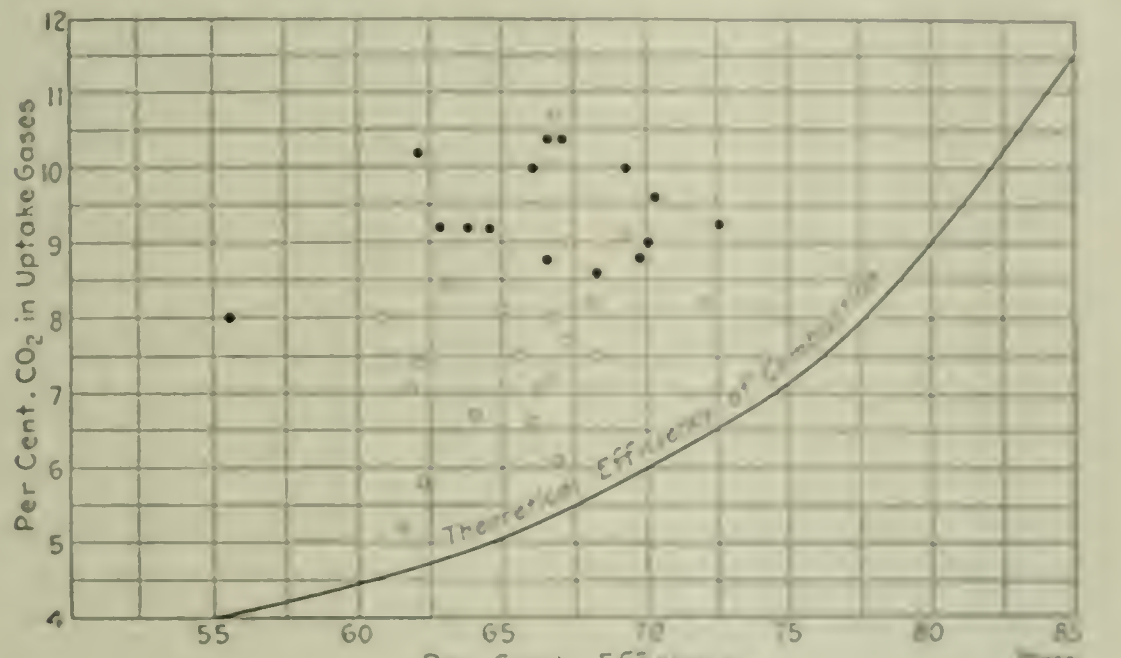

FIG. 1. COMPARISON OF CO_2 PERCENTAGE IN UPTAKE GASES AND EFFICIENCY OF COMBUSTION

were made to establish, if possible, some relation between the percentage of CO_2 in the gases of combustion and the combined boiler and furnace efficiency. They show the results of two series of 8-hour tests on Babcock & Wilcox boilers equipped with mechanical stokers of the inclined type. The tests of the first series, indicated by the black points, were all made on the same boiler and with the same fuel but with various changes in the grate equipment, draft, air admission, etc. In the tests of the second series, indicated by the open circles, several different fuels were burned. All of the coals used were Pennsylvania semi-bituminous.

The CO_2 figures are from continuous samples taken throughout the various tests. In Fig. 1 the samples were from the uptake while in Fig. 2 they were from the top of the first pass. The points at which the samples were collected and the apparatus used were the same in all cases.

The curves showing the theoretical efficiency of combustion were plotted from data given by several different manufacturers of CO_2 instruments and are supposed to show the efficiency of combustion as indicated by the CO_2 content of the flue gases.

I have also used other sets of test figures in the attempt to prove the value of CO_2 records, but with no better results than in the case given.

A word also relative to the paying of bonuses to firemen, based on their CO_2 records, may not be amiss. Two firemen handling boilers side by side may secure results something as follows: "A" burns 2000 pounds of coal in a given hour under his boiler with a CO_2 record of, say, 7 per cent. "B," who fires the adjoining boiler, may burn only half that amount of coal with correspondingly small steam output, but his CO_2 record may be 12 per cent. In other words, "A" does the work and "B" gets the glory and the cash. I do not say that such methods are followed, as, in plants where the system is in use, the supervision is such as to preclude tricks of this kind but, if it lies within the power of the individual fireman to alter his conditions of draft or air supply, such a thing could be easily brought about.

Some of those who have studied the matter of boiler-room management maintain that the chief value of CO_2 recorders lies in the increased attention which is given to the boiler room rather than to the records obtained. In these days, when we hear CO_2 recorders talked of on every side, perhaps some are a little timid about questioning their value. It reminds me of a fairy tale read during my boyhood. The story ran somewhat as follows:

Two strangers, pleasing in appearance and glib of tongue, appeared one day in the court of a certain king, announcing that they were the sole manufacturers of a most beautiful fabric for royal robes. Indeed, its texture was so wonderfully fine that it was rendered invisible to all save the very wisest of men. Samples were displayed to the king who, at a fabulous price, ordered a robe of the material. For days and days weavers worked at their looms weaving airy nothings from nothing. At last, the great day came when the king was to appear before his people arrayed in the wonderful robe which only the "wise ones" could see. Loud were the exclamations of admiration from his awe-struck subjects.

But, at last, a little child who had not yet become as worldly wise as his elders piped out, "But the king hasn't any clothes on at all."

Once more I would not be understood as condemning all gas analysis nor would I "damn with faint praise," but from experience and observation thus far I believe that there are other practical aids to economical operation which should be in every boiler room before the CO_2 recorder. An Orsat or other type of hand apparatus for gas analysis can be purchased for one-tenth part of the cost of a recorder and will often accomplish just as much.

I have not thus far even mentioned the difficulties involved in keeping a recorder in condition for use. Some of those who now have recorders in operation could doubtless write a volume on that subject.

Perhaps this will "start something."

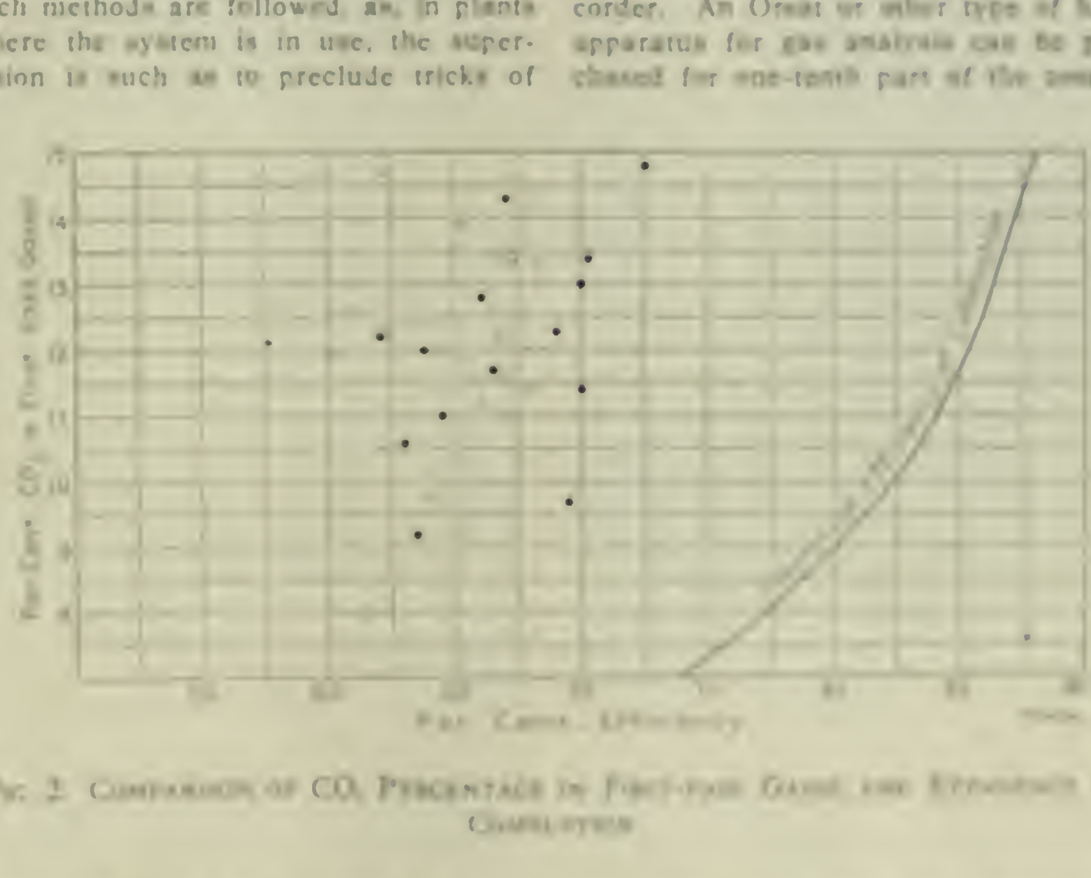

FIG. 2. COMPARISON OF CO_2 PERCENTAGE IN FIRST-PASS GASES AND EFFICIENCY OF COMBUSTION

Electrical Department

Especially conducted to be of interest and service to the men in charge of the electrical equipment

The Care and Operation of Storage Batteries

By Norman G. Meade

An electric storage battery is a combination of cells, each of which is a unit. In the ordinary type a cell is made up of three parts: the jar, the plates and the electrolyte. The jar may be of any good nonconducting and acid-proof material of sufficient strength and rigidity to support the plates and the electrolyte. In the smaller stationary types the jar is generally made of glass or hard rubber. Large cells for central-station work have containing tanks made of heavy planks well joined and lined with sheet lead.

The plates are of two kinds, termed positive and negative, placed alternately, and the number of negative plates is always one more than the number of positives. The group of plates contained in one jar or tank is commonly known as an "element." All of the positive plates in one jar are connected together and all of the negative plates are similarly connected, but the positive plates are separated from the negative plates by insulating strips.

Storage batteries of the ordinary lead-sulphuric acid type are divided into two general types: the Planté and the Faure. Both consist of lead elements in dilute sulphuric acid but the plates are prepared differently. The Planté type of plate is constructed of solid sheet lead so fashioned as to present a large surface area to the action of the electrolyte; the active material is formed on the plates, either electrically, by charging and discharging, commonly called forming, or chemically.

In the Faure type the active material is applied mechanically to lead conducting plates or grids; for this reason the Faure battery is commonly called the "pasted" type. The active material may be in active condition when applied or it may be in such condition that it must be converted into active material by electrical or chemical formation. The positive plate is made of lead upon which a coating of peroxide of lead has been formed or mechanically applied. The negative plate is made of pure lead with a very spongy or porous surface. The peroxide and spongy lead are the portions of the plates which are subjected to chemical action and therefore constitute the active material; the plain lead body of each plate serves as a support for the active material.

The chemical condition of the plates and electrolyte changes when the cell is charged and discharged. At full charge the positive plates have a rich dark-brown coating of peroxide of lead, and the negative plates are a dark slate color. In this condition an electromotive force is set up in the cell, and if the positive and negative terminals be connected through an external circuit, a current will flow through that circuit from the positive to the negative terminals of the cell. When discharged, the positive plates are of a reddish brown or chocolate color and the negative plates a light slate color.

During discharge, the active materials are partly converted to lead sulphate at the expense of some of the acid of the electrolyte, so that the latter becomes weaker. The strength of the electrolyte at any time, compared with its strength when the cell is fully charged, is an approximate indication of the extent of the discharge. The specific gravity should not be more than 1.2 when fully charged nor less than 1.13 when discharged. It decreases proportionately as the cell discharges. The voltage of a cell on open circuit, that is, with no current flowing, is approximately 2.1 volts. This value is reached very shortly after either charge or discharge ceases, though it is somewhat influenced by the strength of the acid, temperature and, to a minor extent, by the state of charge. During discharge the voltage drops, the rate of decrease depending on the rate of discharge and its duration. Toward the end of discharge, the voltage falls off rapidly; when this point is reached the cell should not be further discharged. Conversely, during the charging period the voltage rises. Toward the end of the charge the rise of voltage is quite sharp and, the conversion of the lead sulphate formed during the previous discharge being fairly complete, the water of the electrolyte begins to decompose into its elements, hydrogen and oxygen. When the charge is complete, practically the entire input of electrical energy is used in effecting this decomposition and vigorous "gassing" ensues; then the strength of the electrolyte and the voltage cease to increase.

All of the materials of the plates, the lead, spongy lead, lead peroxide and lead sulphate, are practically insoluble in the sulphuric acid of the electrolyte, especially when there are no traces of other acids present. For this reason the plates are quite permanent. Great care is taken to attain the maximum purity of all materials of the plates and electrolyte so that the action described will not be undesirably varied or modified.

The lead sulphate formed during discharge has a greater volume than either the spongy lead or the lead peroxide; consequently, there is expansion and contraction of the active materials. The lead peroxide of the positive plate being somewhat noncohesive, it is gradually ground up and during the subsequent gassing at the end of charge some of it falls off, forming sediment. In the normal action of the cell the lead underlying the lead peroxide is very slowly corroded, forming new active material. With proper operating conditions the amount of new active material thus formed should balance the amount which falls off as sediment. The spongy lead of the negative plates being quite cohesive, it does not fall off if the cells are kept free from short-circuits and foreign materials, but it gradually becomes somewhat more compact and through the diminution of its porosity the capacity decreases. The rate of this decrease is greatest at the start and finally becomes very small. The negative plates are given sufficient initial capacity to provide for this shrinkage. If, in time, these plates show less than their rated capacity, they may be reversed by separately charging, with the proper precautions. This process causes the material to again expand and the initial capacity is restored.

In the action of the cell some water is lost through decomposition toward the end of each charge; this evaporation is made up by adding pure water to the electrolyte. It is usually necessary to add acid only when cleaning and removing the sediment. As already intimated, both the acid and the water used for making the electrolyte and replenishing it must be as near absolute purity as possible. Foreign acids (organic impurities are usually converted to acids in the action of the battery) must not be allowed to get in; they lead to rapid corrosion of the positive plates. Other impurities lead to local actions with consequent loss of charge and must therefore be avoided.

If a lead-acid cell is allowed to stand partly or wholly discharged for any length of time, the normal action is also departed from, especially at the positive plates. The active material is with difficulty converted back to peroxide and the underlying lead may be rapidly corroded under certain conditions. Charging should therefore follow a discharge as soon as practical.

FIG. 1. SAND TRAY

CELL STRUCTURE AND MOUNTING

Storage-battery cells for light and power plants are usually provided with either glass jars, glass tanks or lead-lined wooden tanks. The smaller cells are usually put in glass jars each of which is set on a bed of sand contained in a glass or wooden tray; the sand tray is supported by four glass insulators placed under the corners, as shown in Fig. 1. Cells of medium capacity are usually built with tanks of pressed glass; no sand trays are used, the glass tank resting directly on the glass insulators except for small cushions of either lead or rubber interposed to keep the hard surfaces of the two glasses out of contact.

Cells of the glass jar or glass tank type are the easiest to install because the plates are grouped at the factory. The plates of each cell are connected by cross-bars and terminal straps of lead, the negative plates to one cross-bar and the positive plates to the other as shown in Fig. 2. The plates and straps are connected by "burning." The cells are connected to each other by bolting the lead terminal straps together with lead-covered brass bolts.

Lead-lined wooden tanks are often used for plates of medium size and always for those of large size. The plates of this type of cell are grouped at the place of installation by lead-burning the lugs of the positive plates to a common bar and the negative plates to another bar. Fig. 3 shows how a tank cell of this type should be mounted.

All types of storage cell are usually installed with the supporting insulators resting on wooden stringers, these stringers having been previously covered with two or three coats of acid-proof paint. Cells of smaller types which are not too heavy are generally installed on two-tier wooden racks in order to economize floor space. The large cells are installed all on a single level, the wooden stringers being supported by vitrified brick set upon the floor or by another set of glass insulators resting on vitrified tiles.

Batteries should be installed in rooms especially prepared for them. The rooms should be dry and arranged for maintaining a moderate temperature during cold weather, otherwise the capacity of the battery will diminish by reason of the reduction in temperature. The batteries should also be located so that they will not be subjected to artificial heat during

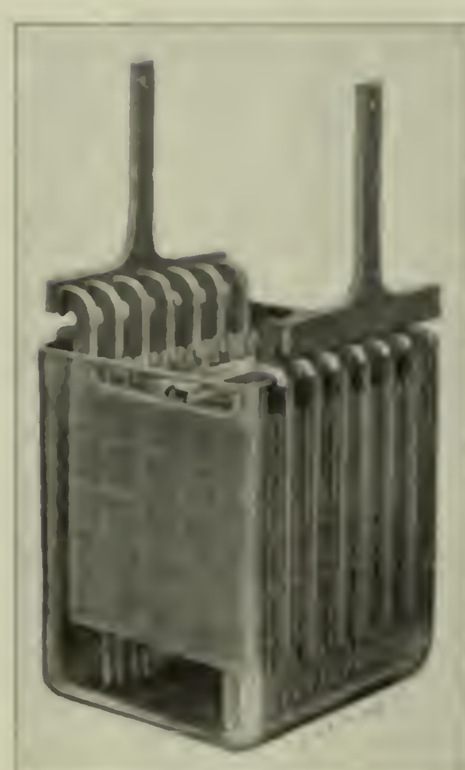

FIG. 2. CELL IN GLASS JAR

the summer and the temperature thereby raised above that of the external air.

Provision for ventilation and the removal of acid fumes should be made. The floor should be of asphalt, tile or cement, the last-named being the least desirable, and should slant slightly toward discharge drains in the floor. All copper work should be coated with tin or lead and all other metal work should be covered thoroughly with an acid-resisting paint. The cells should be arranged so that each one may be easily inspected and tested.

INSTRUMENTS AND IMPLEMENTS

For the proper care and inspection of the batteries certain accessories should be provided. One of the most important of these is a low-reading voltmeter with a range of zero to three volts; it should be accurate and of such design that its needle quickly comes to rest. A substantial thermometer should also be provided in order that the temperature of the electrolyte can be ascertained. Its mercury bulb should not be too thin; if broken while in a cell, the mercury would damage the tank lining and the plates. A hydrometer is indispensable because its use is for testing the strength of the electrolyte, which must be done frequently. It comprises a weighted glass bulb with a long graduated stem and is used in the following manner: Some of the electrolyte is siphoned out of the cell to be tested into a tall cylindrical jar, large enough in diameter to contain the hydrometer; enough liquid is withdrawn to float the hydrometer. The number on the scale of the hydrometer at the point where the liquid surface is in contact with the stem is the specific gravity of the liquid, expressed in degrees. The specific gravity varies with the temperature and it is therefore necessary to reduce the readings to a standard temperature, which is taken as 70 degrees Fahrenheit. The correction is approximately 0.001 degree specific gravity for each three degrees by which the actual temperature differs from 70 degrees; the correction is added if the liquid is warmer than 70 degrees and subtracted if it is cooler.

A convenient means for ascertaining the specific gravity is a hydrometer syringe, which consists of a glass tube about an inch in diameter, one end of

FIG. 3. METHOD OF MOUNTING A WOODEN TANK

which is drawn down to a nozzle of small diameter to take a rubber hose, and the other end is closed by a large rubber bulb. A hydrometer is contained in the barrel of the syringe and by squeezing the bulb, inserting the rubber tube in the electrolyte and then releasing the bulb, sufficient acid can be drawn into the tube to cause the hydrometer to float and give a reading.

Soldered joints cannot be used in the [illegible] rooms and [illegible] connections outside of the cells must be practised with caution. Soldering fluxes must not be allowed to get into the cells even in the minutest particles. In repairing, all joints must be made by lead burning. In this process a hydrogen flame is used which frees the melted lead from any slag, whereupon it welds readily. The hydrogen generator and the balance of the outfit can be obtained from dealers in storage battery supplies but it must be employed only after thorough instructions, as accidents may readily result through ignorance of the precautions to be taken.

In making bench tests of a battery it is advisable to know the relative condition of the positive and negative plates of the different cells. This may be done on the discharge of the battery by reading the voltage between either group of plates and an auxiliary electrode, preferably of cadmium, immersed in the electrolyte but not allowed to touch the plates. Cadmium can be obtained in sticks about a quarter of an inch in diameter and 6 inches long. One end of the stick should have a terminal wire soldered to it and over the other end should be drawn a piece of perforated pure soft-rubber tubing long enough to cover about three-quarters of the length of the stick. It should always be immersed in a glass of electrolyte for several hours before using. Cadmium sticks, properly made up, can be procured from storage-battery supply dealers and manufacturers.

The Electrolyte

It is always preferable to purchase the electrolyte already mixed and of guaranteed purity. If, however, concentrated acid is used in preparing electrolyte, the latter should be made by pouring one volume of pure concentrated acid of 1.84 specific gravity into about five volumes of distilled water. The vessel used for mixing should be preferably a lead-lined tank unless the quantity is small; then a vessel of hard rubber, earthenware or glass is suitable. In mixing the electrolyte, always pour the acid into the water very slowly and constantly stir the mixture, as much heat is generated by the mixing of acid with water. Never pour the water into the acid, as the resulting splashing is liable to cause painful and dangerous burns. The solution must be left for several hours to cool. Never add hot or even warm electrolyte to a cell, as the plates are liable to be very badly sulphated by so doing. The strength of the electrolyte should always be tested by a hydrometer reading, reduced to 70 degrees Fahrenheit. It is always advisable to use distilled water for the preparation and replenishing of the electrolyte because ordinary city water usually contains foreign substances of an objectionable nature.

Charging

As soon as the electrolyte is poured in the cells, charging should begin, because it hurts the plates to stand in the liquid without being charged. The first charge should be carried on for a much longer period than the subsequent or working charges, as it virtually completes the formation of the plates.

The positive terminal of the generator must be always connected to the positive terminal of the battery. The charging process commences at about 2 volts per cell and rises to approximately 2.6 volts at full charge while taking current at the normal rate specified by the maker. The first charge should be continued for at least ten consecutive hours, and twenty or thirty would be preferable. The first charge is usually about twice the capacity of a battery, and should be made at the normal current rate.

The specific gravity of the electrolyte will drop during the first few hours of the first charge but will rise again as the process continues; its maximum point is reached at full charge.

As the charge nears completion, bubbles will rise from both plates and the charging current should then be reduced, as the active material is almost fully formed and therefore cannot take up all the gas set free from the decomposition of the acid at the normal rate. As the amount of the gas liberated is in proportion to the current flowing, gassing will decrease when the current is decreased. It will take from twenty to thirty charges to fit a new battery to give its full capacity, and it is well to charge for 25 per cent. longer time at the normal current rate for the first few months. In ordinary work the battery will retain its normal condition with a charge of 10 per cent. in excess of the discharge.

During ordinary charging the normal rate or lower should be used, except in case of emergency. Under normal conditions 2.5 volts may be considered full charge, although the battery can be charged higher than that. After repeated charges, the water in the electrolyte will have evaporated to such an extent that the reduction in volume will expose the top of the plates unless water is added; this should be done through a hose or tube reaching to the bottom of the cell, as water added otherwise will stay on top, being lighter than acid.

Although it is not always the most economical procedure, the highest efficiency and longest life are obtained when the battery is charged slowly, never exceeding the normal rate. Conditions of plant operation will determine the most economical practice for each installation.

Discharging and Care

When discharging at the normal rate a battery should never be discharged below 1.8 volts per cell. In discharging at a higher rate than normal, however, 1.8 volts per cell will be reached before the battery is discharged to the same condition as at normal discharge, owing to the internal resistance producing a greater drop of potential, in accordance with Ohm's law.

The battery cells must be kept clean and the terminals covered by a coating of vaseline. Corroded copper, iron or any other foreign materials must not be allowed to get into the cells. If through accident this occurs, all of the electrolyte in such cells must be thrown away and new electrolyte put in them. Matches or exposed flames of any kind must not be allowed near a battery, especially when it is being charged, because the gases then given off are combustible and, if sufficiently concentrated, explosive. Temperatures higher than 100 degrees Fahrenheit should be avoided because the corrosion of the positive plates is accelerated by such temperatures.

Each cell should be tested with a voltmeter and hydrometer once a week. Any cell showing low voltage should be examined thoroughly for any foreign substance that may have short-circuited it. This will be indicated by a low specific gravity and deficiency or absence of gassing, the voltage rising slowly at the end of a charge when it should rise rapidly.

When inspecting and overhauling battery cells it is best to have them in a suitable battery house, placing the cells on a bench. Any sediment should be removed and the deficiency of electrolyte resulting from the sediment removal should be made up by the addition of fresh electrolyte.

Cells in poor condition can always be recognized through certain characteristics. The plates may be of poor color; the color of a wet positive plate in good condition varies from rich dark brown, almost black, when the plate is fully charged, to a reddish, chocolate brown when discharged. A light grayish coating on the positive plate is not a bad indication if by rubbing with a clean stick or a piece of hard rubber the proper color is evident under the surface. The color of dried plates is much lighter. Wet negative plates are of a light slate-gray color when charged and somewhat darker when discharged. When dry they are considerably lighter and may be even somewhat yellowish if allowed to heat in drying. If the color of a plate is not as described, it is probably sulphated. If the voltage of a cell is conspicuously lower during discharge or higher during charge than it should be, sulphating (the formation of lead sulphate on the active material or between it and the lead supporting grid) is indicated. If the strength of the electrolyte is low, the cell should be investigated for short-circuits or sulphated plates. Always be sure that the sediment does not touch the plates; it must be removed as soon as there is danger of contact occurring.

Usual Causes of Trouble

Plates may get in poor condition from any of the following causes:

Impure Electrolyte—This may be due to a poor quality of acid being used at the start or to the use of impure water or to foreign substances getting into the cell. The remedy, if the plates are in fair physical condition, is to displace the old electrolyte with new when the cell is in the discharged condition and then to give the battery a thorough charge.

Short Circuits—These are not frequent if the sediment is removed before it reaches the plates. When they do occur, the cell should be completely dismantled, the plates straightened and the cell assembled again, the separators being completely replaced. The cell should then be thoroughly charged.

High Temperature—At a temperature above 100 degrees corrosion is rapid. If it be possible to prevent it, the temperature should not exceed 90 degrees. The positive plates may be sulphated considerably from this cause and be considerably distorted. If they are thoroughly corroded, they must be displaced by new ones; if not, they should be discharged, straightened and recharged. The conditions should be changed so that the battery will not again be subjected to high temperature.

Standing Discharged—The positive plates are especially liable to be badly sulphated from this cause. The indication of this condition is a light color of the positive plates, possibly with blotches of grayish color. The remedy in this case is also a complete charge, though care must be taken that too much active material is not thrown off during the charge. The active material under this condition sometimes becomes quite granular and noncohesive; if it comes off easily the cells must be alternately charged and discharged until the plates are restored to normal condition.

General

In all cases of recharging a cell after treatment, the charge should begin at the "starting" rate of current and be kept at this value until vigorous gassing begins. The current then may be reduced to the "finishing" rate, at which it should be maintained until both the electrolyte and the voltage have remained at constant values for six or eight hours. If too much active material is thrown off by the gassing of the cells, the charge should be discontinued and the cells discharged, the subsequent charge being carried out as explained in the beginning of this paragraph. This process is to be repeated until the plates are again of good color and in good condition. Charging rates less than the "finishing" rate must not be employed under any condition; low charging rates are especially injurious to cells in poor condition.

The excessive use of water in cleaning batteries should be discouraged; it causes the positive plates to sulphate and lose their charge rapidly. The plates may be rinsed by dipping each group into a comparatively large tank filled with electrolyte. A good procedure is as follows: First, see that the battery cells are fully charged and provided an extra tank or other container suitable for immersing the plates. Remove an element from its tank and take out the separators, making sure that the plates are free from any particles liable to cause short-circuits. Replace the old or apply new separators and rinse the element in the clean tank which has been previously filled with electrolyte of the proper specific gravity. Special care should be taken that the plates are kept out of the electrolyte as short a time as possible because the air coming in contact with the negative plates causes them to heat and lose their charge. If the transfer is quickly effected, this method will be very efficient. The battery should then be charged until the specific gravity has ceased rising and remains stationary for one hour. Should any of the cells not come up in voltage along with the others they should be disconnected from the battery and treated separately. The specific gravity of the electrolyte should then be adjusted to the proper strength. If time permits it would be well to make a capacity test to make sure that the battery is in serviceable condition.

If the method just described cannot be carried out, the positive plates may be allowed to stand in the air for several hours without any damage, as the plates dry out slowly and do not lose much of their charge. The negatives, however, must be at once immersed in water or electrolyte, preferably the latter, for the reason already given.

LETTERS

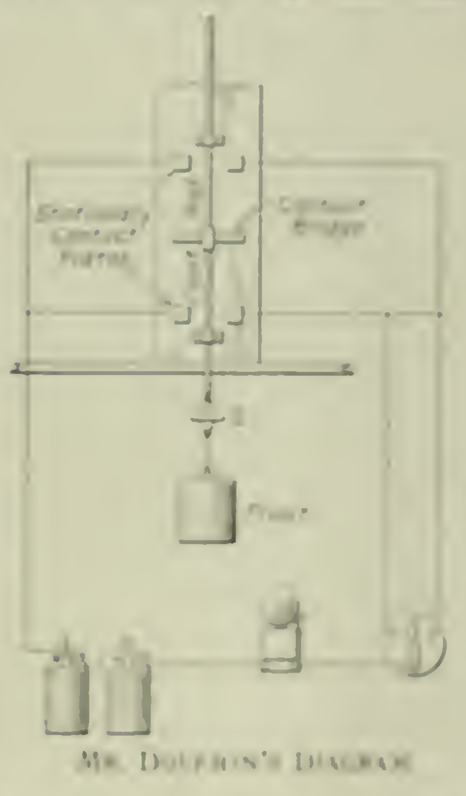
Water Tank Signal Systems

It seems to me that the water-tank signal system described in the March 28 issue may be improved as indicated by the accompanying sketch, which is practically self-explanatory. Only one bell is used instead of two and the battery wire has no motion and therefore no tendency to break off; moreover, provision is made in the insulating coupling S, to avoid grounding through the water.

The contact on the rod shown in the March 28 diagram is liable to turn away from the stationary contacts because the rod inevitably will revolve. The shape of the contact on the rod shown in this sketch will make such an occurrence impossible.

Alexander Dolphin

Jamaica, N. Y.



Mr. Dolphin's Diagram

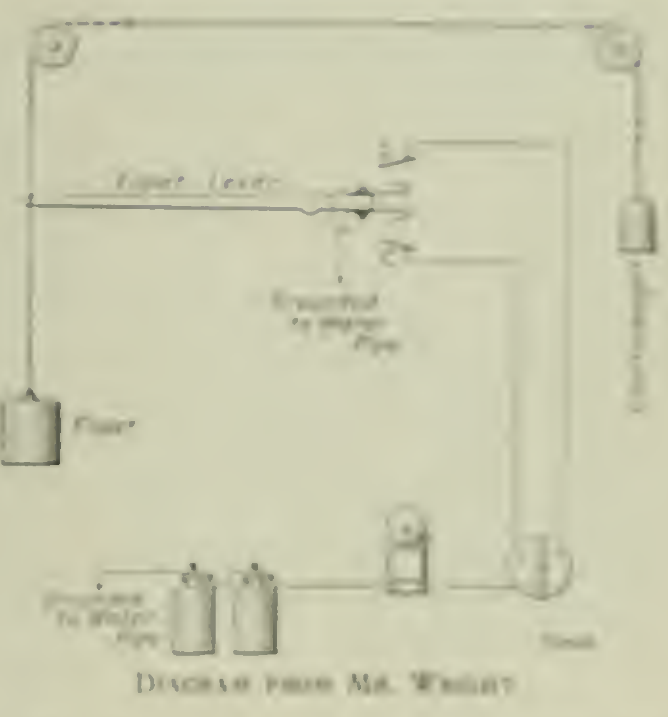


Diagram from Mr. Wright

The accompanying sketch represents a system that I installed some time ago and have been using satisfactorily ever since. It consists merely of a wooden lever pivoted near one end on which are mounted two contacts, made out of an old clock spring, and to the long arm of which are attached the float and counterweight suspensions. In line with the spring contacts are stationary contact plates C and C₁ connected to the two-wire bell switch. To allow the use of only one bell, that bell is connected between the switch and the battery, the return circuit is through the water piping instead of a third wire. The operation is obvious from the diagram.

John A. Wright

Jamaica, L. I.

[The use of one bell, connected as shown in both of these sketches, has also been suggested by Thomas W. [illegible], New [illegible]. It is, of course, preferable to the two bells originally shown.—Editor.]

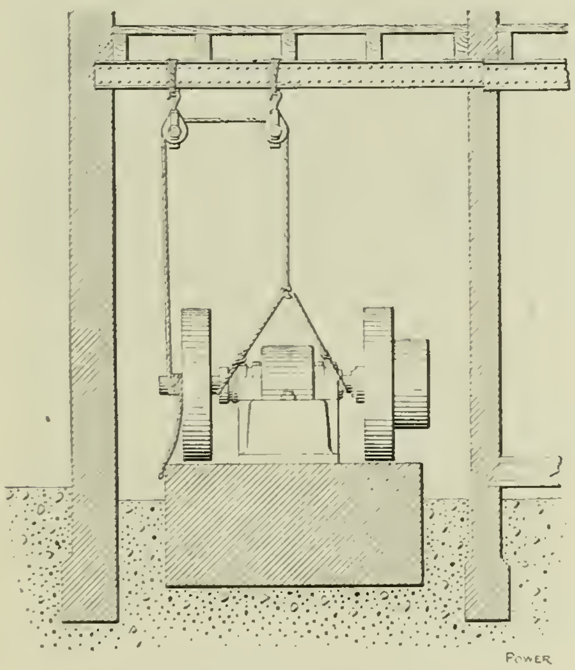
Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Making an Engine Lift Itself to the Foundation

By F. B. Hays

A short time ago I was called upon to set on its foundation a horizontal gas engine weighing about 1500 pounds. There was no crane, hoist, derrick or other lifting mechanism available, nor any means of installing anything of the sort if we had had any. The foundation bolts were very much out of alinement, due to a mistake on the part of the masons who built the foundation, so that the bolts would have to be sprung into the holes in the engine frame as it was let down into place. The space in which the engine was to be set was so small that only two men could work on the job at once, and there was no room to use pinch bars or levers long enough to be of any advantage. In short, the job seemed almost hopeless until the plan which we followed was devised.



Hoisting Itself

Just above the engine there was a heavy beam capable of supporting a couple of tons of weight. Two single-sheave pulley blocks were attached to this and a rope was fastened around the engine frame and run through the pulley blocks to the engine shaft, around which it was given several turns, as illustrated in the accompanying sketch. By revolving the flywheel of the engine, the shaft acted as a windlass and the engine could be raised or lowered with facility.

One man was placed at the flywheel to raise or lower the engine, while another one sprung the foundation bolts into the holes of the engine bed. By this means the engine was raised and lowered to its foundation with very little difficulty.

Development of the Gasolene Engine*

By Joseph C. Riley†

The development of the gasolene engine has been more rapid than that of any other form of motor, not even excepting the steam turbine. We all recollect with what curiosity, not many years ago, we regarded the new horseless carriages and how we wondered whether the noisy little engines which left a smell of half-burned gasolene behind them would ever become really desirable motors. The first part of this period of development saw radical changes in the design of these motors, but the use of light oil had come to stay. Although dangerously inflammable and five times as dear as the heavier grades of petroleum burned in larger oil engines, the cleanliness of gasolene and the ease with which it can be prepared for combustion are alone sufficient to dictate its use.

The gasolene engine has profited enormously by the rapid advance in all branches of mechanical work. Its own special improvements have been, for the most part, such as would naturally come from the thousands of ingenious designers, skilful mechanics and experienced motor-car drivers who have tested and tried it under all possible conditions of service. As a result, advancing by process of trial and error, the engine has reached a fair degree of perfection in two points at least: It has been made to develop greater power per unit of weight than any other form of prime mover and its reliability has been advanced to the stage which warrants its use even for such exacting service as propelling a lifeboat or driving a fire engine.

Little of this development, however, has been made possible by what may properly be called scientific study of the engine's performance. At first there was scarcely time for such work. The demand for engines was often greater than could be supplied, so the engineers' efforts were concentrated on increasing the factory output as fast as possible, consistent with a fair improvement in the product. The time for refinement in design had not yet come. Thorough trials of an engine with all its accessories were usually carried out to make sure that everything was assembled and adjusted well before the product was sold, but measured tests for anything except the power output—under somewhat uncertain conditions—were not considered necessary.

Aside from differences in general excellence of mechanical construction caused by variation in design, unquestionably there are inherent differences in the power developed by different engines and in their fuel economy. When operated at the piston speed corresponding to maximum power (a speed usually between 1100 and 1500 feet per minute) the best automobile engines give results nearly 50 per cent. better than those from the poor ones. But little of this discrepancy can be charged to imperfection of the mechanism causing surface friction, for even the cheaper motors are well built in this respect. It is influenced by the quality and quantity of explosive mixture, the amount of compression, the time and rapidity of ignition and the timing and size of the valves.

The interrelations of these many factors are very complex, but they may be summarized by saying that the power depends upon the pressure in the cylinder. The variation in the force behind the piston as it moves in and out is what does the work; the time at which pressure is applied and the rate at which it changes consequently determine the amount of work realized. The more we know about just how the pressure varies the better able we are to devise means for controlling its rise and fall and thereby producing a greater net output. The piston type of indicator has been of service in analyzing the performance of internal-combustion engines of moderate speed but for light-weight engines such as are used for driving automobiles, aëroplanes and small boats, the speed is

*Abstract of a paper presented before the Congress of Technology at the fiftieth anniversary of the granting of the charter of the Massachusetts Institute of Technology.

†Assistant professor of mechanical engineering, Massachusetts Institute of Technology.

much too high for any of the ordinary commercial forms of indicator. The natural cadence of vibration of the indicator springs and moving parts is altogether too slow for anything like such high speeds; the waves introduced into the diagram by violent explosions would be too long and might be misleading.

What is needed is a recording mechanism with a period of vibration of high frequency, more like that of the electrical oscillograph, say between 500 and 1000 per second. Moreover, if incorrect deductions are to be avoided, great care must be taken to insure that the indicator diagram starts from its dead points exactly in phase with the engine piston. Within the past three or four years optical indicators capable of producing satisfactory results at 1000 revolutions per minute and upward have been used in research work in a few technical schools and private testing laboratories. They cannot be handled successfully, however, except by skilled observers and in general they cannot be used at all with the engine in actual service. The engine must be mounted on a rigid testing block and studied under artificial, ideal conditions.

Little improvement in power can be expected from the best engines; they are already excellent. There are automobile and marine engines today, working on the four-stroke cycle, that give mean effective pressures above 100 pounds, even when driven at extremely high speed. On the other hand, there are small two-stroke marine engines, the mean effective pressures of which range anywhere from 85 down to less than 60 pounds, depending on how well or how badly the fuel charge is supplied, exploded and rejected. The energy wasted in getting the charge into a three-port engine, or in dragging it into the crank case against the pressure of a check valve with too tight a spring, or blowing it into the cylinder after needlessly high compression, materially decreases the horsepower output. In some of the poorer engines the entering charge is further obstructed by insufficient passages through the carbureter; the charge is not merely throttled, it is fairly strangled; the wonder is that it gets in at all. Crank-case diagrams from such engines would set the designers to thinking.

Between the better and the poorer designs of gasolene engines there are wide margins in power, to say nothing of fuel economy. The dynamometer shows that they exist, but it does not show whether deficiency in power is due to constricted passages, defective ignition and combustion, or any other definite fault. Now, the scientific way to remedy a defect of any kind is to begin by investigating first its magnitude and then its cause; and the instrument adapted to such a study in the case of the gasolene engine is the indicator—in the "half-size" pattern within limits and in the optical type beyond those limits.

With all fast-running reciprocating engines the necessity for arranging the cylinders to secure regularity of driving effort and for balancing the moving parts to prevent excessive vibration is apparent. Good mechanical balance is particularly desirable for the class of engines discussed in this paper. The best engines for automobiles, boats and aeroplanes give evidence of having been planned by men trained in the principles of dynamics, as well as in all other elements of mechanical design. Some builders, however, have but hazy notions on methods of balancing. In fact, they seem to associate vibration with the sudden rise in pressure due to explosion within the cylinder, as if the shaking of the frame were due to the shock of explosion. That vibration results from the motion of the masses and that it would be practically the same even if the cylinder heads were removed and the shaft were revolved by power supplied from some other source is new to them.

There are many problems which arise in the design of machinery which cannot be solved even approximately until after the machine is built and tested. The experience gained by operation of the first few imperfect machines then furnishes the information required for modifying and improving existing forms, in varying sizes and powers, and thus the machine is gradually perfected without the application of purely theoretical reasoning.

CORRESPONDENCE

An Inconsistent Engine

If the engine described by Mr. Hall in the March 28 issue does not run faster than normally when *all* the priming cocks are open, the mixture cannot be at fault, except in the unlikely event of each cylinder having a separate air intake. In this case it is possible that No. 3 is not getting enough air for some reason. The first thing to do is to verify the timing of the spark in No. 3 cylinder. It is possible that the spark is timed so as to cause slightly premature ignition and excessive back pressure is relieved by opening the priming cock. Preignition from incandescent deposits or from gas burning in pockets might be the cause of such back pressure, but as the engine is said to be in good condition, this does not appear to be likely to be applicable to this case.

The valve gear of cylinder No. 3 should next be gone over as to the timing of opening and closing and the amount of lift and compared with the settings for the other cylinders. If the valve motions are the same as for No. 2 cylinder and if Nos. 2 and 3 cylinders are fed by a symmetrical manifold from a centrally connected carbureter and No. 2 cylinder does not behave the same way, it is permissible to ignore the possibility of the nature of the charge or its distribution being to blame. If, however, the manifold is so shaped or the carbureter so located that No. 3 gets more than its proper share of gas, it is just possible that, provided all the compression spaces are of equal volume, with normal valve lifts and timing, the compression in No. 3 may be too high, and this, in conjunction with a rich mixture and early timing, might cause the trouble.

All these theories may sound rather far-fetched to those who are not acquainted by experience with the immensity of the range of vagaries that a gasolene engine can display on occasion; but as Mr. Hall did not give any data to enable one to eliminate anything and as I have never observed a similar stunt on the part of a gasolene engine, they are put forward for what they may be worth, which may or may not be much.

If Mr. Hall solves the problem it will be interesting to learn the cause of the trouble, how it was traced and how it was remedied.

John S. Leask.

Manchester, England.

Mr. Hall's trouble is probably due to faulty ignition. Should the charge taken into cylinder No. 3 not be fired, the engine would be working against the compression in that cylinder. Opening the pet cock on this cylinder would, of course, relieve the compression and reduce the amount of work that the remaining three cylinders have to do, thereby speeding up the engine.

New Orleans, La.

Corrosion of Water Cooled Exhaust Pipes

I am in charge of a gas-power plant in which the engines were formerly arranged so that the exhaust gas was cooled by injection of water from the cylinder jackets. After a few months' operation the exhaust piping was so corroded by the action of what appears to be sulphuric acid that it had to be replaced.

I am now running without the water injection and obtaining good results as far as the exhaust piping is concerned. I would like to know if any other readers can tell me how to overcome this difficulty so that I can cool the exhaust gas without detriment to the piping. I have tried cast iron and wrought iron pipe with the same result.

Isolated Power Plant Makes a Good Showing

The original mechanical equipment of the Missouri Baptist Sanitarium, St. Louis, Mo., consisted of two high-pressure return-tubular boilers, furnishing steam for heating and domestic purposes; light and power, however, were purchased from a central station. This arrangement was in force for over ten years.

During the year 1905, a small engine and generator were installed which furnished a portion of the light, and the results were so gratifying that a complete plant was installed during 1908. The new equipment consists of two return-tubular boilers of 100 brake horsepower each; two 60-horsepower, 10x11-inch piston-valve engines that drive two 35-kilowatt, 125-250-volt direct-current generators. The lighting load consists of 540 sixteen-candlepower lamps distributed throughout the institution, a motor load of 47 horsepower for operating laundry, elevators, ventilating apparatus, pumps, etc., a total load of 68 kilowatts.

The buildings are heated by exhaust steam, both direct and indirect methods being employed. The total heating surface is 11,282 square feet. The demands upon a plant of this type are exacting and require heat, light and power throughout the year. The entire equipment is in duplicate, and the service has been uninterrupted since starting the plant, nearly two and half years ago.

The cost of heat, light and power for the fiscal year of 1904, which was the year preceding the installation of the small generating unit, was $5955.09, and of the fiscal year of 1910, the second year after a complete plant was installed, the cost of operation, including cost of fuel, labor, all supplies, maintenance, etc., as charged on the treasurer's books, interest and depreciation on electrical equipment, was $4958.86, a saving in 1910 over 1904 of $966.23. These figures do not take into consideration the fact that the light, power and heat have been materially increased since 1904. For instance, the increase in the lighting load over that of 1904 is 54 per cent.; increase in connected power load over that of 1904, 92 per cent., and the increase in the heating system, 22 per cent.

The cost of heat, light and power for 1910, if electrical energy had been purchased, as in 1904, would have been $7444.86. The cost of this service from the isolated plant represents a saving of $2486.

In this instance the engines, generators and all additional equipment necessary for the electrical plant cost a little less than $6000. The saving in the fiscal year ending with September 10, 1910, over and above the cost of current and heat, if current had been purchased as in 1904, would show a net return on the investment, after allowing for interest and depreciation, of over 40 per cent.

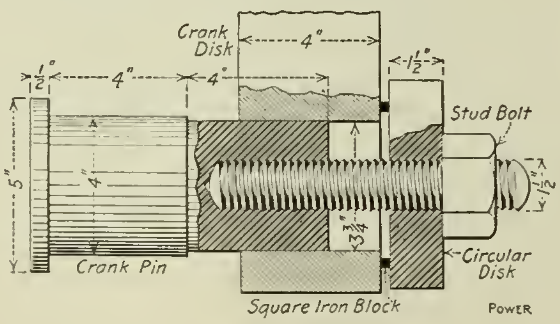
The present service is more satisfactory than the original arrangement, and the splendid showing is due to high-grade equipment and the intelligence with which it is handled.

VICTOR AZBE.

St. Louis, Mo.

Crank Pin Repair

The accompanying illustration shows a method used in putting a new crank pin in the crank disk of an ammonia compressor. The original pin became loose in the disk and a new one had to be fitted in as short a time as possible.



DETAILS OF REPAIRS

The new pin was made at a local shop and had a hole drilled and tapped in the center for a ½-inch stud bolt. The hole in the disk was reamed out 1/32 inch larger than the original hole in order to get it true; the pin was turned for a 20-ton pressure fit.

The pin was started into the hole and a washer put on the back side of the crank disk, with two pieces of square iron between them to act as distance pieces.

The stud, having been screwed into the pin, was slipped through a 1⅝-inch hole drilled in the circular disk and a nut screwed on. While one man with a 24-inch wrench took up on the nut, two others, with a heavy block of wood, driving the other end, soon had the pin in place. The next step was to rivet the back end of the pin over on the disk.

Since this repair was made the compressor has been running constantly for about 12 months and the pin shows no signs of working loose.

Covington, Va.

Changing Shifts

There are a number of ways by which men who are working 8-hour shifts can change from one shift to another at regular intervals. Suppose that the hours for relieving the watch are at 7 a.m., 3 p.m. and 11 p.m.,

Of the various ways of changing, the following two methods are most commonly used. First, by the night crew working a double header of 16 hours, say from 11 p.m. Saturday until 3 p.m. Sunday. The crew that has been working the 7 to 3 shift lay off from 3 p.m. Saturday to 3 p.m. Sunday, and the crew working from 3 to 11 p.m. lay off from 11 p.m. Saturday until 11 p.m. Sunday.

The second plan is for the men going off the 7 to 3 watch, to lay off for 32 hours, that is, from 3 p.m. Saturday until 11 p.m. Sunday. The men coming off the 3 to 11 watch have an eight-hour lay off and come on duty at 7 a.m. Sunday. The night-watch men get through work at 7 a.m. Sunday, and return to work at 3 p.m. the same day.

There is another plan that I have seen worked which I consider very much more advantageous to the men, for the reason that they get one day off duty. By this plan the crew that quits work at 11 p.m. Saturday lays off until 7 a.m. Monday. They thus have all day Sunday free from any thoughts of having to go to work, which would not be the case with either of the other plans. The men who have been working from 7 to 3, lay off from 3 p.m. Sunday until 11 p.m. the same night. The men coming off duty at 7 a.m. Sunday return to work again at 3 p.m. that afternoon. Where this plan has been tried the men rarely wish to give it up for any other.

North Cambridge, Mass.

Condensing Apparatus

Some time ago, while talking with the chief engineer of a large power plant, we fell to discussing condensing apparatus and surface condensers in particular, bringing out some points that are usually taken for granted without very much thought as to the why and wherefore.

One of the first things considered was the location of the dry-air pump and the advantage gained by placing it as close to the condenser as possible. Upon first thought it may seem that the location of the dry-air pump in relation to the condenser is immaterial as long as all the joints, etc., in the dry-air line are kept tight and free from leaks; but suppose, for example, that the temperature of the room where the condensing apparatus is situated is above the temperature of the condensation; then if the pump is placed at a considerable distance from the condenser the air has to travel through a long line exposed to this higher temperature which, consequently, increases the volume of air, forcing more work on the pump and usually resulting in a drop in vacuum. Of course, the conditions may be such that it would be impracticable to have the air pump close to the condenser, in which case the usual method employed to overcome the difficulty is to cover the dry-air pump with a good thickness of lagging.

The next point brought to my attention was the proper size of pipe to use and if any advantage was to be had by using a larger pipe than that for which the pump was designed. For instance, if the diameter of the intake port of the pump were 6 inches, would anything be gained by running a 12-inch line from the condenser to the pump instead of a 6-inch line, as would naturally be the first inclination?

The main object of an air pump is to get rid of whatever air collects in the condenser as quickly as possible and, as pipe friction is something to be taken into consideration, it would seem plausible that the larger the pipe the less the effect of friction, but as there is only a very small quantity of air passing through the pipe the friction is practically negligible; on the other hand, the larger the pipe the more surface is exposed to the effects of the outside temperature.

There is in use in a certain steam plant a combined wet- and dry-air pump of a rather original design. This pump is steam driven and has separate cylinders for air and condensation. The dry-air cylinder exhausts into the wet-air or water cylinder between the foot valves of the wet-air cylinder and the cylinder itself, having to pass through two valves in a small valve chamber located at the bottom of the cylinder. When new, this pump used a normal amount of steam to drive it and was controlled by a throttling governor, but after being in service for several years the pump developed a decided tendency for speeding up and could only be controlled by the throttle.

The logical explanation seemed to be that the governor was badly in need of repairs, but after having been thoroughly overhauled and replaced on the pump the conditions were not changed in the least. Finally the governor was cut out altogether and the pump run on the throttle. This pump is now running with the throttle open a little less than one-quarter of a turn and yet the vacuum is as high, if not a little higher, than it ever was, which causes one to question if sometimes it is not possible to get something for nothing. All other conditions have remained the same, but there is a reason and I would like to hear an opinion from some of the readers of Power as to the cause of this peculiar condition.

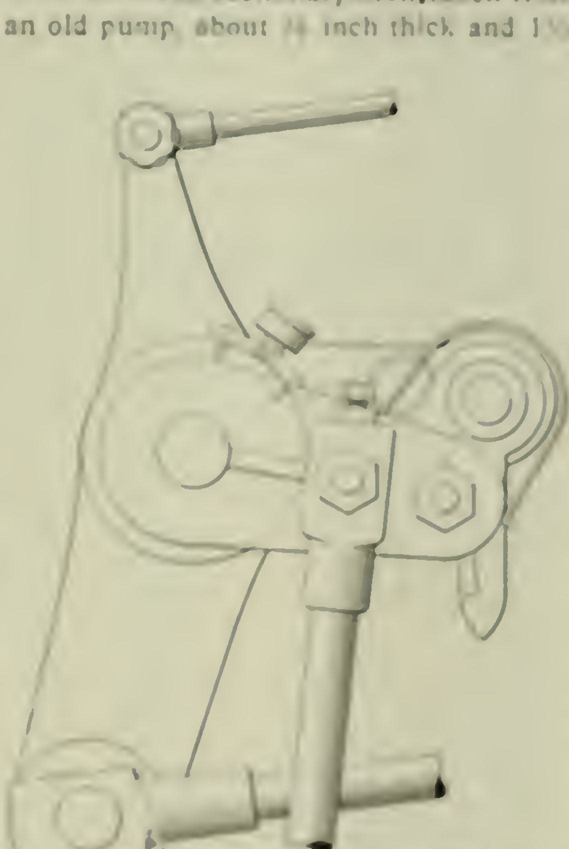
Howard Barr.

New Rochelle, N. Y.

Lubricating the Bell Crank

While visiting an engineer recently, I was interested in his method of lubricating the valve gear of a Corliss engine, as shown in the accompanying illustration.

This engineer had hunted up two pieces of an old brass sectional piston, taken from an old pump, about ¼ inch thick and 1½



Grease Cup on Bell-crank Bearing

inches wide. He fashioned these pieces to fit the outer surface of the bell crank and, drilling and tapping a hole for a ¼-inch pipe, screwed a 2-ounce grease cup in place.

Two ¼-inch holes were drilled and tapped on each side of the slot in the bell crank and holes were drilled in the circular piece of brass plate to correspond. The plate was then screwed fast to the casting by 2 ¼-inch brass screws, first putting a piece of soft leather underneath for a packing to prevent the grease from squeezing out around the edges of the plate.

This rig enabled him to keep the double bearing full of grease at any time, thereby preventing any little noise and wear as the grease did not run through the bearing.

Charles H. Taylor.

Bridgeport, Conn.

Improved Engineering Conditions

It should be very encouraging to steam engineers to note the trend of things that vitally concern him. However, engineers are asking such questions as, "Are conditions becoming better or worse; if better, in what way; if worse, in what particular, and for what class are conditions becoming better or worse?" These are pertinent questions.

It is well to take a broad view of the field of work in which engineers are engaged. Three years ago, we had not a weekly paper devoted to operative engineering in this country. The monthlies, with two or three exceptions, were unpretentious, and the matter they contained would not compare in any way, either in quantity or quality, with that which is supplied today. The contributions and discussions in the technical journals evidence greater activity among operating engineers than ever before, which means that engineers are growing into a more responsible and respected class. One must be blind who does not realize that this change has taken place in many instances and the tendency is toward this condition generally.

A few years ago, fuel cost less than half what it costs now and everything used in the operation of a power plant cost much less than it does now. The charges for public service, however, have not kept pace with the increased cost of fuel, labor and supplies.

So long as fuel and supplies were cheap, employers did not look so closely into matters of fuel consumption and other items of expense in the production of power as they do now. These conditions call for better brains to meet them. Business men began to see that the economical operation of power plants is a scientific proposition, instead of a mere matter of manual labor. From an engine- and boiler-room laborer, the engineer has become the adviser of the management. His position is fast becoming respectable. There is more ahead of the ambitious man at the lower rungs of the ladder than ever before and the prospects are becoming better every year.

Some years ago fuel was never purchased except by the ton. Now heat units govern the price, and the owners of power plants are looking for the man who can turn the last available heat unit in the coal into effective work. They know that the man who can do this is not a cringing thing in greasy overalls, but is a man with real gray matter under his hat.

In the future it is going to be a scramble and a case of the "survival of the fittest." But with the means available for self-education, any man with a reasonable amount of "horse sense" will be able to get in line for the better things in store for the engineering fraternity.

There is ample room for improvement, but the manner in which engineers are meeting the changing conditions promises well for the future, both for the owners of power plants and for themselves.

Ten or fifteen years ago an engineer who could set the valves of a Corliss engine so that it would run at all was considered a very good man. Now we find them conducting hair-splitting discussions as to the proper hight of the compression curve, whether it shall be allowed to run to one-third or one-fourth the hight of the diagram, or less. Lead must be adjusted to a nicety that our fathers never thought of, and operating engineers are found laying off the lines for isothermal and adiabatic expansion on the indicator diagrams and checking the actual by the theoretical.

These things indicate that engineers are progressing, and will be, for several reasons, two of the most important being the increasing pressure of conditions, and the increased ease of obtaining knowledge and applying it. What the engineers of the past had to arrive at by long and tedious calculation is now obtained at a glance from handbook tables.

William Westerfield.

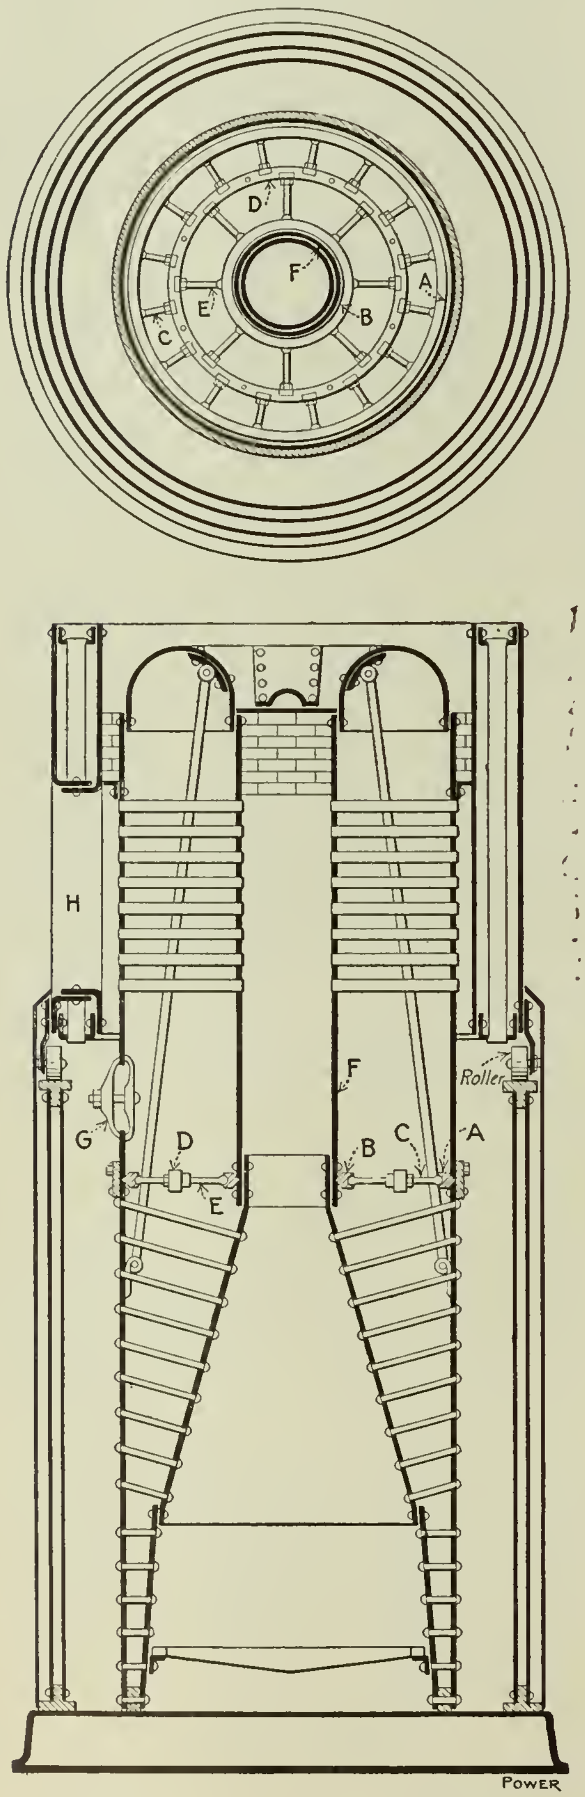
Concordia, Kan.

Novel Boiler Construction

While visiting a small boiler shop, I was shown a boiler that had features which were extremely novel. The boiler was destined for a mountainous part of the country where fuel was scarce and dear, and where transportation of the boiler from place to place would be difficult.

The accompanying illustration shows a sectional view of the boiler, but is drawn from memory and from such description as was detailed to me, and, therefore, is to be considered as simply portraying the chief features and not as accurately setting forth the constructional details. The boiler can be divided into two sections, at the joints *A* and *B*. The lower half of the strap at *A* is riveted and calked in the usual manner, but the upper half is only bolted on and is not calked. The joint is made tight by means of a triangular-shaped cast-iron ring, which fits accurately into the V-slot machined at the intersection of the two halves of the shell. The ring *A* is cut slightly larger than the inside diameter of the shell, like the packing ring of a steam piston.

Before being snapped into position, a narrow strip of a flexible alloy is placed in the bottom of the groove. When in place, the packing ring is evenly set out by the bolts *C*, bearings for which are furnished by the built-up wheel *D*. The inner ring *B* is set by the bolts *E*, and the band *F* is riveted on to complete the joint at this juncture. The ends of the setting-out bolts are upset and rounded to fit into recesses in the packing ring to allow flexibility in case of unequal expansion of the inner and outer shells. Details of the bolts, wheel and packing rings are shown in the plan view. Some of the braces of the upper half connect below the joint to the shell of the lower half. On some of these braces are turnbuckles of a special make, which are used to raise the upper half clear of the other when dismantling the boiler. The two halves of the shell are guided to a correct position by two keys (not shown). Access to the interior of the boiler is obtained through a manhole, the position of which is shown at *G*.



Sectional View of the Boiler

As this boiler had to be operated under economical conditions it was necessary to have a large heating surface proportionate to the grate surface, which was difficult to provide without making the boiler too bulky. The designer, however, hit upon the plan of using a one-tube economizer for heating the feed water. By this means the waste gases are utilized to a certain extent, but the heating surface of the boiler is materially increased by compelling the gases to return along the outer shell before entering the economizer. But the economizer so covers the boiler tubes as to prevent access for cleaning them. To offset this the economizer was set on rollers, and a long but narrow door *H* cut in it. By disconnecting two unions, one on the feed-water inlet and one on the outlet, the economizer can be revolved entirely around the boiler, thus bringing the door opposite each row of tubes. The economizer is set on a framework of T and angle iron, around which is a covering of sheet iron.

The more one studies the design of this boiler, the more he recognizes the ease with which it can be thoroughly cleaned and repaired.

While this boiler may be expected to operate with a fair degree of economy, considering its type, there are several doubtful elements in the construction, which the reader will doubtless perceive.

R. O. Richards.

Framingham, Mass.

Standpipe on Heating System

A certain heating plant will soon have to be extended in order to heat an annex to the main building. The job should be done as cheaply as possible as the building will be vacated next year. The old traps are overloaded, and a new trap is not wanted. The system is made up of 1-inch pipe, and operates by gravity. The pressure is from 5 to 8 pounds, and discharges through traps into an open tank and is then pumped into the boilers.

How about putting up a standpipe of a convenient hight and letting the water overflow into the open tank; would this work and, if not, what else could be done?

Alex Dolphin.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

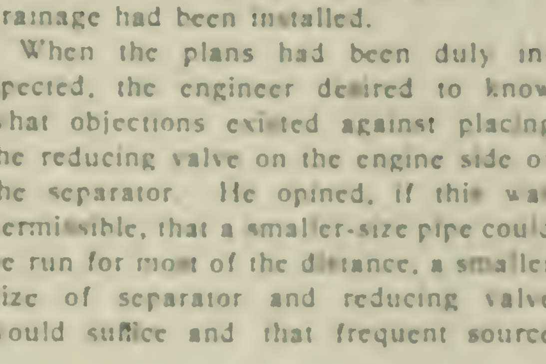
Specialists

I was interested in James Scotch's letter which appeared in the issue of March 21, under the above title. I believe that he writes too harshly of the "dinky little" engineer, who presumes to dictate to specialists summoned for especial work in his plant. Personally, I bear the opinion that the *thinking* man, be he engineer or coal passer, can, at times, present highly intelligent hints to any master-of-trade; especially is this so when the latter is one of that numerous class of craftsmen who have achieved proficiency in their vocation solely by imitation and who not only copy the merits of their models, but, likewise, commit their faults or, ignorantly, maintain a custom that has, since their apprenticeship, become obsolete. I refer to that large class of so called specialists who are adepts at doing things which they have seen accomplished before but who are easily confounded when asked for reasons why one thing is performed this way and another the other way. I contend that these men are but cogs in the huge industrial wheel and, compared with them, the little free-thinking engineer becomes "the man of broader education" that Mr. Scotch refers to "as the man who rises highest in the engineering profession" and, I may add, "sets the cog wheel in motion."

We all find it easy to criticize the handiwork of these specialists; but small indeed is the number of those who can suggest ideas that will correct the faults perceived. When, by concentration of mind, we are enabled to do this, and the expert finds the idea practical, have we not every reason to "crow" of our ability? And if the idea be worthy and general in its application, what better could we do with it than have it appear in the columns of POWER that others may profit thereby? As an instance for comparing a specialist and a *thinking* engineer I commend the following.

At the invitation of a friend whose plant was undergoing partial remodeling, I was present in the engine room when a steamfitter unfolded a blueprint upon which plans were drawn showing a method for connecting an old Putnam poppet-valve engine, built for 70 pounds steam pressure, to a battery of modern boilers capable of withstanding a pressure of 150 pounds. A portion of the drawing is reproduced in the accompanying figure. As a part of the improvements introduced, the Holly system of drainage had been installed.

When the plans had been duly inspected, the engineer desired to know what objections existed against placing the reducing valve on the engine side of the separator. He opined, if this was permissible, that a smaller-size pipe could be run for most of the distance, a smaller size of separator and reducing valve would suffice and that frequent source of trouble, the trap, could be eliminated. Furthermore, he argued that the separator, if installed according to the specialist's plan, would be altogether useless as a means for reducing the percentage of moisture present in the steam as it is well within the bounds of reason to credit the steam upon leaving the reducing valve with more or less superheat depending on the amount of moisture present in the high-pressure steam. Thus, the separator, according to my friend's supposition, would be curtailed in its functions to a mere safety device against the flooding of the engine and even this function would depend on the condition and capacity of the trap. In my estimation, the same object would be accomplished by a pair of well designed relief valves placed on the engine cylinder. In answer to all the arguments enumerated the specialist could invoke but one, that was: "It is not customary to install the apparatus in that arrangement"—a truly characteristic reply of the majority of his class when confronted with debatable reflections.



Specialist's Plan

Engineer's Plan

Of course, it is far from my desire to be understood to mean that there are no bright exceptions and, no doubt, I shall hear from some of these, who will deem it incumbent to swing the cudgels for their more unfortunate brothers, even as I do for the "dinky little one-horse engineer." Yet, it is my sincere conviction that any alert engineer, who keeps abreast of his times by reading, digesting, appropriating and using the thoughts and suggestions found in the abundant literature of his trade, can at times furnish pointers which NO specialist need be ashamed to accept.

OWEN R. OWEN.

Roxbury, Mass.

Size of Turbine Exhaust Pipes

R. M. Neilson, in the issue of March 28, gives an interesting formula for the area of steam-turbine exhaust pipes but he does not give the data from which it was derived. It appears that the formula is defective in not including the length of the pipe and the allowable drop in pressure between the condenser and the turbine or the ratio of these two quantities, or else Mr. Neilson has neglected to state what constant ratio of these quantities he used in constructing his formula.

I have made some calculations from the formula for two assumed cases: 1000 and 20,000 horsepower; steam consumption, 12 pounds per horsepower-hour and 28 inches of vacuum.

The data from the Marks-Davis steam tables are:

V = Volume of one pound of steam = 350.8 cubic feet;

W = Weight of one cubic foot of steam = 0.002851 pound.

The formula is

[illegible]

W = weight of steam in pounds per hour, and f is a factor for the smoothness of the pipe = 2.55 for a riveted pipe.

[illegible]

For 1000 horsepower,

$$W = 12{,}000;\ W^{0.8} = 1{,}834$$

$$A = 1834 \times 18.73 \times 1.715 \div 16{,}000 = 3.682 \text{ square feet}$$

or 26 inches diameter.

For 20,000 horsepower,

$$W = 240{,}000;\ W^{0.8} = 20{,}140$$

$$A = 20{,}140 \times 18.73 \times 1.715 \div 16{,}000 = 40.44 \text{ square feet}$$

or 86 inches diameter. The velocity of the steam in the first case is:

200 *pounds per minute* × 350.8 ÷ 3.682 = 19.055 *feet per minute* = 318 *feet per second*

In the second case it is:

4000 *pounds per minute* × 350.8 ÷ 40.44 = 34,700 *feet per minute* = 578 *feet per second*

The common formula for the flow of steam in pipes (See "Mechanical Engineers Pocketbook," page 845), is,

Loss of pressure in pounds per square inch =

$$p_1 - p_2 = \frac{W^2 L}{C^2 W d^5}$$

in which W is in pounds per minute, and D, the diameter, in inches; C is an experimental coefficient. Taking L at 100 feet and C at 63.4 for the first case and 64 in the second (figures derived from Darcy's experiments on the flow of water) gives in both cases

$p_1 - p_2 = 0.029$ *pound per square inch,* or about 0.06 inch of mercury. As in modern large turbine practice L may be nearer 10 than 100 feet, this would reduce the drop in pressure to one-tenth of these figures, or to 0.006 inch of mercury, an exceedingly low figure.

It is possible that Mr. Neilson intended his formula to cover not only the loss of head (or pressure) due to friction of the pipe, but also the pressure required to cause the velocity, and also the "entry head" or the pressure required to overcome the resistance of the orifice. As the latter may be made bell-mouthed, its resistance may be neglected. If we assume that the steam in the exhaust side of the turbine has no velocity in the direction of the pipe, the velocity head may be calculated from the formula

$$h = \frac{V^2}{2g}$$

in which V is in feet per second and H, the hight, in feet of a column of steam of the given density. For the calculated velocities, 318 and 578 feet per second, h is, respectively, 1570 and 5188 feet. Reducing this to the equivalent pressure of steam occupying a volume of 350.8 cubic feet per pound gives pressures of 4.48 and 14.8 pounds per square foot, or 0.031 and 0.128 pound per square inch, respectively. These figures added to the 0.029 pound already found as the loss of pressure due to friction for a pipe 100 feet in length, gives the total loss of pressure as 0.06 and 0.157 pound, or, say, 0.12 and 0.31 inch of mercury.

As the steam leaving the vanes of the turbine must have considerable tangential velocity, with reference to the earth, and the exhaust pipe may be taken from the casing in the tangential direction, it is probable that there is no such loss of head in creating velocity as the last calculation indicates and, in that case, a material decrease in the diameter of the pipes (with consequent increase in velocity) from the diameters given by Mr. Neilson's formula might be made without any serious loss of vacuum between the condenser and the turbine, especially if the distance between them is short.

The exponent 0.4 of the factor f should be explained. According to the common formulas for flow of water, the area required for a given flow under a given head varies inversely as the square root of the mean hydraulic radius, which would make the exponent of f 0.5 instead of 0.4.

William Kent.

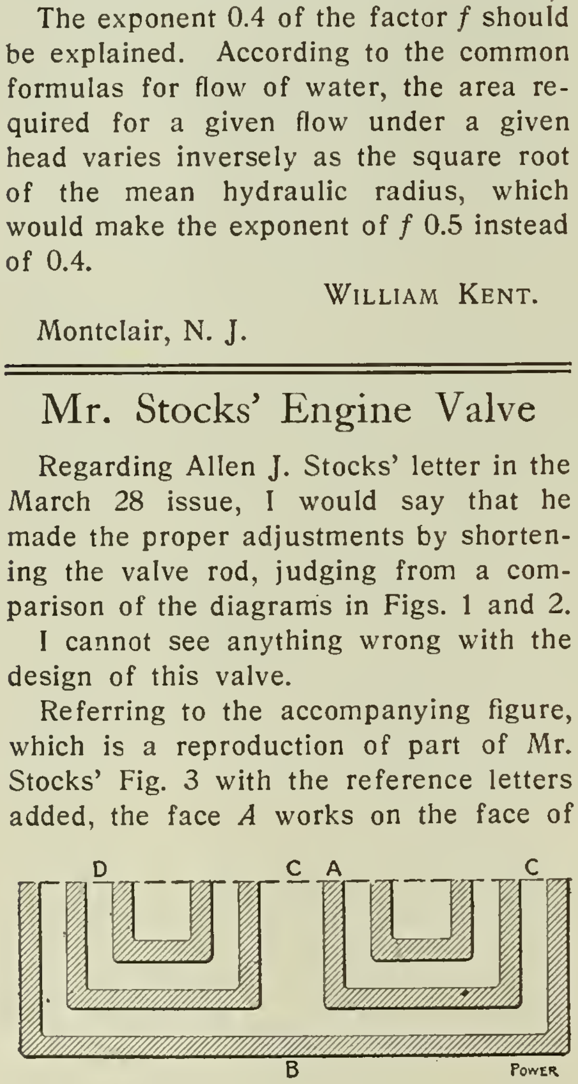
Montclair, N. J.

Mr. Stocks' Engine Valve

Regarding Allen J. Stocks' letter in the March 28 issue, I would say that he made the proper adjustments by shortening the valve rod, judging from a comparison of the diagrams in Figs. 1 and 2.

I cannot see anything wrong with the design of this valve.

Referring to the accompanying figure, which is a reproduction of part of Mr. Stocks' Fig. 3 with the reference letters added, the face A works on the face of the valve seat. The face B is subjected to the steam-chest pressure, which pressure tends to hold the valve hard against the valve seat. The channels C are to allow a certain amount of steam to remain between the valve and its seat, tending to balance or resist the pressure on the face B.



Mr. Stocks' Valve

It seems plain that the inventor's aim was to design a balanced slide valve without a pressure plate and his aim was in the right direction to reduce the friction and allow the automatic cutoff governor to work effectively.

The diagrams showed that the governor was handling the valve all right.

If Mr. Stocks had given a sketch of the valve seat, I might have been able to tell him more about this valve, as I think the channels D are probably meant to give the valve a double-ported effect which is common practice in the design of most automatic single slide-valve engines. The valve is made double ported to get a large port opening with a comparatively short valve travel.

Most designers know something.

W. H. Magee.

Brooklyn,, N. Y.

Record Breaking Turbine Test

The test performance, cited in the April 18 issue, of the 6000-kilowatt turbine unit designed by Brown, Boveri & Co., and installed in the Dunston station at Newcastle-on-Tyne, shows the best steam economy which I have seen reported, and since it was accomplished with a high degree of vacuum, the efficiency is remarkable. There are, however, certain important matters which must be considered in comparing this result with the claims and accomplishments of other large turbines of the Parsons or other types.

The machine at Newcastle is designed for a capacity of 6000 kilowatts, it operates at 1200 revolutions per minute, and in spite of this relatively low speed in proportion to its rating, the low-pressure end is arranged for double flow. The Parsons construction can be made highly efficient at the low-pressure end if space could be afforded for moderate steam velocities. The limitation of most Parsons designs lies in the fact that such space cannot be afforded and it is only in such extreme designs as the one under consideration, that the steam at the low-pressure end is not congested when operating with a good vacuum. A machine of the Curtis type operating at 1200 revolutions per minute can be proportioned with single flow for 11,000 kilowatts output without serious congestion in the low-pressure end, while the machine at the Dunston station is designed for only 6000 kilowatts and is provided with two low-pressure elements in parallel. The building of such an elaborate and expensive machine for so small an output is undoubtedly well justified by the fine results accomplished and is creditable both to the purchasers and to the designers. The practice, however, is very different from that which has been followed by many designers of Parsons turbines, particularly in this country where it is common to find single-flow machines rated at 5000 kilowatts operating at 1800 revolutions per minute, and double-flow machines rated at from 10,000 to 15,000 kilowatts operating at 1800 revolutions per minute.

I do not know how the initial cost per kilowatt of this machine would compare on an equal basis with such Parsons units as have been mentioned. It is obvious that the cost is relatively much greater and that these fine results cannot be accomplished without such increase of cost.

The machine at Dunston was built with an unusual degree of care and accuracy, it is operated continuously without variation of load, and in starting it an unprecedented length of time is expended. Under these very favorable conditions of operation it is probable that it can run with very small clearances so that the leakage losses are presumably smaller than those which are necessary in a Parsons machine run in the usual manner.

Brown, Boveri & Co. have been leaders both as to quality and quantity in the production of Parsons turbines as they have been in many other branches of engineering, and this machine represents the latest product of their experience. If other designers of Parsons turbines follow equally conservative and correct lines, they also can undoubtedly obtain equivalent results if the test reported in this case is correct. If, however, in the interest of economy they follow radically different lines, it may be presumed that they violate principles which govern quality in this art.

Schenectady, N. Y.

Preventing Power Plant Losses

The editorial in the April 4 issue of POWER under the above heading is worthy of careful attention by all progressive engineers and covers a subject that is of vital importance, not only in engineering, but in all branches of human activity.

Many are the men that have gone to the wall because of their failure to look after the little things; they take care of the large items that thrust themselves in the way but never see the small things that have to be searched for. Just as a grain of dust will stop a watch or a bolt wreck a turbine, so unseen losses will wreck a business.

With the very best of equipment and administration hardly more than 10 per cent. of the energy in coal can be realized at the switchboard. Yet, with only this small amount of power as an asset and the many and varied losses as a big debit, the engineer instead of watching such losses and trying to keep them as small as possible, lets them increase because he does not see where they go to and in addition allows a lot of unnecessary ones to creep in.

The causes that lead up to these unnecessary losses are varied, but usually come from a false sense of economy. To spend a dollar today in order to save two dollars tomorrow is unheard of.

Economy is the slogan! Buy cheap supplies! Save the dollars! The fact that the quality is as cheap as the cost is forgotten.

Pay small wages! Cheap men will make the wheels go around just the same as good men. Maybe true, but what is saved in wages is lost many times over in other ways.

Bookkeeping costs money. Cut it out. What do we care how much each item costs, as long as we know the total. Yet that is the only way in which the invisible leaks can be discovered.

All of which reminds me of a friend who walked three miles to save 5 cents carfare, and after he had gone about a mile stopped at a cigar store and spent 15 cents on cigars to keep him company the rest of the way.

W. L. DURAND.

Washington, D. C.

Pressure on Pump Plunger

In regard to B. U. Potter's inquiries in the issue of March 28, the following may be of interest to him:

In Fig. 1, let A be the position of the crank pin at top center and B the position after the crank has moved through any angle θ. Then, AC will equal the displacement of the piston.

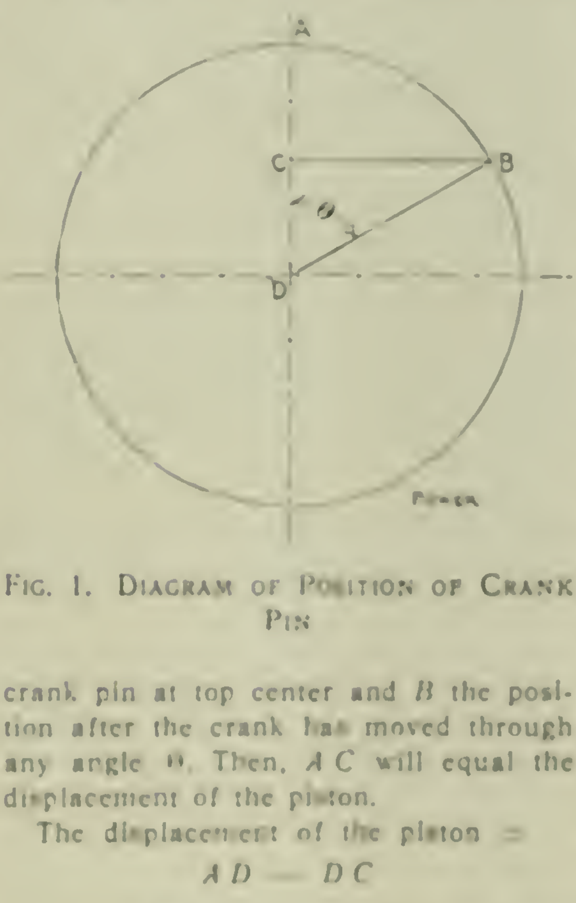

FIG. 1. DIAGRAM OF POSITION OF CRANK PIN

The displacement of the piston =

$$AD - DC$$

and

$$DC = \frac{DC}{BD} \times BD$$

or

$$DC = \cos \theta \times BD$$

and

$$AC = R - (\cos \theta \times R)$$

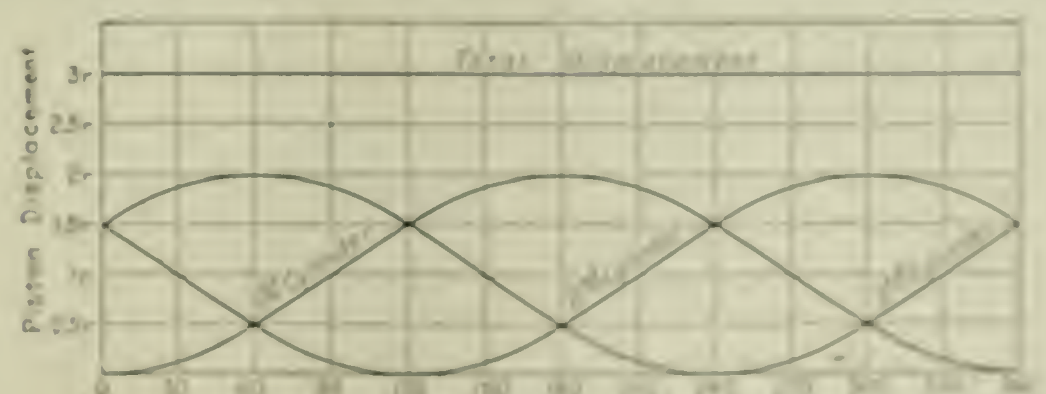

FIG. 2. DIAGRAM OF CYLINDER DISPLACEMENT

In Fig. 2 the displacement of piston No. 1 was plotted as ordinates and the degrees of revolution of crank shaft as abscissas. That of No. 2 was plotted in the same manner, but 120 degrees later, and that of No. 3 120 degrees later still. This gives the three curves as shown.

Adding the ordinates for the different positions of the crank shaft gives the line of total displacement, which is constant and equal to 3r or 1½ times the displacement of one cylinder.

The angularity of the connecting rod would change the volume slightly but not enough to affect the pump.

The easiest proof of the above is to assume any position of the plungers and solve for the total displacement.

JOHN BAILEY.

Milwaukee, Wis.

Advice on Giving Advice

I have read the letter by Owen R. Owen in the March 28 number and I believe the suggestion that the editors review replies sent in by readers is a good one.

I imagine that Mr. Owen's letter will mix things up more than ever for Mr. Morris. He states that my suggestion of adding a drip at the end of the feed branch at the farthest radiator might be inconvenient. What about his idea of increasing the size of all of the pipes under certain conditions as brought up by Mr. Dixon? The drip which I suggested need only be of ½-inch pipe and need not cost very much in cash or labor.

If there is no obstruction, such as dirt of any kind (and the chances are 1000 to 1 there is no such obstruction), the drip will certainly cause the steam to circulate in the radiator.

I do not agree with Mr. Owen that it should be taken for granted that air vents are installed. The suggestions offered were based upon the description given and the sketch shown.

The connection which was shown by Mr. McCabe is quite correct, but I have seen dozens of connections "bull headed," as shown in Mr. Morris' sketch, where dissatisfaction in results was excountered; but in every case ample provision was made to carry away the condensation from the branch feed connections at the radiator end by a drip when these connections were over a few feet long.

The risers shown in the sketch (2½ inches) should be of ample size to heat any three radiators unless they are altogether larger than any generally used, and if the branch pipes are large enough (1¼ inches will supply up to 96 square feet under 5 pounds pressure with a two-pipe system) and contain no pockets, there will positively be no trouble in heating all three radiators with a one-pound steam pressure, gage, providing drips are installed.

The change suggested by Mr. Owen is all right, but it is not a sure cure; drips or bleeders are, if falls are right and all pipes are clear.

J. E. Noble.

Toronto, Can.

Stress in Boiler Sheets

Referring to the editorial in the February 28 issue, consider a rectangular plate as in Fig. 1, with a tension of p_1 pounds per square inch of sectional area applied in one direction and p_2 pounds per square inch of sectional area applied at right angles to the first. Let the thickness of the plate be t.

Now conceive a right-angled triangle cut from this plate as in Fig. 2. The side whose length is A is subjected to a tension of p_1 pounds per square inch of sectional area, and the side whose length is B is subjected to a tension of p_2 pounds per square inch of sectional area. The hypotenuse, whose length is C, is then subjected to a tension whose direction is perpendicular to C and whose intensity is p pounds per square inch (as yet unknown). There may also be a shearing action along C; if there is, let its intensity be S pounds per square inch.

Since t is the thickness of the plate in inches, the sectional area along the edge A is $A \times t$ square inches; hence the total force acting upon A, and perpendiuclar to it, is $A \times t \times p_1$ (Fig. 3). Similarly, the total force acting on the edge B is $B \times t \times p_2$. Acting perpendicularly to the hypotenuse is the force $C \times t \times p$, and if there is a shearing action along this edge, its total value will be $C \times t \times S$.

There must be equilibrium among these four forces. Resolving into components perpendicular to the hypotenuse,

$$C \times t \times p = A \times t \times p_1 \sin.\alpha + B \times t \times p_2 \cos.\alpha$$

and resolving parallel to the hypotenuse,

$$C \times t \times S = A \times t \times p_1 \cos.\alpha - B \times t \times p_2 \sin.\alpha$$

Dividing by $C \times t$ in both cases,

$$p = \frac{A}{C} \times \sin.\alpha \times p_1 + \frac{B}{C} \times \cos.\alpha \times p_2$$

$$S = \frac{A}{C} \times \cos.\alpha \times p_1 - \frac{B}{C} \times \sin.\alpha \times p_2$$

But $\frac{A}{C} = \sin.\alpha$, and $\frac{B}{C} = \cos.\alpha$

Hence

$$p = p_1 \sin.^2\alpha + p_2 \cos.^2\alpha \qquad (1)$$

$$S = p_1 \sin.\alpha \times \cos.\alpha - p_2 \sin.\alpha \times \cos.\alpha = (p_1 - p_2)\sin.\alpha \times \cos.\alpha \qquad (2)$$

These equations give the values of p and S under the most general circumstances.

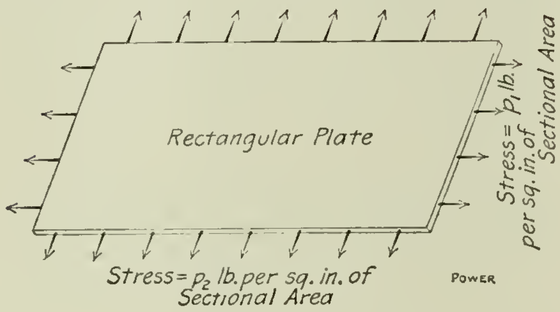

Fig. 1

There is a shear S along the hypotenuse except when α equals zero or 90 degrees, in which case $\sin.\alpha$ and $\cos.\alpha$ are zero respectively; also in the special case where the plate is pulled equally in both directions, that is, $p_1 = p_2$, there is no shear. If p_2 be equal to p_1, equation (1) becomes

$$p = p_1 \sin.^2\alpha + p_1 \cos.^2\alpha = p_1(\sin.^2\alpha + \cos.^2\alpha) = p_1$$

Hence, when the plate is subjected to a stress of the same intensity sidewise and endwise, the tension acting perpendicularly across any diagonal is the same in intensity.

Going back to the general case, in which p_1 is not equal to p_2, assume first that p_2 is greater than p_1.

$$p = \frac{p_1 + p_2}{2} + \frac{p_2 - p_1}{2} \times \cos.2\alpha \qquad (3)$$

This expression may be verified as follows: Substituting $\cos.^2\alpha - \sin.^2\alpha$ for $\cos.2\alpha$, equation (3) becomes

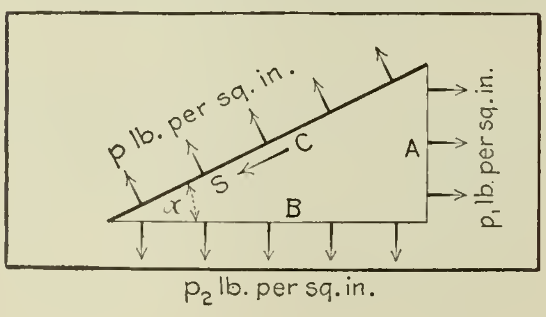

Fig. 2

$$p = \frac{p_1 + p_2}{2} + \frac{p_2 - p_1}{2} . (\cos.^2\alpha - \sin.^2\alpha)$$

$$= \frac{p_1}{2} + \frac{p_2}{2} + \frac{p_2}{2}\cos.^2\alpha - \frac{p_2}{\alpha}\sin.^2\alpha - \frac{p_1}{2}\cos.^2\alpha + \frac{p_1}{2}\sin.^2\alpha$$

$$= \frac{p_1}{2}\sin.^2\alpha + \frac{p_1}{2}(1 - \cos.^2\alpha) + \frac{p_2}{2}\cos.^2\alpha + \frac{p_2}{2}(1 - \sin.^2\alpha)$$

$$= \frac{p_1}{2}\sin.^2\alpha + \frac{p_1}{2}\sin.^2\alpha + \frac{p_2}{2}\cos.^2\alpha + \frac{p_2}{2}\cos.^2\alpha$$

$$= p_1 \sin.^2\alpha + p_2 \cos.^2\alpha$$

which is the same as equation (1).

In the formula

$$p = \frac{p_1 + p_2}{2} + \frac{p_2 - p_1}{2} \times \cos.2\alpha$$

the greatest value that $\cos.2\alpha$ can have is $+1$; hence, the greatest value p can have is

$$p = \frac{p_1 + p_2}{2} + \frac{p_2 - p_1}{2} = p_2$$

This happens only when $\cos.2\alpha = 1$, or $\alpha = 0$. Similarly, the least value $\cos.2\alpha$ can have is -1, which can only be when $2\alpha = 180$ degrees, or $\alpha = 90$ degrees. Then

$$p = \frac{p_1 + p_2}{2} - \frac{p_2 - p_1}{2} = p_1$$

From this it will be apparent that when p_2 and p_1 are unequal, p is always less than p_2 (the greater of the two), except when $\alpha = 0$, when it becomes equal to p_2. Similarly, p is always greater than p_1 except when $\alpha = 90$ degrees, when it becomes equal to p_1.

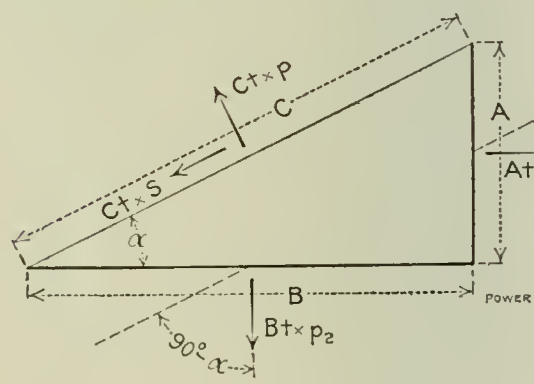

Fig. 3

As for the shear S, it may be expressed as

$$S = \tfrac{1}{2}(p_1 - p_2)2 \times \sin.\alpha\cos.\alpha = \frac{p_1 - p_2}{2} \times \sin.2\alpha$$

The greatest value $\sin.2\alpha$ can have is $+1$. Hence the greatest value of S will be $\frac{p_1 - p_2}{2}$. This occurs when $\sin.2\alpha = 1$, or $2\alpha = 90$ degrees, that is, $\alpha = 45$ degrees.

Some have been confused with the fact that the diagonal extension of a rectangular plate is greater than the extension parallel to the edges. The trouble here is, that the stress in the plate is not proportional to the absolute extension, but to the ratio that the distortion bears to the unstretched length. For example, consider a rectangle acted upon by a force of p pounds in each direction. Representing the modulus of elasticity by E_1 and referring to Fig. 4,

$$\frac{p}{E_1} = \frac{(G\,F)}{(F\,A)} \text{ along } A\,F$$

and

$$\frac{p}{E_1} = \frac{(B\,C)}{(A\,B)} \text{ along } A\,B$$

The test is not that $BC = FG$, but that $\frac{BC}{AB} = \frac{FG}{FA}$.

Let p_o be the diagonal stress. Then

$$\frac{p_o}{E_1} = \frac{DE}{AD}$$

And since,

$$\frac{DE}{AD} = \frac{BC}{AB}$$

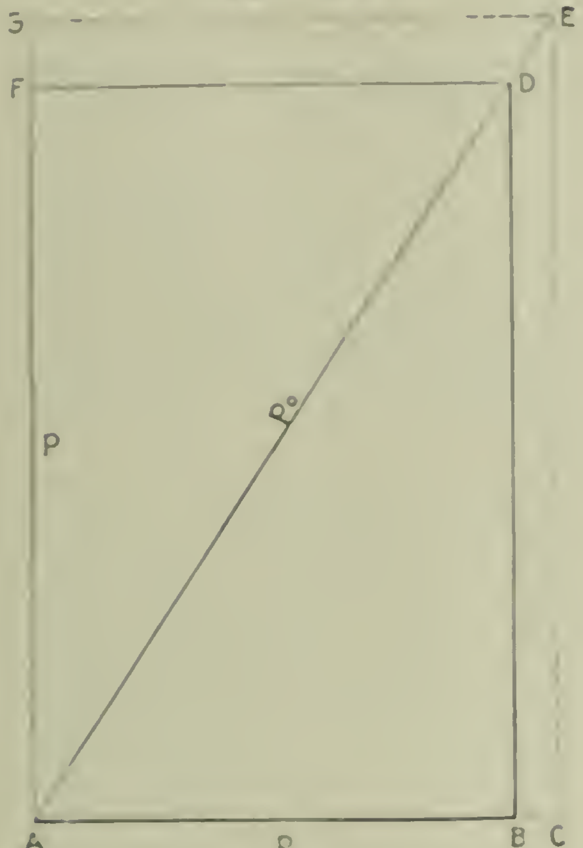

FIG. 4

it follows that

$$\frac{p_o}{E_1} = \frac{p}{E_1}, \text{ or } p_o = p$$

This is when the rectangle is stressed equally in both directions. When stressed unequally the case is more complicated

A. D. RISTEEN.

Hartford, Conn.

The following has special reference to an editorial in the February 28 issue of POWER under the above caption:

Proposition: Through the shell of a steam boiler are there any cross-sections on which the stresses, normal or tangential, are greater than on a cross-section which contains the axis?

A discussion of this problem involves a theorem of internal stress, known as the "Ellipse of Stress." The conditions of the problem give two simple tensile stresses perpendicular to each other, one produced by the pressure on the heads, the other by the radial pressure on the shell; and in a boiler without tubes or stays, the intensity of the stress on a plane parallel to the axis is twice that on a section perpendicular to the axis.

Let Fig. 1 represent a portion of the boiler which is subject to an internal pressure p; then the stress on any horizontal plane XX, per unit of length, is pr, and the intensity of stress or the stress per square inch is $\frac{pr}{t}$, where r is the radius of the boiler and t the thickness of the shell.

The stress on any plane YY perpendicular to the axis is $\pi p r^2$, and the stress per square inch is

$$\frac{\pi p r^2}{2 \pi r t} = \frac{pr}{2t}$$

where $2\pi r$ is the circumference. This also proves that the intensity of stress on XX is twice that on YY as previously stated.

To determine the stresses on any plane ac which makes an angle ϕ with the XX plane consider the small rectangular part of the shell $abcd$, and, by changing the ratio between the length of the sides, angle ϕ may have any value between 0 and 90.

Represent the unit stress acting parallel to YY by p_1, and that parallel to XX by p_2. It will simplify the solution and not change the principles if the thickness of the shell is assumed as unity; then the area of the sections ab and bc may be represented by ab and bc. The total stress on bc is $bc \times p_1$; this will

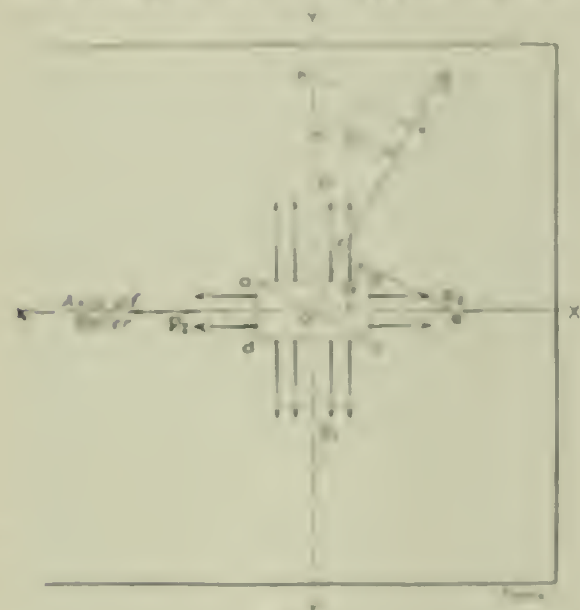

FIG. 1

be distributed over the section ac, acting obliquely thereto, the angle of obliquity being ϕ.

The area of ac is greater than that of bc, and is equal to $\frac{bc}{\sin \phi}$. If the total stress $p_1 \times bc$ is divided by this area the unit stress is obtained, or

$$\frac{p_1 \times bc}{\frac{bc}{\sin \phi}} = p_1 \sin \phi$$

which is the oblique unit stress on ac due to p_1. This oblique stress may be resolved into a normal stress p_{n_1} and a shearing stress q_1. Assume oe equal to the unit stress $p_1 \sin \phi$, then of represents the normal stress p_{n_1}, and fe the shearing stress q_1.

$$of = oe \sin \phi = p_1 \sin \phi \sin \phi = p_1 \sin^2 \phi = p_{n_1}$$

$$fe = oe \cos \phi = p_1 \sin \phi \cos \phi = q_1$$

The arrows indicate the directions in which the stresses act.

Similarly, $p_2 \times ab$ equals the total stress distributed over ac due to p_2. Representing the area of ac in terms of ab and ϕ, area ac equals $\frac{ab}{\cos \phi}$, and dividing the total stress by this area the unit stress on ac is

$$\frac{p_2 \times ab}{\frac{ab}{\cos \phi}} = p_2 \cos \phi$$

the line of action making an angle ϕ with the normal og to ac. Assume oh equal to this unit stress $p_2 \cos \phi$, then ok is equal to the normal stress p_{n_2}, and kh the shearing stress q_2.

$$ok = oh \cos \phi = p_2 \cos \phi \cos \phi = p_2 \cos^2 \phi = p_{n_2}$$

$$kh = oh \sin \phi = p_2 \cos \phi \sin \phi = q_2$$

For the combined unit stresses on ac, take the algebraic sum of the stresses obtained from p_1 and p_2. Noting that the shearing stress q_2 acts opposite to q_1, the normal stress equals

$$p_{n_1} + p_{n_2} = p_1 \sin^2 \phi + p_2 \cos^2 \phi$$

and the shearing stress equals

$$p_1 \cos \phi \sin \phi - p_2 \cos \phi \sin \phi = (p_1 - p_2) \sin \phi \cos \phi$$

This gives the normal and shearing unit stresses on a section making any angle ϕ with the axis of XX.

In this solution, p_1 and p_2 are both taken as tensile stresses, but generally p_1 and p_2 can be either tensile or com-

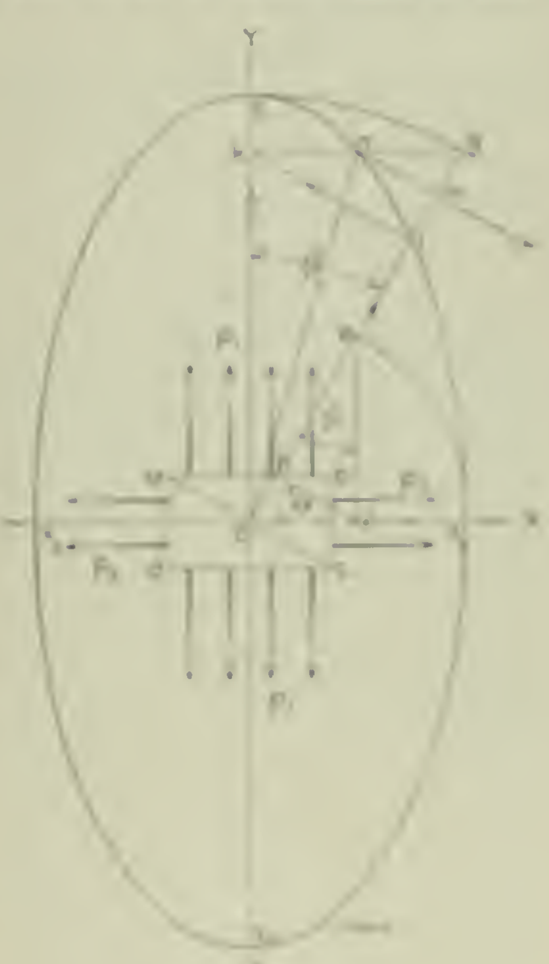

FIG. 2

pressive stresses; when both are tensile or compressive, the shears are of opposite sign; when one is tensile and the other compressive, the shears are of the same sign and the normals are of opposite sign.

In the problem under consideration, p_1 equals 2 × p_2. Substituting this value for p_2,

$p_{n_1} + p_{n_2} = P_n = p_1$ (sin² φ + ½ cos² φ) and

$$q_1 - q_2 = Q = \frac{1}{2} p_1 (sin. \phi \, cos. \phi).$$

Compounding these will give the resultant stress R equal to

$$\sqrt{P_n^2 + Q^2}$$

Next will be shown a graphical method of handling the problem. In Fig. 2, let p_1 and p_2 be the unit stresses on the faces $a\,b$ and $b\,c$. Represent these stresses by $o\,y_1$ and $o\,x_1$. All angles which are equal to ϕ and employed in the solution are marked.

On the normal $o\,g$, take $o\,e$ equal to the unit stress p_2, and draw $e\,f$ normal to $X\,X$. Then $o\,f$ equals the unit stress on $a\,c$ parallel to $X\,X$, since $o\,f$ equals $o\,e$ $sin.\ \phi$. Draw the normal $f\,h$ from f to $o\,g$; then $o\,h$ will equal the normal unit stress p_{n_2} on $a\,c$ due to p_2, since

$$o\,h = o\,f\ sin.\ \phi = o\,e\ sin.^2\ \phi$$

$h\,f$ equals q_2, the shear on $a\,c$ due to p_2, since

$$h\,f = o\,f\ cos.\ \phi = o\,e\ sin.\ \phi\ cos.\ \phi$$

Similarly, take $o\,g$ equal to p_1 and draw the normal $g\,k$ to $Y\,Y$; then $o\,k$ will equal the unit stress on $a\,c$ parallel to $Y\,Y$ due to p_1, since $o\,k$ equals $o\,g$ $cos.\ \phi$. Draw the normal $k\,l$ from k to $o\,g$; then $o\,l$ equals the normal unit stress p_{n_1} on $a\,c$ due to p_1, since

$$o\,l = o\,k\ cos.\ \phi = o\,g\ cos.^2\ \phi$$

and $l\,k$ equals q_1, the shear on $a\,c$ due to p_1, since

$$l\,k = o\,k\ sin.\ \phi = o\,g\ sin.\ \phi\ cos.\ \phi$$

Combining these results

$$o\,l + o\,h = o\,m, \text{ and } - h\,f + l\,k = m\,r + r\,n = m\,n$$

The line $o\,n$ represents the resultant R in direction and magnitude. The point n falls on the line $g\,k$, for the same result may be obtained by combining the unit stresses on $a\,c$ at once; $o\,k$ equals the stress parallel to $Y\,Y$ and $o\,f$ equals $k\,n$ which, in turn, equals the unit stress parallel to $X\,X$, and their resultant is $o\,n$.

The line $y_1\,n\,x\,y_2$ represents the path of the point n when both p_1 and p_2 are tensile stresses; the part below the $X\,X$ axis is the path when the same stresses are considered on the conjugate diagonal planes. If one stress is compressive, the path will be the line $y_2\,x_2\,y_1$. The complete path is an ellipse with the major and minor axis respectively p_1 and p_2. This can be readily proved as follows: The coördinates of the point n are

$$o\,k = y = p_1\ cos.\ \phi,\ k\,n = x = p_2\ sin.\ \phi$$

$$p_2\,y = p_1\,p_2\ cos.\ \phi, \quad p_1\,x = p_1\,p_2\ sin.\ \phi$$

$$p_2^2 y^2 = p_1^2 p_2^2\ cos.^2\ \phi, \quad p_1^2 x^2 = p_1^2 p_2^2\ sin.^2\ \phi$$

$$p_1^2 x^2 + p_2^2 y^2 = p_1^2 p_2^2 (sin.^2\ \phi + cos.^2\ \phi) = p_1^2 p_2^2$$

This is the well known form of the equation of an ellipse: $b^2 x^2 + a^2 y^2 = a^2 b^2$.

The analysis of the problem shows that there are no planes of section on which the stress is greater than on the plane of section parallel to the axis; and it is evident when two simple stresses act on planes perpendicular to each other (on these planes there is no shear) that these are planes of maximum principal stress, since R, the resultant, cannot be greater than the major axis. In fact, the absence of shear on the planes shows that they are planes of maximum principal stress, for any condition of stress acting in the plane of the paper can be reduced to two sections perpendicular to each other and to the plane of the paper on which there is only simple stress, that is, no shear. If the two stresses are of the same kind they will be maximum and minimum values; if of opposite kind, both will be maximum.

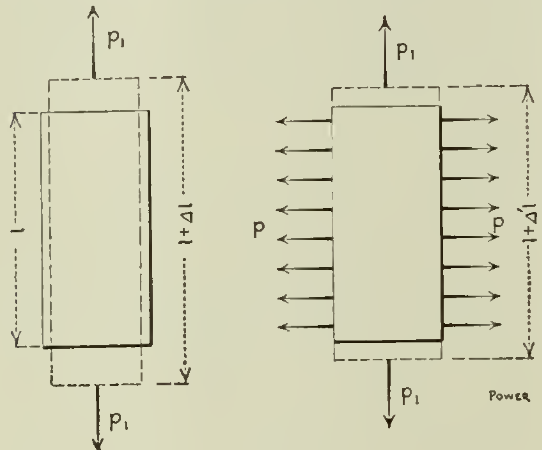

Fig. 3

As to whether the two forces acting at right angles to each other tend to raise or lower the yielding point of the material in directions parallel and perpendicular to the axis, the following extract from Greene's "Structural Mechanics," page 203, may throw light on the subject: "A plate is stronger to resist two pulls at right angles than when subjected to one only." Calculations are also made for a boiler plate subjected to a tension p_1 on a section parallel to the axis, and $\frac{1}{2}\,p_1$ on a section perpendicular to the axis, and this conclusion is arrived at: "Hence the true unit tension is less than the apparent tension by 12½ per cent., and the boiler is stronger than it would be if the longitudinal tension from the steam pressure on the heads did not exist."

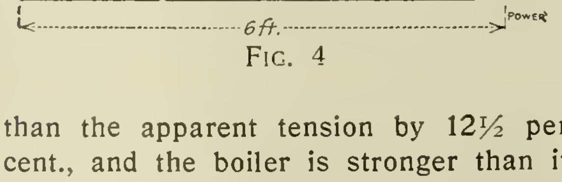

Fig. 4

Cotterill's "Applied Mechanics," page 412, states that the coefficient of elasticity E is increased in value, or, in other words, if the metal is subjected to a lateral pull, the piece will not elongate as much from the direct pull as when this lateral pull is not present.

It is difficult to see just how the unit stress can be reduced, since the stress in a body originally free from stress is caused by an external force and the unit stress is obtained by dividing this external force by the area; hence, to reduce the unit stress it would seem necessary to decrease the external force or else increase the area, and this is not done.

In Fig. 3 the left-hand sketch shows the change in shape of a rectangular piece subjected to the pull of an external force p_1; the full lines represent the shape before the force p_1 is applied and the dotted lines the shape after the force has been applied. It may be seen that when a single force p_1 acts on a bar there is a lengthening parallel to the line of action of the force, and a contraction perpendicular thereto. The unit stress on a right section is p_1 divided by the area.

In the right-hand sketch the piece is subjected to a lateral force p, the intensity of which is such that no contraction takes place when the force p_1 is applied. Here the elongation will be less than in the first case. The unit stress will be p_1 divided by the area as before.

In the left-hand sketch the length after the force p_1 has been applied is $(l + \Delta\,l)$, where l is the original length and Δl is the increase per unit length. In the right-hand sketch the length will be $(l + \Delta' l)$, where $\Delta' l$ is less than $\Delta\,l$. Where E and E' represent the coefficients of elasticity,

$$E = \frac{p_1}{\Delta\,l} \text{ and } E' = \frac{p_1}{\Delta'\,l}$$

Hence E in the first case is less than E' in the second case. The conclusion that E is less than E' may be arrived at by considering the unit stress on a cross-section the same in both cases; and the conclusion that the stress on a cross-section is decreased may be arrived at by considering that E', the coefficient of elasticity, does not change.

From what has been written on the subject it appears safe to assume that the two stresses at right angles do not, on any plane, subject the shell to a stress greater than that on the longitudinal plane, and it is possible that the material may be able to resist a greater pull when subjected to a lateral stress than when not, due to the fact that it will take a greater force to produce the same elongation and not any decrease in the unit stress.

This problem suggests a way in which the weakness of the shell due to the riveted joint may be overcome. Assume, for example, a boiler with a triple-riveted butt joint having an efficiency of 85 per cent. If this joint coincides with a plane on which the resultant stress R is less than 85 per cent. of the stress on a plane parallel to the axis, the joint will be stronger to resist the bursting pressure than the shell itself. Proceed to locate this plane when p_2 equals ½ p_1. Noting that the resultant

$$R = \sqrt{p_1^2 \cos^2 \varphi + p_2^2 \sin^2 \varphi}$$

and that R equals 85 per cent. of p_1,

$$(0.85\, p_1)^2 = p_1^2 \cos^2 \varphi + \tfrac{1}{4} p_1^2 \sin^2 \varphi$$

$$(0.85)^2 \times 4 = 4 \cos^2 \phi + 1 - \cos^2 \phi = 3 \cos^2 \phi + 1$$

$$1.89 = 3 \cos^2 \phi,\ \phi = 37\tfrac{1}{2} \text{ degrees}$$

From this it will be seen that if the seam made an angle of 37½ degrees with the axis, the seam would be as strong as the

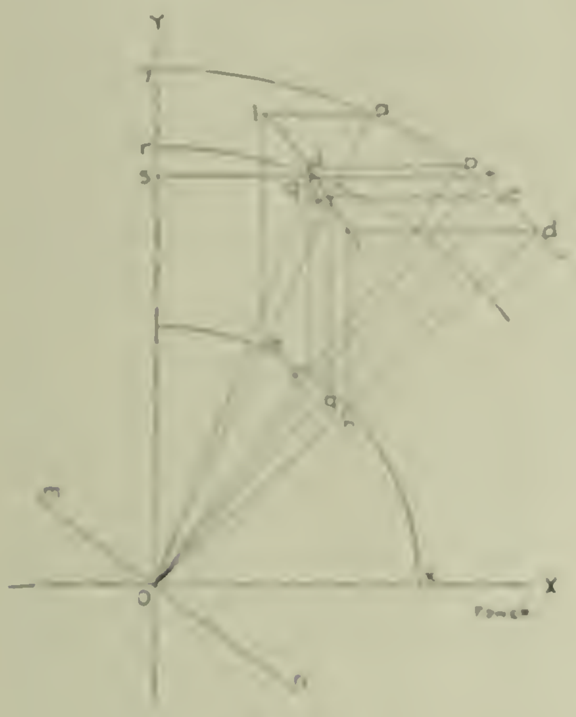

Fig. 5

shell to resist the stresses acting, and this on the assumption that p_2 equals ½ p_1, which, generally, in a steam boiler is not true, due to the tubes and bracing.

Consider a horizontal tubular boiler 72 inches in diameter and with through braces. If it is assumed that the shell carries the pressure on the heads which fall within 6 inches of the shell, the error will be on the safe side. This gives as the total stress on the shell when p is the pressure per square inch

$$p\,(36^2 \pi - 30^2 \pi) = 1244\, p$$

Dividing by the circumference,

$$\frac{1244}{226}\, p = \text{approximately } 5\tfrac{1}{2}\, p$$

as the stress per lineal inch on a section perpendicular to the axis. The stress per lineal inch in the shell due to the radial pressure is 36 p. From this is obtained the ratio,

$$\frac{p_2}{p_1} = \frac{5\frac{1}{2} p}{36 p} = \frac{11}{72}$$

and

$$p_2 = 0.15\, p_1, \text{ or } p_2 = \frac{2}{13}\, p_1$$

Solving the problem on this basis,

$$(0.85\, p_1)^2 = p_1^2 \cos^2 \phi + \frac{4}{169} p_1^2 \sin^2 \phi$$

whence

$$\cos^2 \phi = 0.846 \text{ and } \phi = 32 \text{ degrees}$$

If the sheet be 6 feet wide, the seam will extend around the shell (see Fig. 4)

$$6 \times \tan 32 \text{ degrees} = 6 \times 0.625 = 3.75 \text{ feet}$$

It seems that this should not be a serious difficulty, practically, when it is considered that a quadruple-riveted butt joint is used to increase the efficiency of joint to about 92 per cent., while this construction makes it as strong as the shell.

I also add an easy graphical method of locating the required plane (see Fig. 5). Take p_1 equal to $o\,y$ on the Y-axis; p_2 equal to $o\,x$ on the X-axis; and $o\,r$ equal to the resultant R. Draw arcs of circles with these distances as radii. Through these circles draw the radial lines $o\,a$, $o\,b$, $o\,c$ and $o\,d$, and from the points where these lines cut the circles locate the points i, j, k and l, of the ellipse as shown. A line drawn from o to the point where the ellipse cuts the circle of radius r is the resultant, and a line drawn through this point parallel to the X-axis cuts the large circle of radius p_1 at the point t; $o\,t$ is normal to the plane $m\,n$ on which R is the resultant stress; hence, $m\,n$ is the required location of the seam.

Bradford, Penn. JAMES CLARK.

The editorial under the above caption in the February 28 issue set me to thinking, and I worked out the following:

Laying out a force diagram, as in Fig. 1, with two units of force acting in one direction and one unit of force acting at right angles to the first, the resultant force acts along the hypotenuse and equals 2.23607 units of force.

A piece of boiler plate one inch square is so nearly flat that it may be considered as such, and if twice the stress be applied in one direction as is applied in a direction at right angles it will represent the conditions to which the shell of a

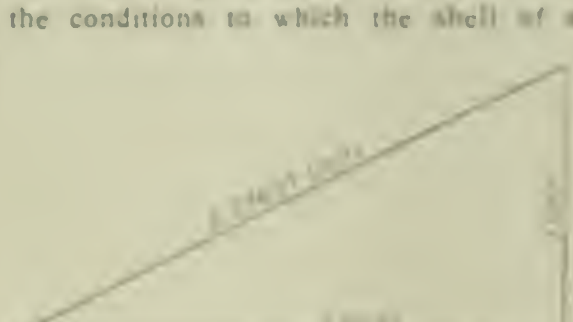

Fig. 1

boiler is subjected, so far as pressure is concerned. Up to the elastic limit the change of length will be proportional to the stress.

Let the two units of force representing the circumferential stress lengthen this side 0.2 inch, and with one unit applied to the other side it will be lengthened 0.1 inch; this represents the girth stress. The square will then have changed to a parallelogram having sides respectively 1.2 and 1.1 inches.

Laying out a second force diagram, as in Fig. 2, the line of the resultant force is found to extend from the lower left-hand corner to a point half way up the short side. This force, as in Fig. 1, equals 2.23607 units, but it is resisted by the metal along a line at right angles to its line of action, that is, along line $A\,B$.

$$\text{Tan. } d\,c\,b = \tfrac{1}{2}$$

Angle $d\,c\,b$ = 26 degrees 33 minutes 53.5 seconds

Angle $a\,c\,d$ = 90 degrees − 26 degrees 33 minutes 53.5 seconds = 63 degrees 26 minutes 6.5 seconds

Line $a\,d$ = sin. $a\,c\,d$ × 1 = 0.89442

Line $c\,d$ = cos. $a\,c\,d$ × 1 = 0.44727

Line $d\,b$ = tan. $d\,c\,b$ × $c\,d$ = ½ × 0.44727 = 0.223635

Line $a\,b$ = $a\,d$ + $d\,b$ = 0.89442 + 0.223635 = 1.118055

Hence

Fig. 2

$$\frac{2.23607}{1.118055} = 2 \text{ units stress}$$

per inch width of metal in the direction of the resultant force.

The cosine of angle $d\,c\,b$ equals 0.89442, and the length of the line along which the resultant force acts is

$$\frac{1}{0.89442} = 1.118 \text{ inches}$$

before the force is applied.

If one unit of force will lengthen an inch of the metal 0.1 inch, 2.0000 units will lengthen the line of the resultant force

$$1.118 \times \frac{2.0000}{10} = 0.2236 \text{ inch}$$

which added to the original length equals

$$1.118 + 0.2236 = 1.3416 \text{ inches}$$

If the long side of the plate be divided by the cosine of angle $d\,c\,b$ the result will be

$$\frac{1.2}{0.89442} = 1.3416 \text{ inches}$$

which was previously obtained.

I believe that this shows that the greatest stress is along the longitudinal line. Of course, the deformations here assumed are greater than an actual boiler plate would be subjected to, but the proportions will remain the same.

West Fitchburg, Mass.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Small Filter Tank

I have a large wood tank which I wish to convert into a filter for boiler-feed water. Please tell me how to do it correctly.

S. F. T.

Across one part of the tank, near the bottom, a loose floor of slats should be laid. On this floor put a layer of burlap, excelsior or gravel, and cover with coarse sand. Let the water in on top of the sand at one end and pump from the bottom of the tank at the other.

Valve Setting on Armington & Sims Engine

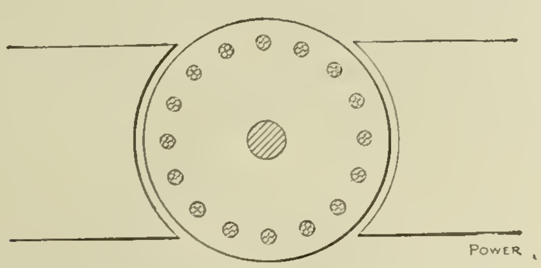
How can I set the valves on a cross compound-condensing Armington & Sims engine? Also, how can I prevent the engine from running away when working condensing and the load is suddenly released?

W. J. P.

The Armington & Sims engine belongs to the class in which the valve setting is by lead. All that the engineer can do is to keep the valve stem of such a length that the lead will be approximately equal at both ends. In this engine the lead is constant for all points of cutoff, and it is possible that with a condenser steam enough may be admitted through lead to run the engine above a safe speed without load. If such is the case a separate speed-limit or safety-stop appliance is the only remedy.

Completely Embedded Armature Wires

If the wires of an armature winding were threaded through holes some distance from the edge of the core, as shown in my sketch, would the armature generate any electromotive force when revolved between field-magnet poles, as in an ordinary dynamo?



ARMATURE WIRES COMPLETELY EMBEDDED

W. C. T.

Yes; but not quite as much as though open slots were used, as in the usual form of armature. Some of the magnetic lines would pass from pole to pole through the narrow strip of core metal between the holes and the periphery without affecting the armature conductors at all, but a large proportion would have to pass to the inner part of the core because the annular strip around the edge would not carry all of them. Those that pass to the inner core body would generate an electromotive force in the wires.

Cause of Knocking

At times my engine has a peculiar knock. If I feed a lot of oil the sound is reduced but not entirely removed. Can you tell me the cause of the knock and the remedy?

G. B. S.

It is doubtful if a lack of oil will cause knocking. Insufficient lubrication will cause harsh grinding noises, but not knocks. It sometimes happens that the piston ring has "play" in its groove, which will result in a knocking that is difficult to locate and a flood of oil will reduce the sound by partially filling the waste space and reducing the lost motion. The remedy in such a case is a new ring properly fitted.

Water Meter in Feed Pipe Line

I am about to install a water meter on my feed line to the heater. The supply pipe is two inches. I have been told that a 1-inch meter will be of ample size to deliver all my water; but I want to know whether the pressure on the discharge side of the meter will be reduced or whether an increased velocity through the meter will hold the pressure.

W. J. M.

The reduction in pressure on the discharge side of the meter in the feed line will be only that required to overcome the friction of the meter and is negligible.

If the demand for feed water requires the use of a 2-inch pipe, a meter with 2-inch connections should be installed, as one with 1-inch connections will require a velocity of flow through the meter four times as great as that for which it was designed.

Blow Back in Crane Safety Valve

Can the amount of blow back in the Crane Company's pop safety valve be changed by dismantling the valve and changing the tension of the auxiliary spring?

L. B. R.

The blow back in the Crane pop safety valve depends on the tension of the auxiliary spring, which is adjusted at the factory. If there were no tension at all on the spring, the disk which forms the huddling chamber would slide up the stem whenever the valve opened, and there would be no blow back at all. If the tension of this spring were made equal to or greater in proportion to the area of the huddling chamber than that of the mainspring, the blow back would depend on the area of the huddling-chamber disk. Hence, at any tension between zero and that of the mainspring, the blow back will depend on the auxiliary spring, and may be adjusted or altered by increasing or diminishing its tension.

The Six-stroke Cycle

What are the successive strokes in the six-stroke gas-engine cycle?

L. A. B.

(1) Mixture intake; (2) compression; (3) expansion; (4) expulsion or exhaust; (5) intake of air alone; (6) scavenging, driving out the air just taken in, together with a large part of the burned gases from the previous combustion.

Compounding and Overcompounding

What is the difference between a compound-wound and an overcompound-wound dynamo?

E. R. K.

A "flat"-compounded dynamo gives exactly the same voltage at its terminals at full load that it does at no load. An overcompounded dynamo gives a higher voltage at its terminals at full load than at no load. The difference is produced either by proportioning the series field winding differently or by the adjustment of a resistance strip in parallel with the series field winding, commonly called a "shunt" strip. POWER

The Alaskan Coalfields

The *Philadelphia North American* is authority for some disclosures regarding the Alaskan coalfields which should make the conservationists sit up and take notice.

According to this report it appears that on October 28, eleven days before the last election and several months after the attempt to turn over the Alaskan coalfields to the Morgan-Guggenheim interests had been frustrated by public sentiment, President Taft himself gave actual control of the coalfields to this same syndicate.

In the Ballinger investigation the fact was brought out that the claimants to these coalfields, which had been thrown open to public entry, had signed an agreement with the Morgan-Guggenheim syndicate by which a half interest in the property was to pass to the latter. Furthermore, all coal was to be sold at a fixed price to the syndicate, which was already building a railroad to the fields from Cordova bay, and any further sale to consumers was to be made by the syndicate. The unexpected opposition which developed against turning over these public lands to claimants who were no more than representatives of the Morgan-Guggenheim interests, made the outcome of the scheme somewhat doubtful. Hence, the syndicate began to look about for other outlets, from the mines to the sea, than those already under its control.

There remained just one other outlet to a natural harbor (Controller bay) and this lay in the Government forest reserve and was thus protected against private interests. The President, however, signed an order withdrawing this strip of land from the reserve and throwing it open to public entry. It appears that this order was not made public until a short time ago and it is charged that during the intervening time representatives of the Morgan-Guggenheim interests have taken up claims upon the land and have thus secured for the syndicate absolute control of the only possible outlet from the mines to tidewater, not already under their control.

To the general public the motives underlying the President's actions in this case must remain more or less a matter of conjecture. He may have been the victim of misrepresentation, or he may have taken the stand that these coalfields should be developed as soon as possible and that only a concern of such magnitude as the Morgan-Guggenheim syndicate would be in a position to effectively carry out the development. Whatever the motives, the action was untimely in view of the pending investigations and the public attitude regarding conservation, and the preservation to the people of their interest in the country's natural resources.

Firing Boiler Furnaces

Various articles have been published giving advice as to the best method to pursue to get better results in the boiler room.

It is well known that the principal losses are due to poor firing, improper working of the stokers, where used, excessive air admitted to the furnace and improper furnace design. Then there are scaly boilers, steam pipes radiating heat, and leaky inlets and valves.

It is within the province of every engineer to eliminate to a great extent these sources of loss, if he goes about it in the right way. Doubtless the problem of getting the firemen to handle their fires properly is the most difficult one that the engineer has to solve.

How often should the firemen fire the boilers? How much coal should they put in the furnace at one firing, and how thick a fire should be carried? It has been urged that the greatest economy is obtained when the least amount of fuel is put into a furnace at any one time that will maintain a constant steam pressure. Throwing in from ten to fifteen shovelfuls of coal at one firing is wasteful and should not be countenanced.

Some engineers contend that a thin fire is the better; others that a thick fire gives better results, and still others that a medium fire is the most desirable.

Doubtless the advocates for each thickness of fire have good and valid reasons for preferring one method over the other, but how have they arrived at the conclusion that their methods are the best and most economical?

In a certain plant in a manufacturing city, the firemen fire at a given signal, slice the fires at another signal, and level at a third signal and good results are said to be obtained. In another plant the firemen fire when they think the fires require a new charge of fuel. In fact, they use their own judgment as to the way the fires ought to be handled and, although an exceedingly thick fire is carried, the plant is said by those who are in a position to know to be one of the most economically operated plants in the New England States.

Why should two steam plants, operated under such radically different lines, give the good results that are claimed for them?

It would seem that there is more to this firing problem than has been determined. It would also seem that it is not a safe thing for an engineer to follow one method of firing just because someone else has been obtaining good results. A better way would be to carry on experiments with various methods of firing to find out just what method is the most economical for any particular plant. If a thin fire and frequent firing are best, use this method; if heavy firing and a thick fire give better results, use that method. It is not the way coal is fired that counts; it is the economical results obtained from the burning fuel that are of real importance.

Who Is Responsible

If the news items sometimes seen in the daily press are a criterion of the intelligence of the men who are often entrusted with the care of steam-power machinery, the efforts of the advocates for engineers' license laws should also cover the field of watchmen and wipers.

It is recorded that "a watchman in the employ of the Diamond Sand and Gravel Company, of Bedford, O., was severly scalded while attempting to make some slight repairs to a safety valve." How he discovered that repairs were necessary or on whose authority he started the work does not appear. There was pressure on the boiler, so he drew the fire, climbed to the top of the boiler and with a large monkey wrench started to unscrew the valve from the boiler. While doing this the valve opened, the discharge striking him fair in the face, scalding him badly and probably destroying his sight.

It is a pitiful story. A young man blinded and disfigured for life because someone blundered. But who? Was it the man himself or the one who made him a watchman? Why should a watchman in a State full of licensed engineers meddle with a safety valve whether on or off a boiler?

Did he think that the steam pressure would cease as soon as the fire was drawn?

Every few days someone is killed or injured because someone else did not know that the gun was loaded. But everybody knows that the steam boiler is loaded. Yet accidents both painful and fatal are of daily occurrence because the simplest of natural laws are recklessly violated.

In one State a boiler explodes because the man in charge screws down on the safety-valve spring and in another because the stop valve is opened too suddenly. Who is responsible for such blunders, the man who knows no better or his employer?

The paths of progress in all lines are marked by martyrs and perhaps the human race will not be slower to learn at the costly school of experience than are the lower animals. It is to be hoped not.

Machine-Made Engineers

There seems to be an impression permeating some quarters that the Institute of Operating Engineers is to be used for the purpose of turning out a supply of "machine made" engineers to compete with and displace the homemade variety now operating most of the power plants.

Nothing could be further from the truth. The primary idea of the Institute is to direct intelligently the education of the present engineer, and of the power-plant worker who desires to become one. Far from bearing the "machine made" earmarks of mediocrity, each individual will be advanced in his standing in the Institute as he demonstrates his fitness for advancement.

The Institute has nothing to offer to the contented worker but everything to the one who, possessed by an intelligent dissatisfaction with his present position and attainments, is willing to earn preferment.

To the engineer who recognizes the fact that he owes to himself as well as to society the duty of making the most of his opportunities for mental and manual training the Institute will be an ever welcome guide and help. But there is no room on its membership roll for the names of those who are satisfied to continue as manual workers for wages alone.

Comparative Steam Turbine Performances

Upon page 595 of the April 18 issue was given a comparison of results obtained with Curtis turbines as built by the Allgemeine Elektricitäts Gesellschaft, of Berlin, and the General Electric Company, of Schenectady. While the steam actually used is less for the German turbine, 11.9 and 11.97 pounds per kilowatt-hour against 12.9 and 13 for the American, the German turbine was tested with a much higher degree of superheat, and in the later test with a better vacuum. The pressure was about the same in all four tests, from 188 to 195 pounds, but the temperature in the German tests was 601 and 630 against 525 and 505 degrees, giving the German turbine 256 and 285 degrees against 95 and 125.1 for the American. Here is a difference of 160 degrees of superheat and the experience of the General Electric Company has been that the performance of its turbine is improved one per cent. for about 12.5 degrees of superheat. The performance of the German turbine in question with the higher degree of superheat is only about eight per cent. better than the American with 160 degrees less which ought to improve its performance about 13 per cent.; and the German turbine had a somewhat better vacuum.

The American turbine was designed for the conditions under which it ran and converted 66.2 per cent. of the heat available by the Rankine cycle, while the German turbine converted only 63.6 of the available heat under the conditions of its test.

The use of high degrees of superheat is not common in America, and it is hardly fair to compare water rates obtained under conditions involving greater possibilities with those obtained here under less favorable conditions.

Investors in water-power development want to know what the Government will do with their property at the end of a limited franchise.

Self-respect and a definite knowledge of one's ability are requisite to complete success in engineering or anything else. But self-inflation and the unproved assumption that you are just as capable as any other man are fatal, especially in power-plant work.

Because it is sold as "carbonless antifriction unchangeable cylinder lubricant," some men will unquestioningly torture the cylinder of a gas engine with stuff that is about as healthy for it as axle grease would be for a watch.

An average boiler efficiency of 80.47 per cent. is unusually high. This was obtained at the Redondo plant of the Pacific Light and Power Company, using crude oil as fuel.

Where a cooling tower is used a moderate vacuum under some conditions is preferable to a high vacuum.

In the power-plant field there are specialists in all branches of the trade—even brake specialists. See page 723 of this issue.

The season of refrigeration is now at hand and our new department will be right in line. Good practical articles on the operation of refrigerating machinery and special kinks installed in your plant is the kind of material needed to make this department a success. We are depending on our readers to come to the front.

It is one thing to know how to play a scientific game of pool and another to run a power plant; the pool game will not give many pointers.

Government Water Power Developments

In the power field there is no question of more pressing importance than Government control and development of water power. The recent discussion before the National Electric Light Association brought out some interesting points on the subject. It is high time for the Government to get busy and establish some definite policy. On this same general question an interesting editorial on water powers was recently published in the *Engineering Record* and is reproduced in the following paragraphs:

The utilization of water power in Sweden at the present time has an aspect which deserves to be investigated carefully and the details put on record for the benefit of those interested in the rational development of our own water powers. New York State has an area only one-fourth that of Sweden, but its population is almost twice as great. Although its resources, per capita or per square mile of territory, are much greater than those of the Scandinavian kingdom, and, although a State Water Supply Commission has made an analysis of its water-power possibilities which points with the utmost clearness to the desirability of developing these resources under some system of State control and aid, nothing has been done along these lines but to talk. As a result, the choicest power sites in the State are being developed quite quickly by companies and, if legislation is not more rapid than hitherto, the people of the State will shortly find that any rational utilization will be extremely costly, owing to the rights that are now being secured so diligently and unobtrusively by private parties. No one can read the reports of the New York Water Supply Commission and the monograph on hydraulic power development written by M. O. Leighton for the United States Geological Survey without being thoroughly convinced that State control and State aid in this work are desirable theoretically and very necessary practically.

In Sweden the early hydraulic-power development was done by the private companies and there are many of them in that country. A study of the water resources of the State showed, however, that a large amount of power was not being utilized by those companies which could nevertheless be developed and sold on a profitable basis. Coal is expensive in Sweden and power developed at hydroelectric plants has a wider range of commercial value than is the case where fuel is less costly. The government has undertaken the construction of hydroelectric plants which it proposes to run as revenue-producing establishments, if possible, and in any case in such a way as to meet all charges. The government works now under construction at the Trollhättan and Porjus falls have been described in numerous electrical publications and these will be ready for service before long. Their manifest success has led to the development of a third project, at Alfkarleby falls on the Dals river, which it is believed will receive the approval of the legislature. Some figures recently published in *Engineering* show that within 65 miles of the power station there is a probable consumption of nearly 15,000 kilowatts, which will call for development of about 22,000 hydraulic water power. If the uses of electricity are still further extended the plant can be increased to a capacity of 45,000 horsepower. The initial installation will cost something like $125 per horsepower, but the total cost of the final installation of 45,000 horsepower will be at the rate of $55 per horsepower. These figures are only approximate, for the information at hand does not indicate how much reserve capacity is included, although it is understood that there is a reserve and that the rating of the station is that for continuous operation.

The technical details of these government plants are decidedly interesting, but they are subordinated by the important economic principles involved in their construction. The Swedish government sends engineers to this country to report on what is being done in the way of developing water power in the United States. It is highly desirable for our Government or for one of the States to send representatives to Sweden in order to find out just what that enterprising kingdom is doing. It is certainly showing more sense in dealing with hydraulic power than we are.

A Busy Day at the Plant

By A. E. Dixon

Of course, you know things happen in bunches. Well, we got ours the other day. First round was called off in the smiths' shop, where the boss told one of the "Hunkies" to liven up a fire a bit. Well, he just selected the wrong Hunkie, and one who happened to know the location of a loose five-gallon can of benzine. Mr Hunkie sure did liven that fire some. The boss got his share of it, or rather more than his share, while the Hunkie got his hands burnt. Better luck than management.

The next episode was trying to put a belt on. This was called off before we'd got quite quieted down from the explosion. The machine hand had seen that belt put on a dozen times and so he concluded he'd put 'er on. Well, he sure was a lucky boy; his overalls was old, but he was one scared kid and will leave the putting on of belts to the right man hereafter. He climbed the ladder and got the belt on, but he got the skirt of his overall jacket in the belt and a single yank took it off him. The cloth was rotten from alkali and tore easy or Johnny would have gone over the shaft and into the ambulance. He was so scared he could not get down the ladder.

Mechanical Engineers at Pittsburg

The application of mechanical engineering in the field of cement manufacture will be one of the important questions considered by the American Society of Mechanical Engineers at their annual spring meeting, to be held in Pittsburg, Penn., May 30 to June 2. Papers will be presented covering different phases of the subject.

In addition to papers dealing with machine-shop practice, there will be papers on the "Commercial Application of the Turbine Turbo-Compressor," by R. H. Rice, of the General Electric Company, West Lynn, Mass.; and upon "Hydraulic Forging Presses and Blowing Engines"; and on miscellaneous topics, including papers on "Stresses in Tubes," by Reid T. Stewart, professor of mechanical engineering of the University of Pittsburg; the "Purchase of Coal on the Heat Unit Basis," by Dwight T. Randall, engineer in charge of the fuel-engineering department of Arthur D. Little, Incorporated, Boston, Mass.; "Energy and Pressure Drop in Compound Steam Engines," by F. L. Cardullo, of the department of mechanical engineering of the New Hampshire College of Agriculture and the Mechanic Arts; and "A Pressure Recording Indicator for Punching Machinery," by Gardner C. Anthony, dean of the engineering school of Tufts College. There will also be a session on gas power, with papers to be announced.

The convention will open on Tuesday afternoon, May 30, with the registration and reunion of members at the headquarters in the Hotel Schenley, followed by an informal reception for members and guests on the evening of the same day. There will also be an opportunity on Tuesday and Wednesday afternoons for inspection of the Foundry and Machine Exhibition Company's exhibit, which will be in progress in the exhibition building. On Wednesday morning, "The Mechanical Engineering of Cement Manufacture" will be the subject of the first of the technical sessions, all of which will be held in Carnegie Institute, in close proximity to the society's headquarters. In the afternoon a trip to the works of the Universal Portland Cement Company will be made, with a stop at East Pittsburg to allow those who desire to visit the plants of the Westinghouse Electric and Manufacturing Company and the Westinghouse Machine Company. The second technical session, at which the papers on "Machine Shop Practice" will be presented, is scheduled for the evening of the same day. The professional session of Thursday morning will deal with miscellaneous topics and will be as brief as possible, in order to leave ample time for an excursion up the Monongahela river, including a visit to the National Tube Company's works at McKeesport. A reception and informal dance will take place in the evening at the convention headquarters. The concluding professional session, at which "Steel Works Practice" will be the subject for consideration, will take place on Friday morning. An inspection trip to the Mesta Machine Company's works at Homestead, Penn., is planned for the afternoon of Friday, and the convention will close that evening with a smoker and entertainment given by the Engineers' Society of Western Pennsylvania at their rooms in the Oliver building. A ladies' committee, Mrs. Chester B. Albree, chairman, will care for the pleasure of the guests of the society and will, as is usual at these conventions, do much to add to the social features of the occasion.

N. A. S. E. State Conventions

The following is a list of the annual conventions of the various State associations, giving the place of meeting and the date for each State in alphabetical order:

California	San Francisco	June 5-10
Colorado	Pueblo	June 9, 10
Connecticut	Hartford	June 23, 24
Illinois	Ottawa	May 19, 20
Indiana	Terre Haute	June 9, 10
Iowa	Ottumwa	May 25-27
Kentucky	Louisville	June 2, 3
Massachusetts	Worcester	July 14, 15
Michigan	Saginaw	July 21, 22
Minnesota	St. Paul	August 23-26
Missouri	Kansas City	July 12-14
New Jersey	Newark	June 3-5
New York	Albany	June 9, 10
Ohio	Cincinnati	September 11, 12
Pennsylvania	Johnstown	June 2, 3
Texas	San Antonio	
West Virginia	Clarksburg	
Wisconsin	Milwaukee	June 8-11

SOCIETY NOTES

At the second annual meeting of the American Institute of Steam Boiler Inspectors, held at the Parker house, Boston, the following officers were elected for the ensuing year: President, J. F. Molloy; vice-president, A. D. Evans; treasurer, Adam Oldfield; secretary, T. G. Ranton, 112 Water street, Boston; executive committee, E. R. Doherty, M. S. King, E. J. Scanlan, H. Van Ormer and R. L. Hemingway.

The tentative program of the coming convention of the National Electric Light Association, May 30 to June 2, provides for two sessions daily for four days and over sixteen sessions in all, there being several parallel sessions. There are twenty-four papers in the program and nearly forty committee reports. In all there are some seventy items in the order of business and it will take the full time of the convention to dispose of them.

Detroit is planning for the convention of the National Gas and Gasolene Engine Trades Association meeting of June 20 to 23, inclusive. President C. O. Hamilton is planning a convention that will consist of snappy sessions, comparatively short in length, with plenty of opportunities for discussions, seeing of the exhibits, viewing the many civic and commercial attractions of Detroit and leaving time for much in the way of entertainment. Exhibit space will be provided without charge for any light articles which can be shown without damage to woodwork or floors of the Hotel Pontchartrain, where the convention will be held.

The third international congress of refrigeration will be held in the United States in 1913 under the auspices of the American Association of Refrigeration. The second international congress was held at Vienna in October of 1910. Theodore O. Vilter, of Milwaukee, who represented the American association at the Vienna congress, who was active in obtaining the third congress for America and who is now the president of the American association, has isued an urgent appeal for members and contributions to an extent which will allow the American association to provide a reception and entertainment which will compare with that which was accorded to the congress at Vienna.

PERSONAL

A. H. Foster, formerly with the Clement Restein Company, has recently changed his position and is now connected with the Henry Johnson Packing Company, of Jersey City.

Henry R. Cobleigh has resigned as mechanical editor of *The Iron Age*, which position he has held for the last seven years, to take charge of the advertising and publicity of the International Steam Pump Company, 115 Broadway, New York City. He entered upon his new duties May 1.

Percival Robert Moses, consulting engineer, 366 Fifth avenue, New York City, announces that he has associated with him the following engineers as permanent additions to his staff: John Fallon, industrial engineer, recently mechanical engineer of the Tennessee Copper Company, and Stanley G. Flagg & Co.; Arthur V. Farr, textile engineer, formerly Szepesi & Farr, 90 West street; Alphonse Kaufman, formerly manager and chief engineer of the Alaska Chemical Company, and associated with Charles B. Jacobs industrial laboratories; J. N. Walton, recently power engineer and storage-battery expert of the Brooklyn Edison Company. The office is prepared to handle complete industrial equipments.

BUSINESS ITEMS

The Rateau turbine, which has been heretofore built in this country by the Bail & Wood Company, is now manufactured by the Southwark Foundry and Machine Company, Philadelphia. The company, already has under construction some large turbine-driven centrifugal biowers for steel-works service.

Beginning May 1 the Bundy steam trap, which has always been manufactured by the Nashua Machine Company, Nashua, N. H., and marketed through selling arrangements, formerly with the A. A. Griffing Iron Company, and later through the American Radiator Company, will be sold through the selling department of the Nashua Machine Company, located at 127 Federal street, Boston, Mass. The sales manager will be John Sabin, who was the first man to introduce a tilting trap on the market over twenty years ago and who has been closely associated with the Bundy trap ever since.

A book which should prove very attractive to engineers has just been issued by the George M. Newhall Engineering Company, of Philadelphia, manufacturer of the Vance steam trap. The book is called the "Engineers' Reference Book," and is more than half composed of valuable information for the engineer, gleaned mostly from Kent's "Mechanical Engineers Pocket Book." There are between 50 and 100 subjects reprinted from Kent's alone, embracing information which the engineer has almost daily need for. It will be sent to anyone requesting a copy, and is partly devoted to a discussion and comparison of the different types of steam traps: a large portion of which is regarding steam-trap capacities. A very original and practical method is given for determining what capacity of traps are required under all different conditions. The book also contains complete description of the Vance steam trap. Anyone desiring a copy can obtain one without cost from George M. Newhall Engineering Company, 136 South Fourth street, Philadelphia, Penn.

HELP WANTED

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

POWER

NEW YORK, MAY 16, 1911

MANUFACTURING in the New England States dates back to the landing of the Pilgrims at Plymouth, Mass. It was not always carried on by means of the steam boiler and engine. The early looms and spinning wheels were deftly operated by the dexterous fingers of the settler's wife and daughters.

Whenever the arms tired with the wielding of the "wheelboy" the speed of the spinning wheel was reduced and the output of home-spun yarn fell below the average.

Conditions have changed since the days of the spinning wheel. Today more cotton and wool are spun in one hour in the mills of New England than could have been spun in years by all the settlers' wives put together.

But the relation of speed and output remains the same. If the engineer today allows the steam pressure to drop and the speed of the engine is reduced but one-half turn per minute, the speed of the spindles on the spinning machine in the factory is reduced several revolutions, the threads of yarn are not twisted as rapidly and the output of the mill falls below its rating.

This is one of the losses which is hidden by the turning of the wheels. To all appearances the speed is as it should be, but the loss of that one-half turn of the engine flywheel is multiplied a good many times by the thousands of spindles in the mill.

And the engineer is the one man to blame. He can prevent this loss if he will. There are some mighty good engineers in the New England States in charge of cotton- and woolen-mill steam plants, but it is a certainty that all of them do not keep their engines right up to the maximum speed all of the time.

It is evident that the engineer who does keep his engine up to speed is the man who is giving his employer the better service.

Of course, loss of speed reverts back to the boiler room, but it is the business of the engineer to run the boiler room. If he does not get 100 pounds of steam it is his own fault.

Thousands of dollars are never earned in manufacturing plants because the speed has been below that required to give normal capacity.

The loss of one-half turn of the flywheel per minute is seemingly a small matter, but it costs money. The loss is seldom traced to the engineer, but if he knows of the loss and fails to improve conditions, he is missing a great opportunity to make a saving for the firm.

In many cases it means just as much as keeping the cost of fuel down to the lowest possible amount.

By the way, how much does the speed of your engine affect the output of your finished product?

New Power Plant of Dennison Mfg. Co.

By W. O. Rogers

> *This modern installation takes the place of two old plants. Noncondensing Corliss engines, coupled to direct-current generators, are installed, and the exhaust steam is used for manufacturing purposes. Four Wickes boilers fitted with Dutch-oven furnaces and mechanical stokers supply the steam.*

The Dennison Manufacturing Company, South Framingham, Mass., has just completed a new, modern power plant. The building, 110 feet long by 110 feet wide, is constructed of brick and is large, light and roomy.

Engine Room

In the engine room, Fig. 1, are two Hewes & Phillips twin engines, each cylinder being 14x33 inches and capable of producing 225 horsepower or 450 horsepower for each engine. There is also one single unit of 225 horsepower, having a cylinder of the same size as the twin engines. Each engine is direct coupled to a Crocker-Wheeler direct-current generator. Each twin engine drives a 350-kilowatt generator, which delivers a voltage of 240 to the line, at 150 revolutions per minute. The single engine is direct coupled to a 150-kilowatt generator, of the same voltage and speed as the other two units. These three engines are fitted with the new Franklin valve gear.

No pipes show in the engine room, as the live- and exhaust-steam pipes are attached to the cylinders underneath and drop to the basement, where they connect with the main steam and exhaust lines. The live steam is controlled by means of floor-stand operated valves located conveniently beside the engine cylinders. The engine cylinders are lubricated by force-feed lubricators. The engine oil drains from the engine bearing into a filter located in the basement and is then elevated to an oil reservoir, placed above the smoke flue in the boiler room, thus keeping the oil warm, without the aid of heating coils in the filter.

An interesting device is shown in Fig. 2, midway between the two frames of the twin engines. It consists of a floor stand supporting an arm from which an adjustable hanger containing two rollers is suspended. The cross rod extending from the governor on one side of the engine to the reach rods controlling the valve gear on the other side passes this hanger and is supported at the center by the two rolls, the hight of which can be adjusted by moving the bracket up or down. This prevents vibration, supports the rod and reduces friction.

A gageboard, on which is mounted a clock, steam gages for live steam, steam heating and vacuum, also the water pressure on the city main, is mounted on the wall between the engine and boiler rooms. There is a Laidlaw-Dunn-Gordon 10 and 10 by 10-inch air compressor that supplies air for shop work. The pressure is maintained at 45 pounds per square inch. There is also a 40-horsepower Terry turbine, direct coupled to a Diehl direct-current generator of 25 kilowatts capacity, which runs at a speed of 2500 revolutions per minute. This unit is used for lighting the engine and boiler rooms, and several rooms in the factory building when the main units are shut down.

Fig. 1. View of the Engine Room of the New Power Plant of the Dennison Manufacturing Company

The foundations of the twin engines have been so designed that one of the high-pressure cylinders can be removed and a low-pressure cylinder substituted in case it ever becomes necessary to do so. Provision has also been made for installing a receiver between the two cylinders should the engines be compounded.

The switchboard shown in Fig. 3 is located between No. 1 unit and the end wall of the building and is designed in two sections, devoted to motor and lighting circuits, each section having its own recording instruments and circuit-breaker control.

The former plant operated upon 115 volts and in various departments were located 125 motors ranging from 1/10 horsepower to 60, many of these being special motors for variable-speed work and direct connected to special machinery. Provision was made when installing the new plant to keep all motors in use up to and including the 15-horsepower sizes on 115 volts. All motors larger than this size and all new motors were installed for 230 volts.

Both power and lighting circuits are carried into the plant on a three-wire system and two balancers are installed with a capacity of 100 and 200 amperes respectively. The balancers can be run separately on power and lighting circuits or can be operated in parallel.

Fig. 3. Switchboard and One of the Balancing Units

Boiler Room

In the boiler room, Fig. 4, there are four Wickes vertical water-tube boilers set in two batteries. Each boiler is equipped with a Murphy stoker, with an extended dutch oven giving a large combustion chamber. A smoke flue connects with the bottom of each boiler and extends up to the main smoke flue, which runs the entire length of the boiler room and connects with the 150-foot brick stack, located on the outside of the building.

Each boiler is fitted with a damper in its individual uptake; the main flue is also fitted with a damper which will eventually be operated by a damper regulator and the draft of all the boilers will then be controlled by the one damper.

The settings of these boilers have been built in accordance with the specifications

Fig. 2. View of Engines from the Generator Side, Showing the [illegible] System

demanded by the Massachusetts Board of Boiler Rules. Each boiler is set on a concrete base, which is made hollow, as shown in Fig. 5, an end elevation of the engine and boiler rooms. The bottom head of the boiler extends down into this hollow foundation so that it is easily accessible for external inspection, a space having been especially provided opposite the riveted joint of the head and barrel of the boiler, as shown in Fig. 5. This permits of inspection of every rivet of the bottom head joint at any time and decreases the liability of the failure of the joint or the wearing away of the head at this point by external corrosion occurring without being noticed.

Piping

The boiler blowoff pipe extends down from the center of the bottom head and passes out through the concrete foundation, and is fitted with a tee connection, the outer end of which is fitted with a blank. From the side connection of the tee, two valves connect with a Y-connection on the blowoff pipe, as shown by the dotted lines in Fig. 6. The valve nearest the boiler is of the asbestos-packed type; the second is a straight-way valve. All blowoff pipes run under the boiler-room floor and the valve-stem extension rods pass up to and almost through the boiler-room floor; the valve stems are operated by means of a detachable wrench. When not in use the opening over each valve-stem extension rod is covered by a floor plate. This blowoff arrangement is a very desirable feature, as a fireman is not obliged to go down under the boilers when blowing them down, thus reducing the element of danger in case a blowoff pipe should burst.

Steam is taken from the top of each boiler through a 6-inch extra-heavy pipe, fitted with a long radius bend and is led down to a 12-inch steam header, that is supported on suitable concrete piers arranged back of the boilers. The header is divided into two sections by a valve, so that either section can be cut out of service. From this steam header, 7-inch steam pipes are run to the two twin engines and a 6-inch pipe is run to the single engine. Two 8-inch pipes connect the 12-inch main steam header to an 8-inch steam header, which extends from a point under the second twin engine to the pump room, from which the auxiliary units are supplied and from which live steam is taken to feed into the exhaust-steam main in case there is insufficient exhaust steam supplied to the factory.

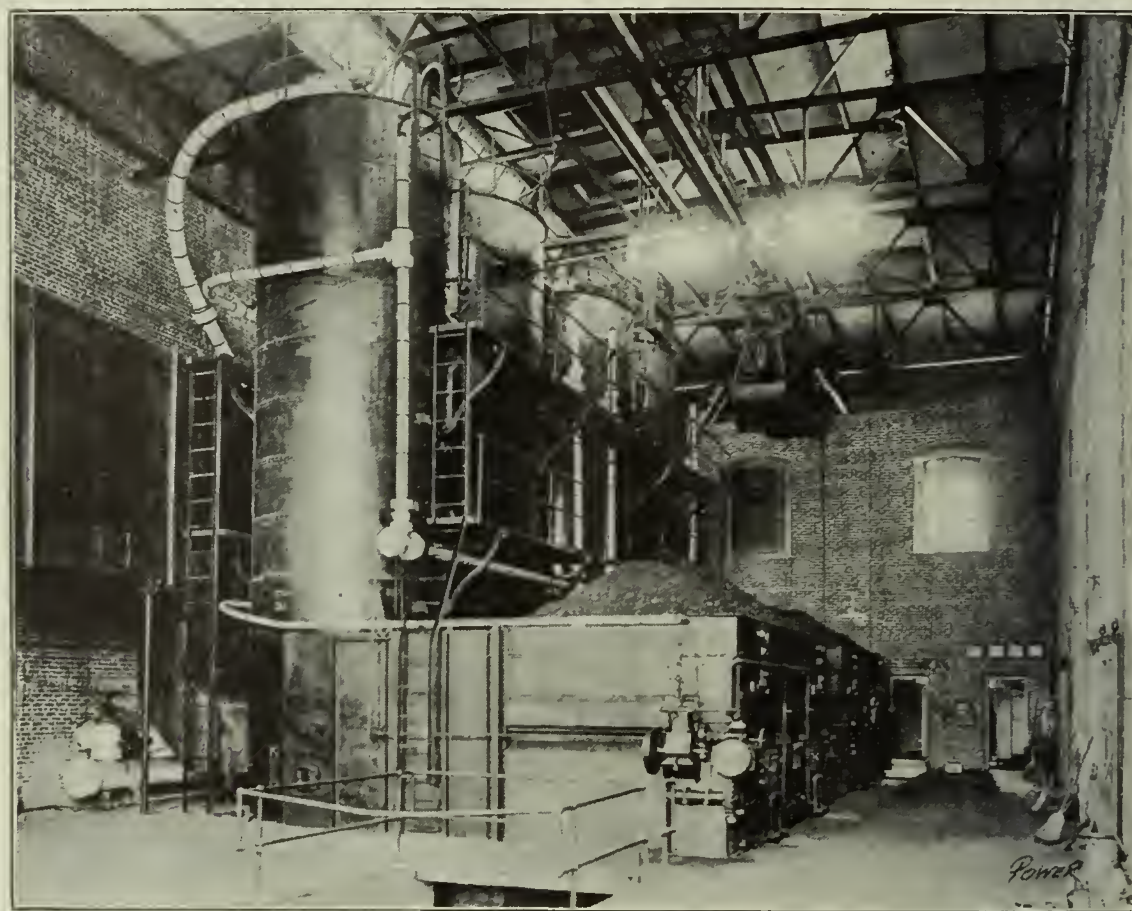

Fig. 4. Boiler Room Containing Four Wickes Boilers

Another live-steam line is tapped to both sides of the cutout valve in the main 12-inch steam header which extends to the pump room located at the front end of the building. The exhaust pipe from the single unit is 7 inches in diameter; it increases to 10 inches for the second unit and to 15 inches at the third engine, beyond which connection is made with a

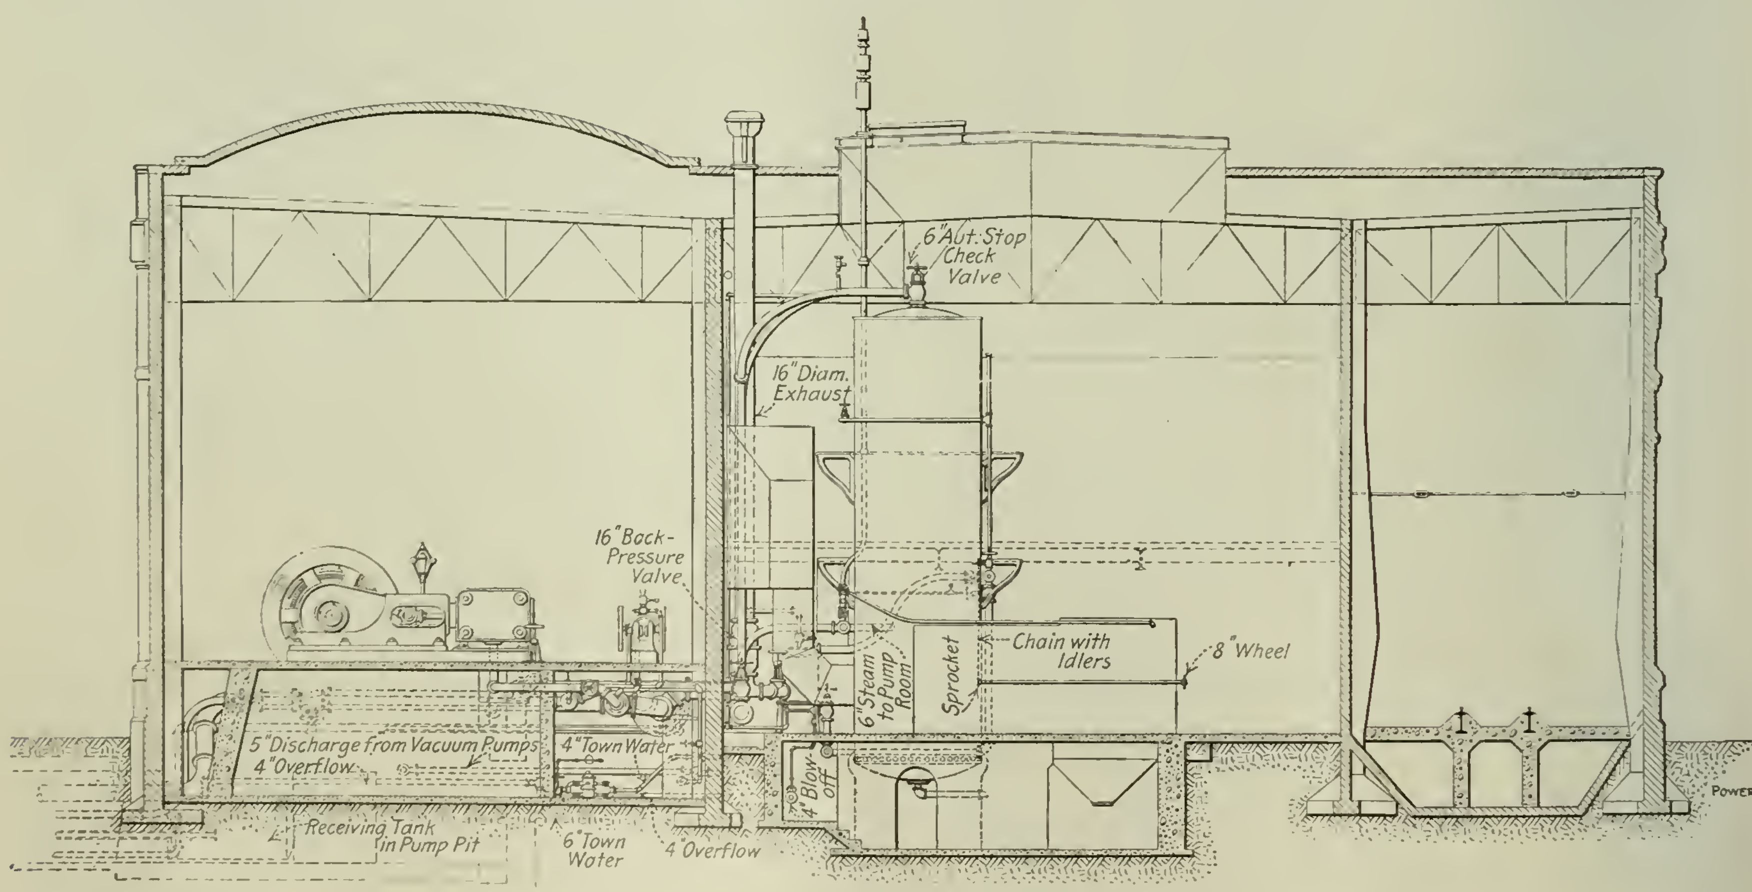

Fig. 5. Elevation of the Engine and Boiler Rooms

17-inch exhaust main, which provides for a future unit and which runs the length of the engine room in the basement toward the front and on to the factory through a tunnel that is 200 feet in length. All wires, pipes for live and exhaust steam, water and air are carried to the factory through this tunnel.

A 16-inch Hoppes oil eliminator is placed in the exhaust line; connection is also made through the wall between the boiler and engine rooms, so that exhaust steam can be passed through a Reilly multicoil feed-water heater. A vertical galvanized, spiral-riveted exhaust pipe

driven by a 20-horsepower Diehl motor with a speed variation of three to one. The speed of the pump is regulated by hand by means of a field control. Surplus is bypassed into the suction pipe by means of a regulator valve. There is also one 12 and 7 by 12-inch Deane duplex pump, used for boiler feeding, when electrical power is not available. Fig. 7 shows the layout of the piping in the pump room.

Fire protection is afforded by a Knowles 18 and 10 by 12-inch duplex pump which has a capacity of 1000 gallons at 70 revolutions per minute. This

in which these pumps are piped up either one can take water from the heating system direct and at the same time from the receiving tank, the height of water in the receiving tank being controlled by a Utility pump governor. Suppose the pump is pumping from the return main of the heating system. As the water in the receiving tank lifts a float ball, a valve is operated in the governor chamber, which permits the water to be drawn from the receiving tank through the governor, until a certain predetermined level has been obtained, when the valve closes, which operation takes place

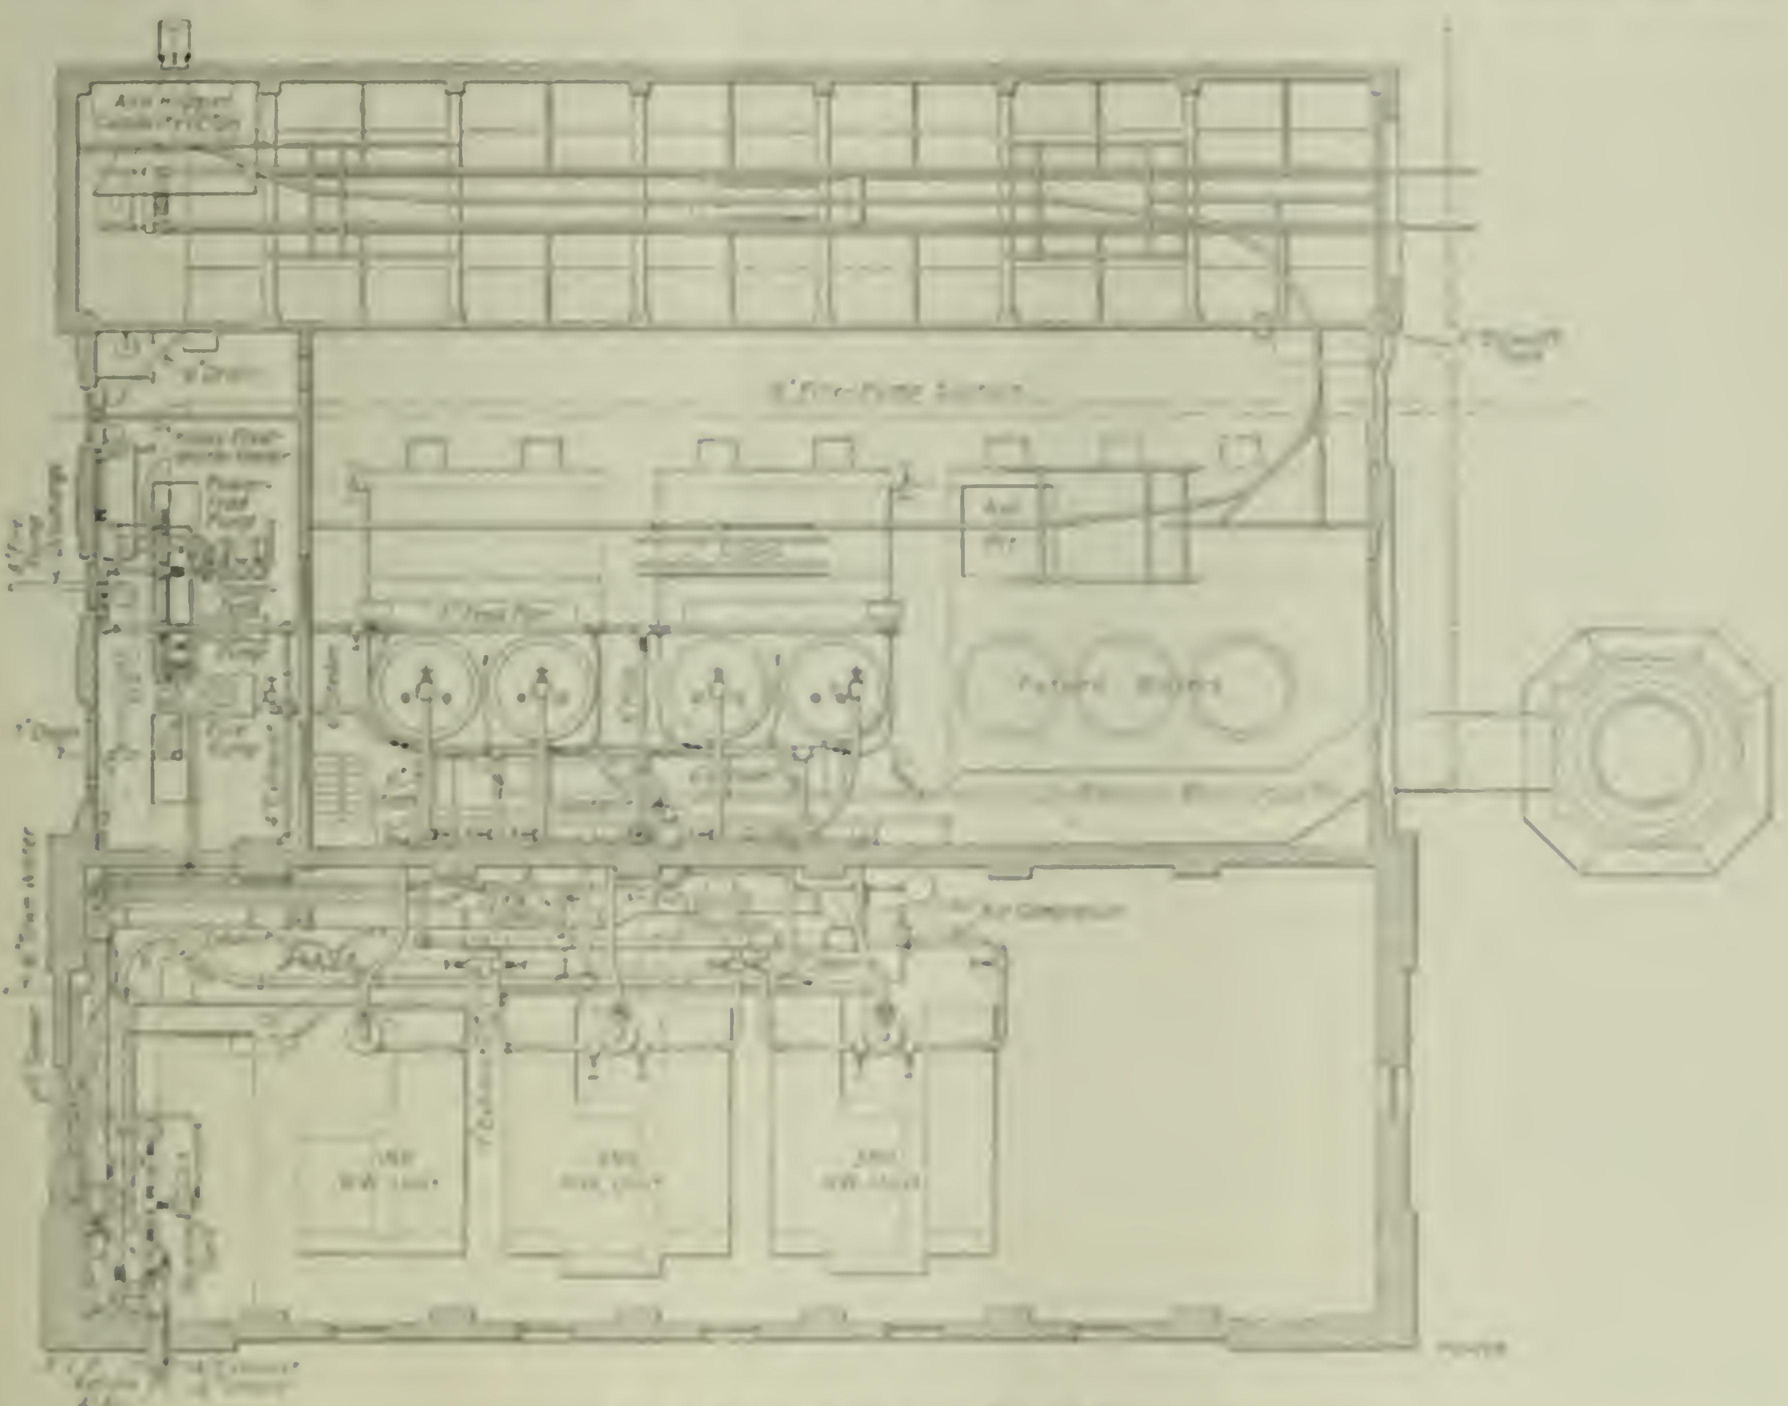

Fig. 6. Plan View of the Power Plant

extends to the atmosphere and is fitted with an Atwood back-pressure valve; this pipe connects with the exhaust pipe between the main exhaust header and the heater. The general arrangement of the piping is shown in Fig. 6, which also gives a view of the layout of the plant, showing the space reserved for three additional boilers in the boiler room.

Pump Room

In the pump room there is one Rumsey 8½x10-inch, triple-plunger, motor-driven power pump. This pump is

pump is connected by means of a 12-inch suction pipe to a reinforced-concrete reservoir in the rear of the power house. This reservoir is about 54 feet in diameter and has a capacity of 125,000 gallons of water.

In a pit under the engine-room floor, is an 8 and 10 by 12-inch Blake vacuum pump for handling the returns on the heating system. There is also an 8 and 10 by 12-inch Knowles pump, either one of which can be used on either the vacuum heating system or to pump from a receiving tank. On account of the manner

before air can be drawn into the pump cylinder.

Feed-water System

A feed-water heater is placed between the two batteries of boilers and next to the dividing wall between the engine and boiler rooms. Feed-water is taken from the make-up tank and is forced through a Blackburn-Smith feed-water filter and the heater to the feed line. The feeding of water in the boilers is regulated by means of a handwheel and shaft, the latter extending to a point under the feed pipe and connection made to a sprocket wheel on the valve stem by means of a chain. This enables the fireman to regulate the water from the front of the boiler furnaces.

The 5-inch brass feed-water main extends along the front of the boilers, and vertical pipes are run up and over to the rear of the boiler, connecting near the top; a tee joint is placed where the vertical and horizontal branch pipes connect and a vertical piece of pipe, capped at the top end serves as an air chamber to prevent water hammer in the feed pipe.

Coal and Ash

Coal is delivered to the stokers by means of a ¾-ton Sprague electric traveling conveyer, which runs on a suspended track reaching from one end of the coal shed its entire length and, making a curve at the stack end of the plant, extends back over the stokers of the boilers. Before the bucket discharges its load, the coal is weighed on a Fairbanks scale which enables a tally to be kept on the amount of coal delivered and the amount burned each day. A spur track extends the length of the coal room on heavy beams and the coal is discharged into the pit below the rails. The coal shovel is of such proportions that it can be dropped between the rails when picking up its load.

Under the boiler-room floor, and directly under the outlet of the ashpits, which are made with slanting sides, is an industrial car track, on which an ash car runs. When ashes are to be removed, they are dumped into this car, which delivers them to the ashpit, shown in Fig. 6. From the ashpit the traveling coal bucket picks up the ashes and conveys them to an ash hopper, shown in Fig. 6, located at the extreme end of the coal shed. This hopper has a capacity of 12 tons and is fitted with a gate on the outside of the building, so that the ashes can be readily loaded into a wagon and carted away.

The author is indebted to the engineering staff of the Dennison Manufacturing Company for data and illustrations concerning this installation.

License Agitation in Rhode Island

By William E. Francis

In Rhode Island, as in many other States, boiler-inspection and engineers'-license legislation is being urged by progressive engineers. That these efforts are meeting with a great deal of opposition from those who imagine that their interests are threatened, is evidenced by the statements made by persons who were called before the House Judiciary Committee on the afternoon of March 29, where it was disclosed by evidence that there are two steam boilers in use at the Technical High School which are considered dangerous and which, though made in Massachusetts, the manufacturers admitted at the time of putting them in do not comply with the Massachusetts law and could not be used in that State.

Among others who appeared before the committee was B. McCabe, of Boston, Mass., who said he was opposed to the bills and that he had come to the hearing to intercede for the engineers and to save the public of this State from the troubles which had been experienced in Massachusetts. The object of the bills, he said, was to legislate certain men out of positions. He told of the injustice which he claimed the law had worked in the neighboring State, in depriving good men of positions they held in order that someone else might get them.

After the hearing, one of the aldermen said that he was unaware that anything was wrong with the boilers but that about a year ago his attention was called to the fact that the building was being heated with condensed steam and that there was a big waste because the return steam could not be used. This was due to the poor circulation of the oil in the boilers and a leakage in the tubes sometimes resulted. Large quantities of caustic soda had to be used in order to prevent this and a request was made for an oil filter. This was obtained and since that time he has heard no complaint as to the condition of the heating apparatus. Continuing along these lines he further said that the boilers consumed an extravagant amount of coal and that it cost more to heat the Technical school building than it did to heat all the buildings of the new City Hospital.

One thing stands out quite prominently: The statement of the engineer in charge that these boilers, bought and installed in the Technical High School building, were known to be at the time of installation of such construction as would not meet the requirements of the Massachusetts boiler-inspection laws. This would appear to be poor business policy, but if the board having this matter in charge was as intelligent as regards engineering subjects as the alderman quoted, it can be easily understood. It is a little surprising to learn that a Boston man spoke against the bill on the ground that it intended to legislate good men out of positions, that others might get them

License laws are usually intended to keep out the poor men, not the good ones. I once met a bright appearing young fellow who had served as an oiler in a power house for three months and who intended to take an examination for a second-class engineer's license. He was very positive that he knew all about getting a license.

"This license business is all graft," he said. "Take a pint of whisky with you and you get your license." I guess he forgot to take along the whisky, for he didn't get so much as a fireman's license and as a result is very bitter against the license laws.

Is this the kind of good men who will be kept out of positions by the license law? The objection of a Boston man who said that the grading of licenses by classes is class legislation and unconstitutional is absurd. The claim is often made that a man who can handle a 50-horsepower plant of a certain type can handle a 500- or 1000-horsepower plant of the same type. While this should hold good in theory, it does not in practice, hence classification is advisable.

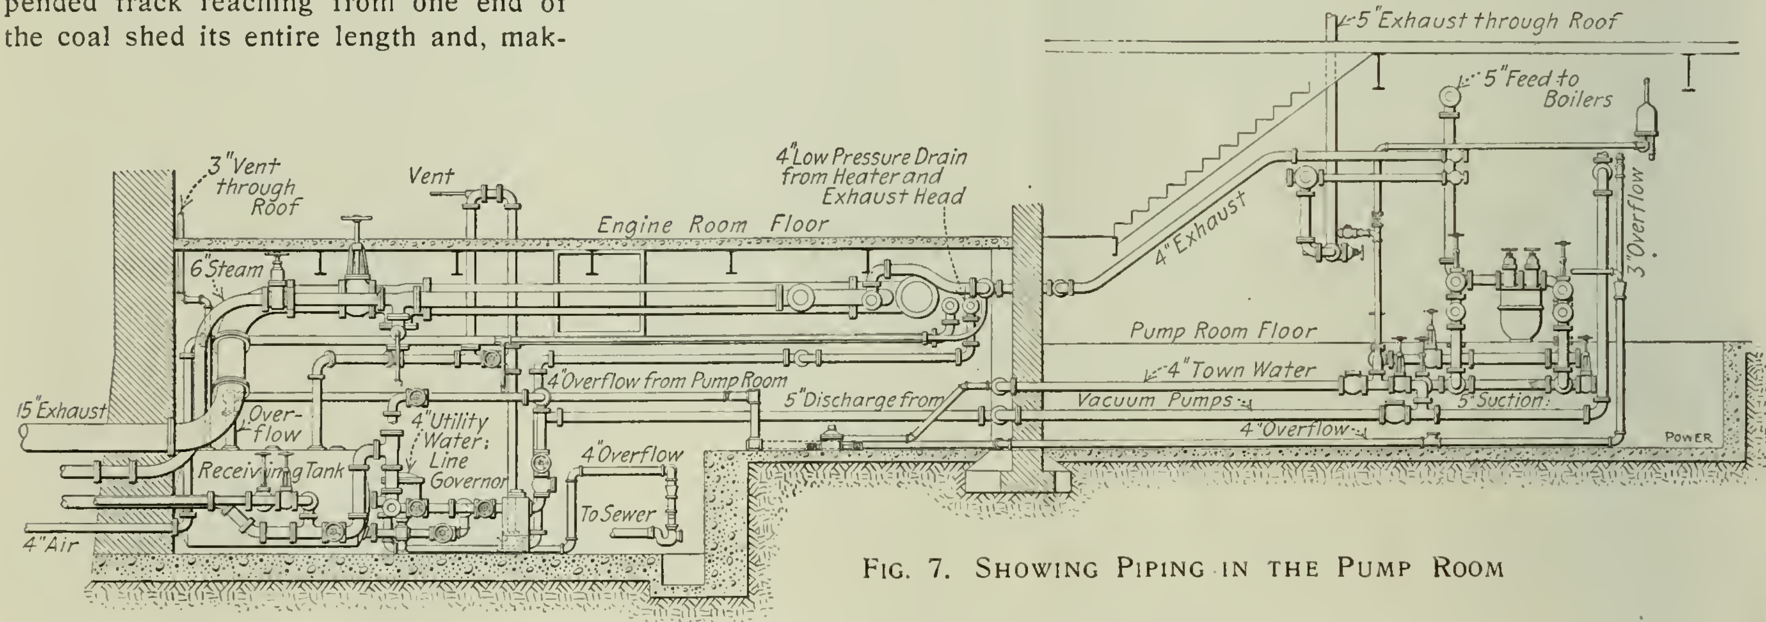

Fig. 7. Showing Piping in the Pump Room

Overcoming Shortage in Feed Water

> *The water supply to a large power plant was suddenly cut off, owing to drought. By means of locomotives, tank cars and an oil barge enough water was supplied to keep the plant in operation until a permanent water supply was obtainable.*

"Is this Mr. Wildin, mechanical superintendent of the New York, New Haven & Hartford Railroad? Well, this is Mr. Peterson, chief engineer of the Cos Cob central station. The Greenwich Water Company has just notified me that it will be obliged to shut off our water supply in 15 minutes as their supply has run dry."

While this was not the actual conversation that took place over the telephone three days before Christmas of 1910, it presents the important point, that owing to the exceedingly dry season throughout Connecticut last fall, the Greenwich Water Company's water supply failed, which necessitated cutting off the supply to the Cos Cob water plant of the New York, New Haven & Hartford Railway, with but 15 minutes' notice.

FIG. 1. LOCOMOTIVE PUMPING AIR INTO TANK CAR, FORCING WATER INTO THE RESERVOIR

This power plant supplies electrical current to electric locomotives running between Mott Haven, N. Y., and Stamford, Conn., a distance of about 20 miles. All passenger trains are drawn by electric locomotives over this stretch of track, and shutting down the power plant meant a suspension of passenger traffic until steam locomotives could be put in commission.

Without water it would be impossible to keep the steam plant going and with Christmas but three days away, when the passenger service would be taxed to its utmost, the power plant could not be shut down; it just had to run.

There was no time to sit down and cuss the weather or fate. Action was required, and quick work at that. The first thing Mr. Wildin did was to order out the wrecking train with a supply of piping and a locomotive water tank placed on a platform car which was run onto a siding at the power plant and the tank deposited on the ground near the concrete reservoir shown in Fig. 1. At the same time four freight locomotives were despatched from New Haven, each with a tank full of water, and by the time they arrived at the plant, a temporary pipe line had been run from the siding at the end of the boiler room in through the door, around in the back of the boilers to a hotwell that was located below the boiler-room floor at the extreme end of the building. This pipe line consisted of boiler tubes that were kept on hand for repairs. They were placed end to end, the joints plastered with putty and wrapped with rubber and burlap. One of the freight engines was run to a point opposite the end of the pipe line at the boiler house. The injector was started, but the water was allowed to escape through the overflow pipe into the pipe line running to the hotwell. This, together with a portion of the salt circulating water, which made the water somewhat brackish, was sufficient to keep the wheels moving, which was the main thing.

While this makeshift was keeping the plant in operation, two of the locomotives were placed at a point opposite the cement water tank that held 600,000 gallons of water.

When word was received that the supply had failed, about one-half of this supply ran back into the water main of the water company before the valves could be shut. As about 12,000 gallons of water were used per hour, it was a necessity to get this reservoir filled in order to have a reserve supply. The discharge pipes of the injector on these locomotives were connected to a line of wrought-iron pipe that ran to the concrete reservoir, and the water in the tank was injected into the cement reservoir at a rate of about 12,000 gallons per hour.

This gave two sources of water supply; but, in order to be on the safe side,

FIG. 2. OIL BARGE LOADED WITH WATER FOR THE POWER PLANT

20 tank cars were put into service drawing water from Stamford, four miles distant. When these arrived in trains of six cars each, one car was allowed to discharge its contents into the pipe leading to the hotwell. Two other tank cars discharged their contents into the water tank, from which it was pumped into the concrete reservoir by means of a steam pump that had been loaned by a contractor. This pump was supplied with steam from the boiler room through a temporary pipe line run on the ground. Two other cars were placed opposite the reservoir and the outlet connected to pipes leading to the cement reservoir. The locomotives were supplied with two air connections, one on the front and one on the rear end of the engine. Each of these air pipes was connected to the top connection of a tank car. The air pump on the engine was started with the air valve so set that a pressure of 30 pounds per square inch was maintained. This air pressure on the water in the tank car forced it up into the reservoir, and as each car held 8000 gallons, the reservoir was filled by Saturday morning, less than 48 hours after the water supply failed. As there was no knowing how long the water famine would last, it was decided to utilize another method of supplying water; therefore, an oil barge having a capacity of 200,000 gallons was obtained. A 3-inch pipe was run from the reservoir to the oil barge that was tied up to the coal-delivery pier, shown in Fig. 2. A steam pump on the barge, supplied with steam from a tug accompanying it, pumped the water into the reservoir through this pipe. A 2½- and a 2-inch fire hose were also used. After the reservoir was once filled, all but the 3-inch pipe was removed, the engine and tank cars were put back to their legitimate service and the barge of water kept up the necessary supply, although but two barges could be delivered per day owing to a sand bar at the mouth of the river which necessitated the barge coming in at high tide.

Due to these methods, the plant was kept in operation, the public was not incommoded, and the operating officers of the road were well pleased with the able way in which a most difficult problem had been handled.

The writer is indebted to G. W. Wildin, mechanical superintendent, for the foregoing details, who not only directed the work, but lived on the job until all danger of a possible shutdown had been avoided.

The Old Mill at New London, Conn.

There are many historical points of interest scattered through the New England States. Some of them date back to the settler days and their traditions are interwoven with romance and legend. The "Old Mill" now running at New London, Conn., and illustrated in Fig. 1, takes a prominent place among the many historical relics of days long past. It was built in 1650, after a special town meeting, held for the purpose of considering the question of erecting a mill to grind corn for the settlers. Gov. John Winthrop was the leading spirit of this new enterprise. Under his supervision the plans were perfected. The erection of a dam and the mill on his estate, then called Winthrop's Neck and now East New London, was the outcome.

This old grist mill was built under the direction of Governor John Winthrop in 1650. For 261 years it has been grinding corn into meal. It is 19 feet in diameter and is 6 feet 8 inches in width.

Six men were appointed to build the dam and mill and they were instructed to make it "substantial and sufficient." They did so, for the original wheel was in use up to four years ago, when it was supplanted by a new one. The old framework of the mill appears to be as solid now as on the day it was put in place. The management of the mill in the old days savored somewhat of the trust methods of today, for with the building of this mill it was agreed that:

"No person or persons should set up any other Milne to grind corn for the town of Pequott within the limits of the town, either for the present nor for the future so long as John Winthrop or his heirs do uphold a milne to grind the town's corn."

Fig. 1. The Old Mill at New London, Built in 1650

Fig. 2. Sluiceway Running from the Dam to the Waterwheel

The old mill is located beside a rocky glen, and the flow of water is through an iron pipe to a sluiceway that is supported by a trestle illustrated by Figs. 2 and 3, and upon reaching the overshot waterwheel, fills the buckets.

The water is controlled by a gate valve in the iron-pipe outlet and by a trap gate in the sluice. This gate is hinged on the end next to the waterwheel and is held up at the other end by means of a rod and lever which reaches into the mill. This allows the water to flow through an opening in the bottom of the sluiceway on the inverted buckets of the wheel. When it is desired to run the wheel the gate is dropped and the water then flows to the end of the sluice and into the buckets of the wheel. After leaving the wheel the water flows through a raceway into the bay fronting the city of New London. All surplus water not

FIG. 3. SLUICEWAY AND SUPPORTING TIMBERS

used by the wheel passes over a low portion of the dam and after dashing over and around the rock-studded glen, flows into the bay.

The wheel has a diameter of 19 feet and is 6 feet 8 inches wide. The outer rims which support the buckets are secured to wooden spikes which fit into a hub 26 inches in diameter. The hight of each bucket is 15 inches, the width 10 inches and the length 6 feet 8 inches. The wheel runs at a speed of 15 revolutions per minute, and it is estimated develops approximately 18 horsepower with a full head of water. The capacity of the mill is between 40 and 50 bushels of meal per hour. The old mill is now operated by George H. Smith, of New London.

The dam is now covered by a wide gravel walk. The old Winthrop home site is now occupied by the modern Winthrop public school. The old wheel has been replaced by a new one and the building has been so repaired that but little remains but the old timbers and inside woodwork that made up the framework of the structure.

One can scarcely imagine that this old mill has stood so many years or that it has witnessed so many exciting scenes. It stood through the shedding of revolutionary blood. It has looked upon the warships of England and the Indians creeping through the thick undergrowth of the forest. Today it looks out from the glen upon a city, and still performs its mission, grinding corn in the same old way that it did 261 years ago.

Boiler Room Bulletin

E. B. Ford, the chief engineer of the Harvard power station of the Boston Elevated Railway Company, Cambridge, Mass., has a boiler bulletin which shows at a glance the status of every boiler in the plant.

This bulletin consists of a board in which there are 20 vertical rows of holes. A number of plugs have been prepared and enough are inserted in the different holes to give all the information required about every boiler in the plant.

In the column headed Boiler Parts is a complete list of all the parts of the Babcock & Wilcox boiler. This column could be made to apply to other boilers also. There are 10 boilers and each one has two columns of holes on the board. When a boiler is in operation and it is found that some particular part needs repair, the man in charge puts a plug in the column of the boiler number, and opposite the name of the part needing repair, on the left half of the board. For example, No. 2 boiler is in operation and it is found that the blowoff valve needs repair; the man finding this would plug the column for No. 2 boiler opposite the blowoff line. Then when the boiler is out of operation it may be readily seen what is to be done.

At the right of the board there is also a set of columns for each boiler. On this side a record is kept of the watch, the day of the week and the month that the boiler is either taken off or put on the line. On this side also there is a method by which the chief engineer can notify the watch engineers at what watch day of the week or the day of the month a boiler is to be put on or taken off the line. This is accomplished by plugging the put-on or take-off line.

Referring to the bulletin it is seen that boilers 1, 2, 5, 7, 9 and 10 are in operation but that the blowoff on No. 2 needs attention, and therefore is to be cut out of the line on the third watch on Tuesday, March 7, while Nos. 3 and 8 are to be cut in by the first watch of the same day, after the arch and side walls have been put in good order.

Much has been said from time to time regarding "theory and practice," but the following extract from an address by R. S. Hale, at a recent meeting of the National Electric Light Association, seems to sum up the whole thing in a nutshell:

"A theory is a statement of a case that should consider all the facts, but when it does not, hence the results of using such a theory may be bad. On the other hand, good practice, if it is good practice, takes into consideration all the facts in deciding what to do, even omitting some of them from its statement. Therefore, good practice is better than bad theory; but a correct theory that takes into account all the facts is necessarily the best practice."

Captain Charles H. Manning

One of the most prominent mechanical engineers in New England is Capt. Charles H. Manning. His reputation, however, is not local, for he has been associated with such engineers as Haswell, Isherwood, Kafer, Loring, Melville, Thurston and others, some dead, some living, and is known to hundreds of steam engineers throughout the country.

Captain Manning is the son of Joseph C. Manning and Rebecca Parkman Jarvis (Livermore) Manning. He was born in Baltimore, Md., June 9, 1844. His early education was received in private schools in Baltimore, in the high school of Cambridge, Mass., and in 1860 he entered the Lawrence Scientific School of Harvard University to study civil engineering

In the fall of 1861 he returned to Baltimore, due to business reverses brought on by the war, and became an apprentice in the marine-engine works of Charles Reeder. While there he met many officers of the naval-engineer corps, and as a result he was appointed third assistant engineer of the Navy, February 19, 1863.

His vast knowledge of scientific matters brought him to the attention of Chief Engineer Isherwood, who assigned him to the making of experiments on superheating steam on the "Adelaide" and other vessels. As a consequence, Captain Manning's active service "under fire" was confined to some brief fighting in Hampton Roads. He served on the "Adelaide" for two years, when he left her to join the sloop-of-war "Dacotah," and later served on other vessels of war. In 1870 Captain Manning was assigned to shore duty as an instructor at the Naval Academy, where he remained five years. While serving as instructor, Manning assisted in organizing a course of instructions for cadet engineers at the academy, which in his own estimation and that of others is one of his most valuable achievements.

Captain Manning served as a member of the first Advisory Board, in 1881, which body prescribed the first general characteristics of the warships of what was termed the new navy. Other members of the board were Rear-Admiral John Rogers and Chief Engineers Benjamin F. Isherwood and Charles H. Loring. Captain Manning has the distinction of being the only engineer on the board who had the courage to vote for steel vessels.

Captain Manning was granted a year's leave of absence in 1882, after 12 years of continuous duty. He immediately accepted a position as mechanical engineer of the Amoskeag Manufacturing Company, Manchester, N. H., the largest of the cotton mills in the world. This position he now occupies.

In 1884 Manning was placed on the retired list of the Navy, to the regret of his engineering associates. During the Spanish-American war, when he was 54 years of age, he was again called into active service and was stationed at the naval station at Key West, as chief engineer of repairs of the machinery on warships which gathered there.

The position now held by Captain Manning is of importance and calls for more than ordinary skill. Besides having charge of all the power plants of the company, he is in addition the architect and builder of the new Coolidge mill recently completed. Something of the extent of his duties can be gathered from the following:

To operate the 110 acres of mill area there are 16,488 horsepower of water turbines, 24,800 horsepower of steam engines and 17,500 horsepower of steam turbines. To supply the steam units, and to produce steam for manufacturing purposes, there are installed 65,700 nominal horsepower of boilers. These are all of Captain Manning's design.

Manning was the pioneer in designing and installing in 1885 a 2000-horsepower horizotal water turbine, the first large installation of its kind.

The resourcefulness of Captain Manning has never been questioned. In the fall of 1891, a 30-foot flywheel burst and, being dissatisfied with the metal put into the rim of flywheels at that time, he designed a new 30-foot flywheel, with a face of 108¼ inches and a thickness of 12 inches. This rim was made up of 44 rings of ash. This was doubtless the largest wooden-rim wheel in the world. The wheel is still in operation after a service of 20 years.

In addition to his position with the Amoskeag company, Captain Manning is consulting engineer for several other large mills. He is a past vice-president of the American Society of Mechanical Engineers. He is also a member of the Army and Navy Club of New York, American Society of Naval Engineers, United States Naval Institute, American Society of Naval Architects and Marine Engineers, American Association for the Advancement of Science and the American Society of Cotton Manufacturers.

Captain Manning's career has been brilliant. He is known as a man of sterling qualtities, of a manly and generous nature, one of the men whose friendship is well worth cultivating.

Charles H. Manning, Mechanical Engineer of the Amoskeag Manufacturing Company

Desirable Improvements in Boilers

By F. W. Dean*

Boiler joints, settings, heating surface, factor of safety, elastic limit, vertical boilers, large units and blank flanges on pipes are the topics touched upon by the author.

A few years ago I advocated before the American Society of Mechanical Engineers the adoption by boiler designers of a longitudinal joint having all rivets in double shear and getting all the rivets as near the center line of the joint as practicable. The lap joint is now well understood to be almost the sole cause of boiler-shell explosions, and any joint which gives one-sided resistance to rupture is likely to cause explosions at some time. The form of butt joints commonly used in this country, that is to say, those with narrow outside and wide inside straps, is of that class. A part of the joint is lapped and in that part the rivets are overhung and in single shear. These rivets are poor things for resisting a pull, and the whole joint may be deformed under strain. The result of this is that longitudinal cracks may occur in the joint due to bending by steam pressure, and changes in the bending by changes in the pressure. I think that the ruptures of the joints at Woonsocket and Torrington were hastened, if not caused, by this action. I expect to see this form of butt joint abandoned.

In the paper referred to I advocated a form of butt joint in which both straps were of the same width and all rivets in double shear. The pitch of the outside row was wide, but the outside strap was thick enough to render calking effective. The efficiency of such a joint cannot well be over 85 per cent., and in this respect is hardly satisfactory. Fig. 1 shows a design of a Scotch boiler having joints of this design, made by me for the Deer Island station of the Metropolitan Water and Sewerage Board of Massachusetts.

More recently I have adopted as my regular practice an extension of the same idea, taking the form used on the S. S. "Kaiser Wilhelm der Grosse" some 15 years ago. I understand that this is the form of joint used in Germany quite generally. It is easy to obtain an efficiency of about 92 per cent. with it, and it fulfils every ideal. This form of joint is shown in Fig. 2, which is a design of an 84-inch horizontal return-tubular boiler for 150 pounds of steam, which I made for the Diamond State Fiber Company, of Bridgeport, Montgomery county, Penn. The extra cost of this joint is insignificant. Other features of this design may be interesting; for example, the thinning of the plates at the circular seams so that the double thickness will not exceed well established limits.

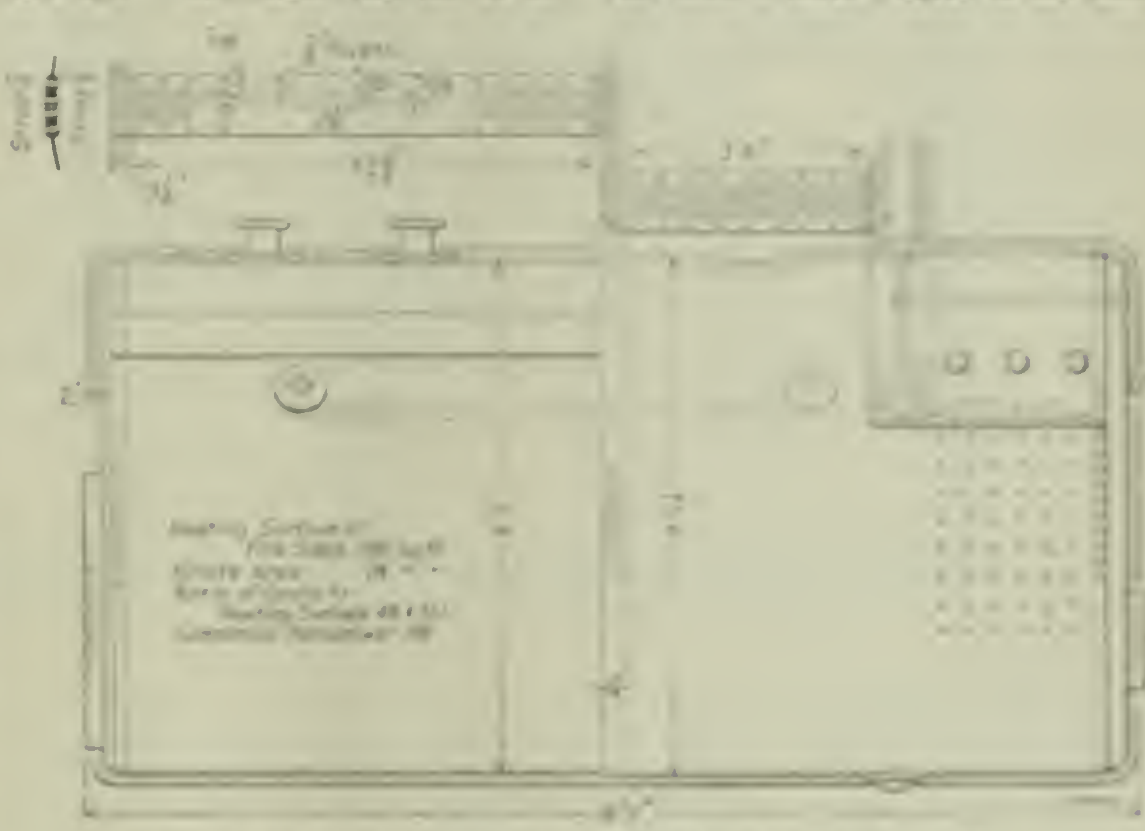

Fig. 1. Method of Riveting 110-horsepower Scotch Boiler

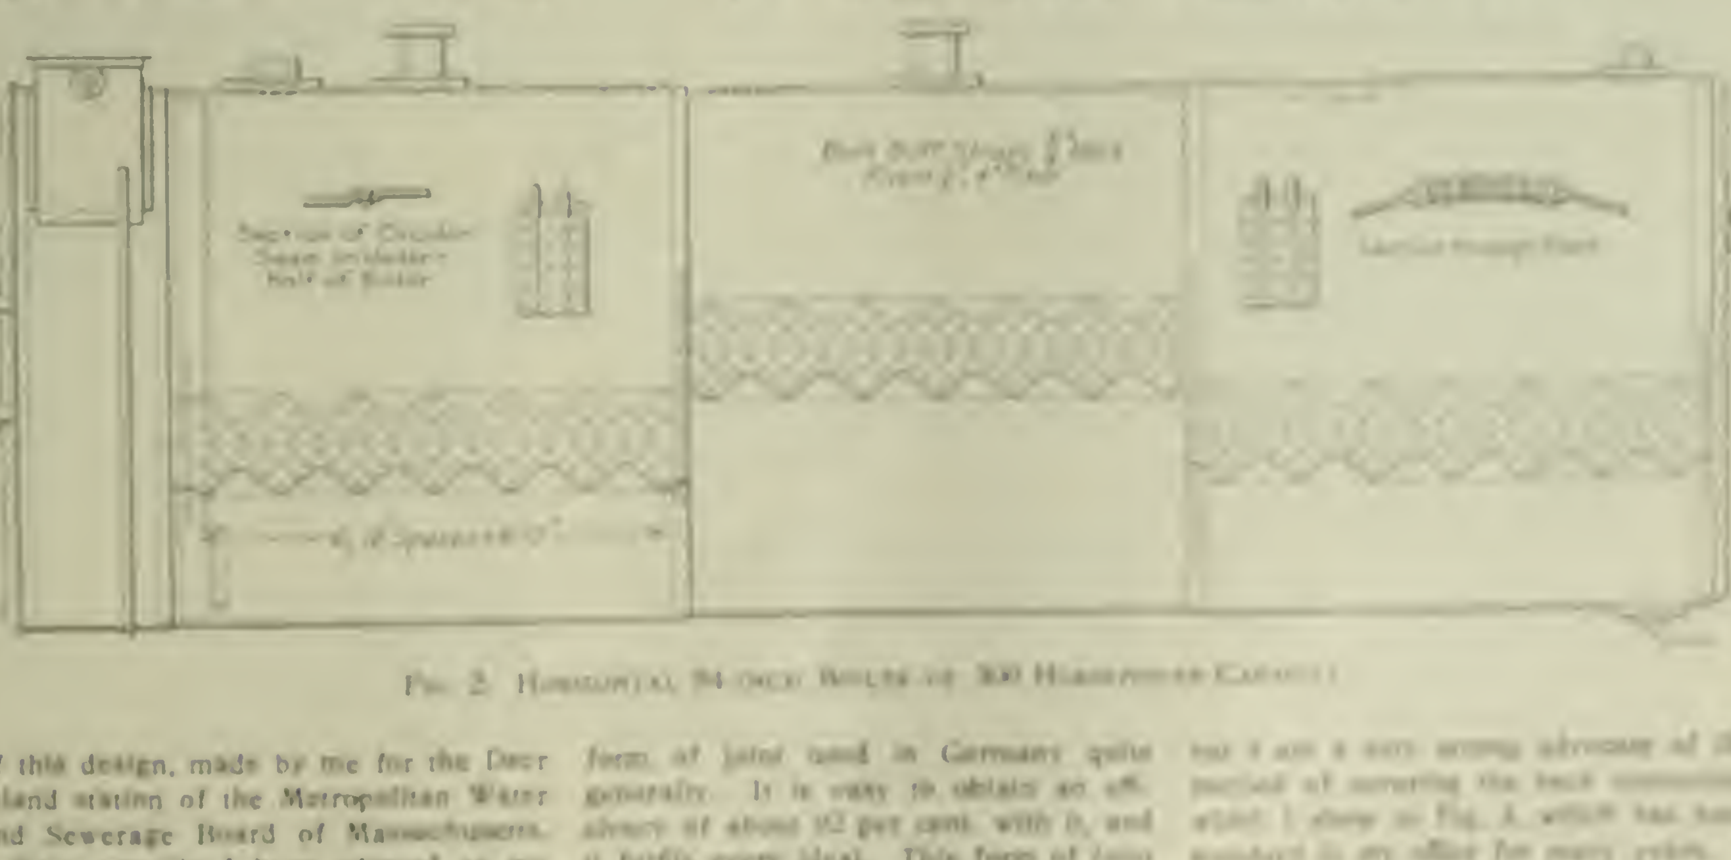

Fig. 2. Horizontal 84-inch Boiler of 300 Horsepower Capacity

Boiler Setting

Recently there were published in Power two articles on the proper method of setting horizontal return-tubular boilers. With these articles I agree in the main, but I am a very strong advocate of the method of securing the back connection which I show in Fig. 3, which has been standard in my office for many years. If

*Mill engineer and architect of Boston.

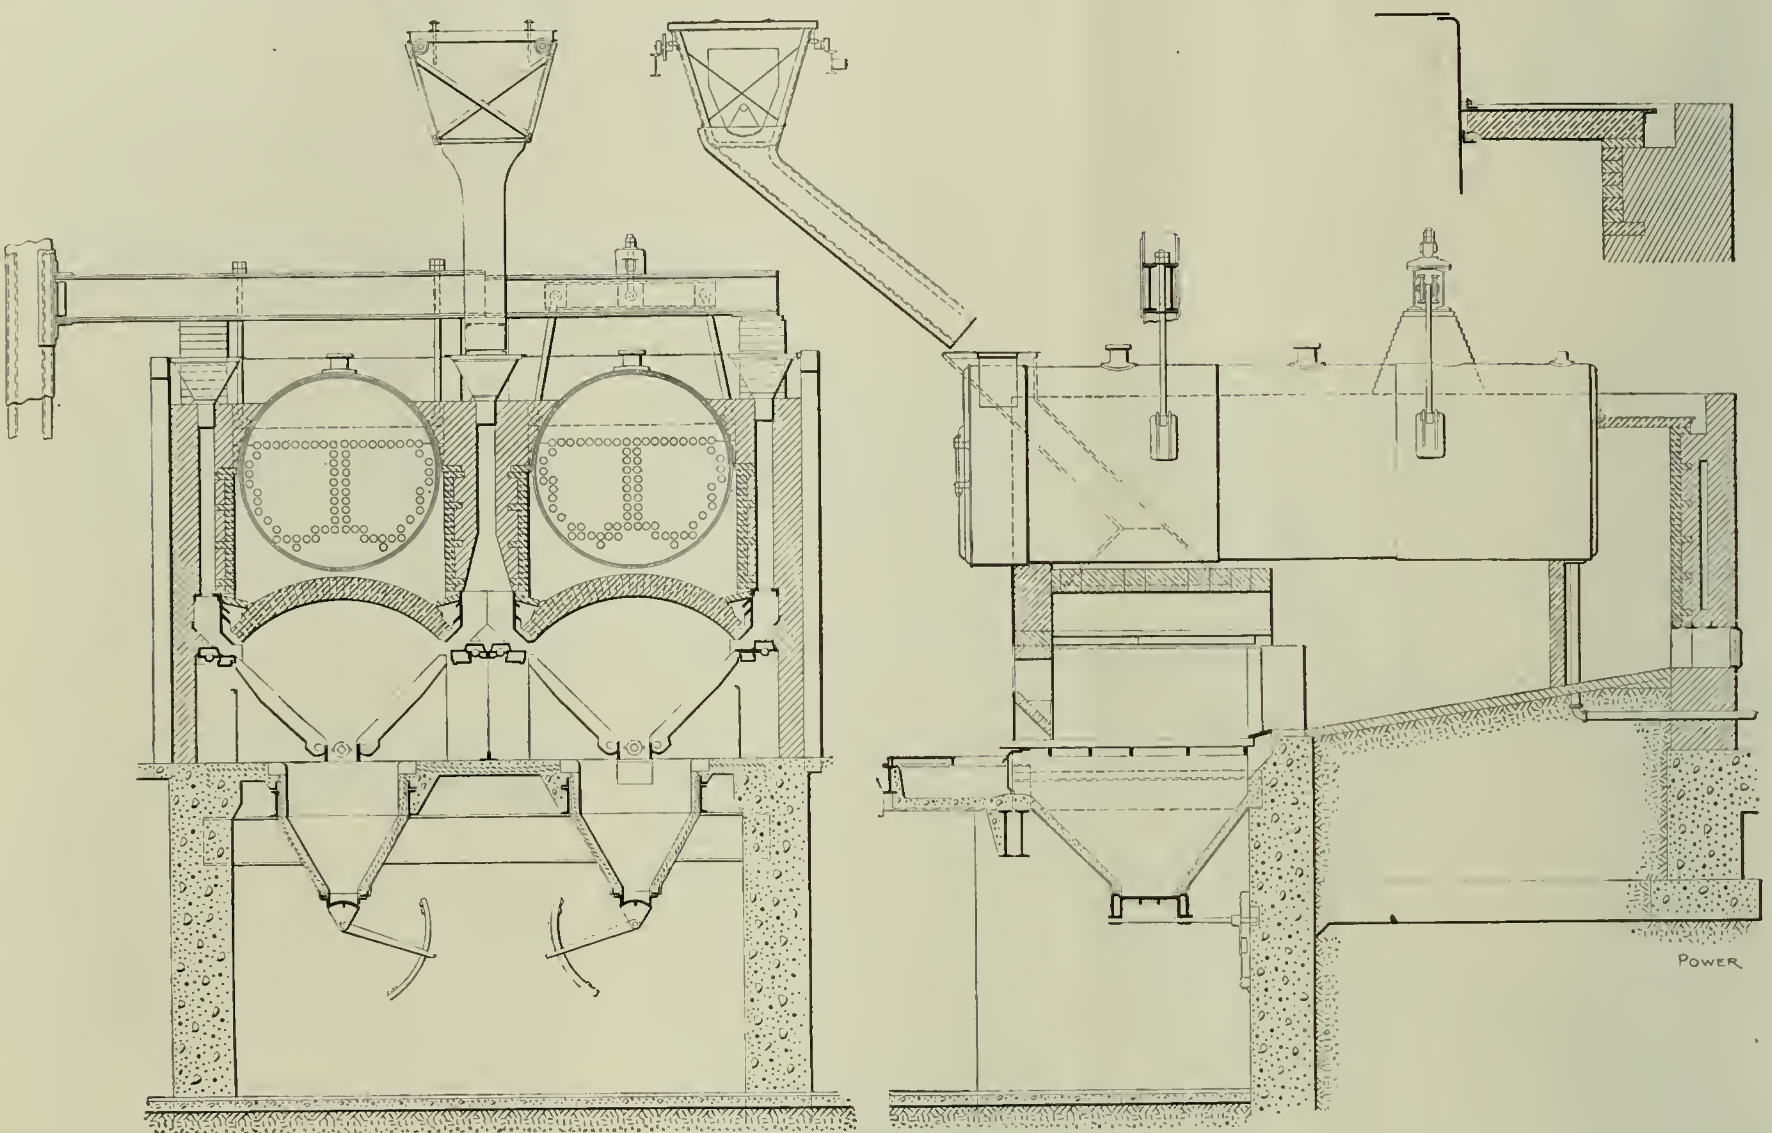

Fig. 3. Illustrating Three-point Suspension and Special Back-arch Construction

consists of some long slabs of firebrick which cover the back connection and slide back and forth over it as the boiler expands and contracts. It is pushed back by the boiler and pulled forward by the angle on the underside of the outer end of the steel plate above the slabs. The steel plate protects the slabs from breakage when walked upon. When boilers are set with this feature the cracking of the walls at the back end is prevented, as there is nothing to push them as the boiler expands.

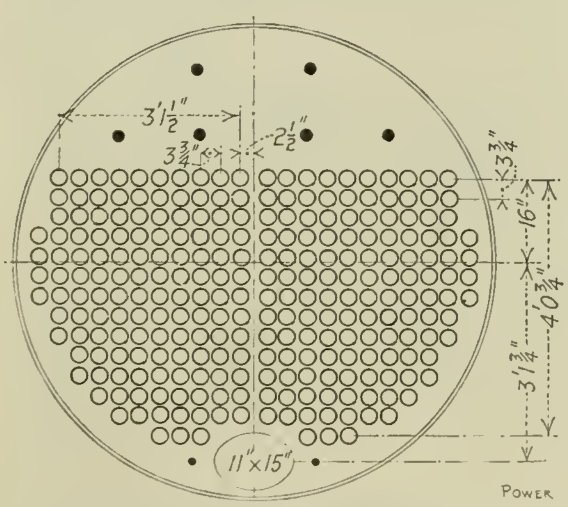

Fig. 5. Tube Layout for 90-inch Horizontal Tubular Boiler

It is my practice to suspend the boilers from above, and I prefer Mr. Woolson's three-point suspension. This and the setting for the Diamond State Fiber Company are shown in Fig. 3.

Vertical Boilers

Many vertical fire-tube boilers have been built having the diameter of the outside shell reduced above the crown sheet by a reversed flanged connection, often called an "ogee." Many of these flanges have cracked circumferentially on account of bellows action caused by changes in pressure and by vertical vibration caused by the opening and closing of the inlet valves of steam engines. An examination of such boilers will often show a vibration coinciding with the revolutions of the engine. It can be said, in fact, that this is the only kind of boiler that breaks in two. The defect has been diminished by making the reversed flange thicker and less flat, and thus reducing the action that has been, by some, thought important in vertical boilers for permitting free expansion of the tubes.

The recent explosion of such a boiler at the Amoskeag mills and the action of the reversed flange in an experimental boiler recently tested to destruction, should serve to open people's eyes to the unsuitability of such a design, especially for high pressures. Such boilers are unquestionably dangerous because they elongate seriously under pressure, make the upper tube plate convex downward, the lower tube plate convex upward and tend to pull the outer tubes out. This is what occurred in the exploded boiler, and although the tubes of that boiler were not beaded, the additional safety caused by beading must make a very narrow margin between safety and danger. The reversed flange can be replaced by a long conical course which will not yield, and which will give whatever advantage is accomplished by a reduction in diameter. Many such boilers have been built and one is shown in Fig. 4.

Quantity of Heating Surface

It is a custom of boilermakers to make too little of the opportunity of getting a great deal of heating surface in horizontal return-tubular boilers. By so doing they make a boiler plant unnecessarily large and expensive.

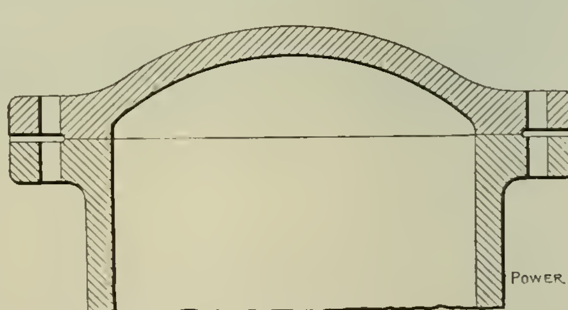

Fig. 6. Preferred Design for Blank Flange

Boilers can have tubes as follows with no resulting disadvantage and with important gains in horsepower and saving of room:

72" boiler, 140–3" tubes, 2033 sq.ft. h.s.(18' tubes)
78" boiler, 166–3" tubes, 2376 sq.ft. h.s.(18' tubes)
84" boiler, 192–3" tubes, 3056 sq.ft. h.s.(20' tubes)
90" boiler, 260–3" tubes, 4016 sq.ft. h.s.(18' tubes)

In the last case (90-inch boiler) the tubes are ¾ inch apart, and very high. These boilers are rated each at 400 horsepower and when run at nearly 800 horsepower they send over dry steam and cause no trouble. There is no reason for being afraid of putting much more heating surface in boilers of this type than is common.

Large Units

There is likewise fear on the part of many persons of making large fire-tube boilers. It has been conclusively shown by several installations that 400-horsepower horizontal return-tubular, and 500-horsepower vertical boilers are satisfactory, and either can be run at double or more their usual rating. There is no limit to the sizes of these types except shipping possibilities. In a large plant there are great advantages in large units as follows:

Smaller number of boilers; smaller number of pipes and valves; smaller buildings; smaller number of men required; greater economy by reduction of losses; less number of chances for explosions and troubles; reduced cost of plants.

These facts are becoming recognized and will be taken advantage of more and more.

For the arrangement of tubes in a 90-inch boiler see Fig. 5.

Factor of Safety

The factor of safety in boiler shells is of less importance than is generally supposed. In 1908 the Massachusetts Board of Boiler Rules increased the factor of safety from 4½ to 5. In my opinion this is a mistake, for boilers never explode because the shell is too thin. Explosions are due to cracking of plates due to causes which do not come from thinness, and it is probable that increasing the thickness intensifies these causes.

Elastic Limit

Some engineers base the factor of safety of boilers upon the elastic limit of the material, and this is the logical way. The value of the strength of a plate lies between zero and the elastic limit, and the difference between the elastic limit and the ultimate strength is so much lumber. It is common to say that the elastic limit of steel plate of boilers shall be not less than one-half of the ultimate strength. If it is one-half, the factor of safety with reference to it is 2½ if it is 5 referred to the ultimate strength. If it can be 2½ referred to one elastic limit, it can be to another, and this clearly establishes the propriety of this principle. Steel can be made by anybody with a high elastic limit and a low ultimate strength, accompanied with all desirable properties. Such steel is very desirable because it will make a strong, thin, light, cheap and more durable boiler than that customarily used. It will be more durable because it is less likely to crack either in making or operating. If I were not prevented by established legal rules I should specify boiler plate to have an elastic limit between 35,000 and 40,000 pounds and an ultimate strength as low as possible, say about 50,000 pounds per square inch.

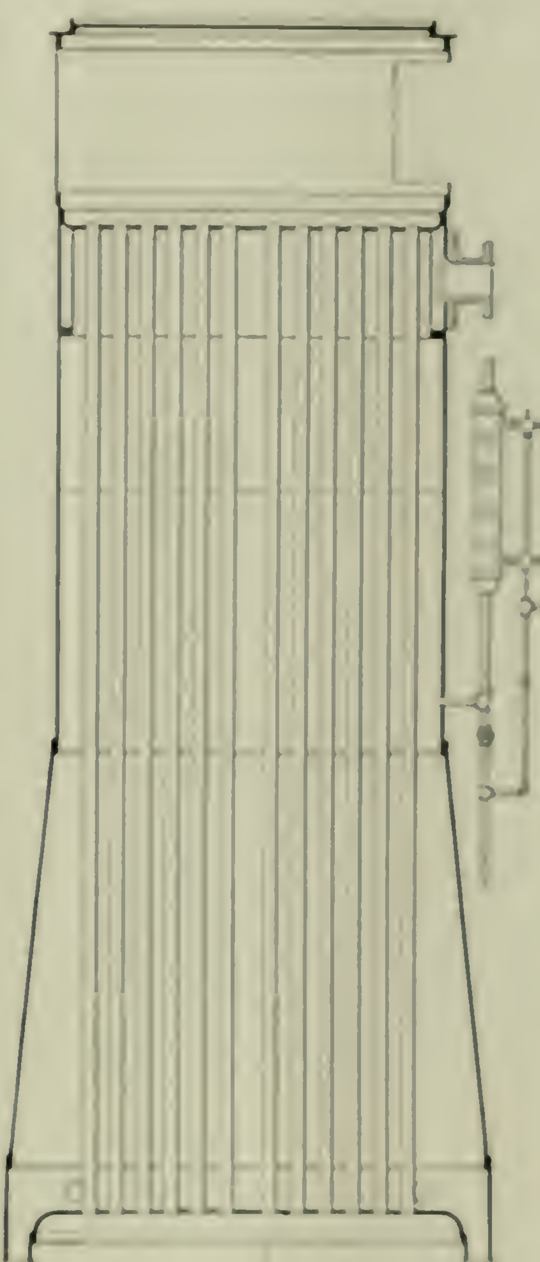

Fig. 6. Vertical Boiler of 175 Horsepower Capacity

Blank Flanges on Pipes

The recent explosion of a blank flange on the end of a large steam pipe at the Amoskeag mills should cause steam engineers to require that these flanges should always be not only very heavy, but made spherical in form inside of the bolt circle. If they are not they are weak unless they are very thick. If they are flat and ribbed they are worse than if they had no ribs, when the ribs are outside, and the ribs are of little value when they are inside. If they are spherical, ribs should not be used. The extra cost of a spherical blank flange is trifling. See Fig. 6.

Smokestacks for Natural Draft

By M. E. [illegible]

To solve the problem of correct dimensions for a proposed stack it is first necessary to approximate as closely as possible the capacity of the plant based on the commercial evaporation. Then if there is the least probability of any increase in the demand for power, make proper allowance for such increase and do not be afraid to err a little in favor of bigness.

After the horsepower capacity of the plant has been determined a simple and easily remembered rule for proportioning the stack is to multiply the number of horsepower by 6. This will give the area of the stack in square inches. Thus, a 500-horsepower plant requires a chimney with an area of 3000 square inches. This would equal a circular stack of about 62 inches diameter. A comparison with stacks already built will show that this figure is approximately correct.

The hight of a chimney is sometimes governed by local conditions, such as the hight of the building to which it is attached or the hight of surrounding buildings. The ratio of hight to diameter may be from 20 to 36 diameters of a circular stack or lengths of one side of a square stack.

One rule establishes the hight of the stack at 25 diameters. This would be correct for some sizes, but would not apply to all. The hight of the larger chimneys must be limited to keep down the cost of construction, and the hight of smaller stacks must be sufficient to give draft enough to maintain the desired rate of combustion. Thus an 8-foot stack multiplied by 20 gives 160 as the proper hight, and a 2-foot chimney multiplied by 36 gives 72 feet as the hight.

Stability or resistance to wind pressure is secured by constructing the base with an outside diameter equal to one-tenth of the hight.

Corrosion is generally due to air which has been absorbed by the feed water and which cannot be removed. Its action is intensified by common salt and by chlorides of magnesia and lime; its action is diminished by suitable additions of soda and of lime. Purified water, in addition to obviating scale, also reduces corrosion. Excesses of soda in boiler compositions attack brass fittings and cause leaky seams.—Ex.

Oil Fuel for Steam Boilers*

By B. R. T. Collins

The possibilities of oil fuel along the Atlantic coast; its advantages and disadvantages and the principles involved in the efficient burning of fuel oil.

In view of the present gradually increasing cost of coal for steam-generating purposes in the Atlantic coast States and especially in New England, the question of a satisfactory and economical substitute naturally arises. Among various possible substitutes crude petroleum and its residual product, commonly known as fuel oil, have attracted more or less attention since the discovery of the Texas oilfields about ten years ago.

Fuel oil is more satisfactory for burning than crude petroleum because practically all of the light and easily ignited products, such as naphtha, gasolene and kerosene, together with any water which the crude oil may contain, have been removed by a process of partial distillation. Hence, while the crude oil is burned in large quantities in the Gulf States and along the Pacific coast with safety under proper precautions, fuel oil, which has a considerably higher flash point and calorific value, can be used for fuel by men of ordinary intelligence with practically the same safety as coal.

The cost of fuel oil in the New England States has been decreasing recently so that at the present time it can be purchased there more cheaply than in the western part of Texas. This is due to the fact that the cost of transporting oil in tank cars to western Texas is greater per barrel than the cost of transporting it to New England in barges and tank steamers.

At present the major portion of the supply of oil for fuel purposes for the north Atlantic States comes from Texas, Louisiana, Oklahoma and Kansas, this group of States producing about 62,000,000 barrels in 1909, or over one-third of the total production of petroleum for the United States in that year, in spite of the fact that California made an increase of over 20 per cent. above her production of petroleum for 1908. During the year 1910 there was an increase to 72,000,000 barrels in the production of crude oil in the States mentioned, as well as a phenomenal increase of 50 per cent. to 77,000,000 barrels in California, thus making the total production for the United States 216,500,000 barrels, or about two-thirds of the total production of crude petroleum for the world. The increase in the production from 1898 to 1910 is shown in the chart.

The interest that fuel users along the Atlantic coast have in California oil may seem at first to be very small, but with the opening of the Panama canal now promised for 1915, a means will be provided for the easy and cheap transportation of California's surplus production to Atlantic coast ports. Furthermore, the strip of country between the mountain ranges and the Paeific ocean in Mexico, Ecuador, Peru and Chile is known to be rich in petroleum, and with the completion of the canal all of this region as far south as Valparaiso, Chile, will be brought nearer to the Atlantic seaboard than the port of Los Angeles, Cal.

It is understood, of course, that the supply of fuel oil at the present time would take care of only a small portion of existing steam plants now using coal, but judging from the fact that the production of crude petroleum in this country increased over threefold during the last ten years, there should be sufficient fuel oil to take care of a gradually increasing class of plants which for various reasons and conditions can use it economically. Included in this class would be:

1. Plants where the cost of handling coal by hand is higher than the average because of local conditions, and where the installation of suitable coal-handling equipment would not be warranted by the saving effected.

2. Plants in which the boilers are fired by hand and more than one fireman is required on each shift.

3. Plants where greater capacity is required than can be obtained with the coal available. With oil, 35 per cent. or more additional capacity can be obtained than with high-grade coal.

4. Plants where the boiler capacity is limited by the capacity of the existing stack or stacks and where it is not desired to install more stack capacity, although more boiler capacity must be obtained. Oil fuel can give this added boiler capacity without increasing the stack capacity, as the stack area required for the same boiler capacity with oil is only about 60 per cent. of that required for coal.

5. Plants where it is necessary to keep smoke below certain fixed limits at all times, due to smoke ordinances.

Oil Analyses

The accompanying table shows comparisons between the calorific value and other properties of crude oil, fuel oil and coal.

Advantages and Disadvantages of Oil Fuel

The advantages of oil fuel may be summarized as follows:

1. Calorific value per pound 30 per cent. higher than that of high-grade coal, less weight of oil being required to give the same heating effect.

2. Space required for storage of oil is less than that for an equal weight of coal.

3. Oil does not deteriorate by storage, as coal does to a greater or less degree.

4. Lower temperature in boiler room.

5. Area of stack 60 per cent. of that required for coal for equal boiler capacity, thus enabling a plant having insufficient draft with coal to have an excess amount with oil, a change from coal to oil making the installation of additional stack capacity unnecessary.

6. Less heat lost up the stack, owing to cleaner condition of tubes and to smaller amount of air which has to pass through furnace for a given calorific capacity of fuel.

7. Higher efficiency due to more perfect combustion with less excess air, more equal distribution of heat in combustion chamber, as doors do not have to be opened and very little soot is deposited on the tubes.

8. Increase in capacity over coal.

9. Heat is easier on the metal surfaces, being better diffused over the entire heating surface of the boiler.

10. Ease with which fire can be regulated from a low to a most intense heat in a short time or entirely extinguished

COMPARISON OF PROPERTIES OF CRUDE OIL AND FUEL OIL

*From an address before the Boston section of the American Society of Mechanical Engineers, on April 21. Mr. Collins has been engaged in the burning of oil fuel for the past 17 years.

instantly in case of emergency, such as water dropping out of sight in gage glass, and quickly relighted when the emergency is over. In less than half an hour a boiler can be brought up to 150 pounds steam pressure from cold water, if necessary.

11. Smoke can be entirely eliminated.

12. No cleaning of fires.

13. Much lower cost for handling oil than handling coal.

14. Absence of coal dust and ashes.

15. No firing tools used, consequently, no damage to furnace linings from this source. No clinkers to be removed from grate bars or furnace side walls.

16. Saving in labor of all kinds.

The disadvantages of oil fuel are:

1. Low flash point. Fuel oil should have a flash point not lower than 140 degrees Fahrenheit, and with oil of this quality, handled by men of ordinary intelligence and common sense, there is practically no more danger than with coal.

2. The ordinary underwriters' or city requirements specify that storage tanks for fuel oil be located underground and at least 30 feet from the nearest building. This can generally be complied with in the case of the power plant of the average manufacturing concern, but in the case of a plant in the congested districts of a city it is likely to be prohibitive.

3. With boilers using feed water of considerable scale-making qualities, the cost of repairs is likely to be increased by changing to oil, owing to the intense temperature developed in the furnace.

Principles Involved in Efficient Oil Burning

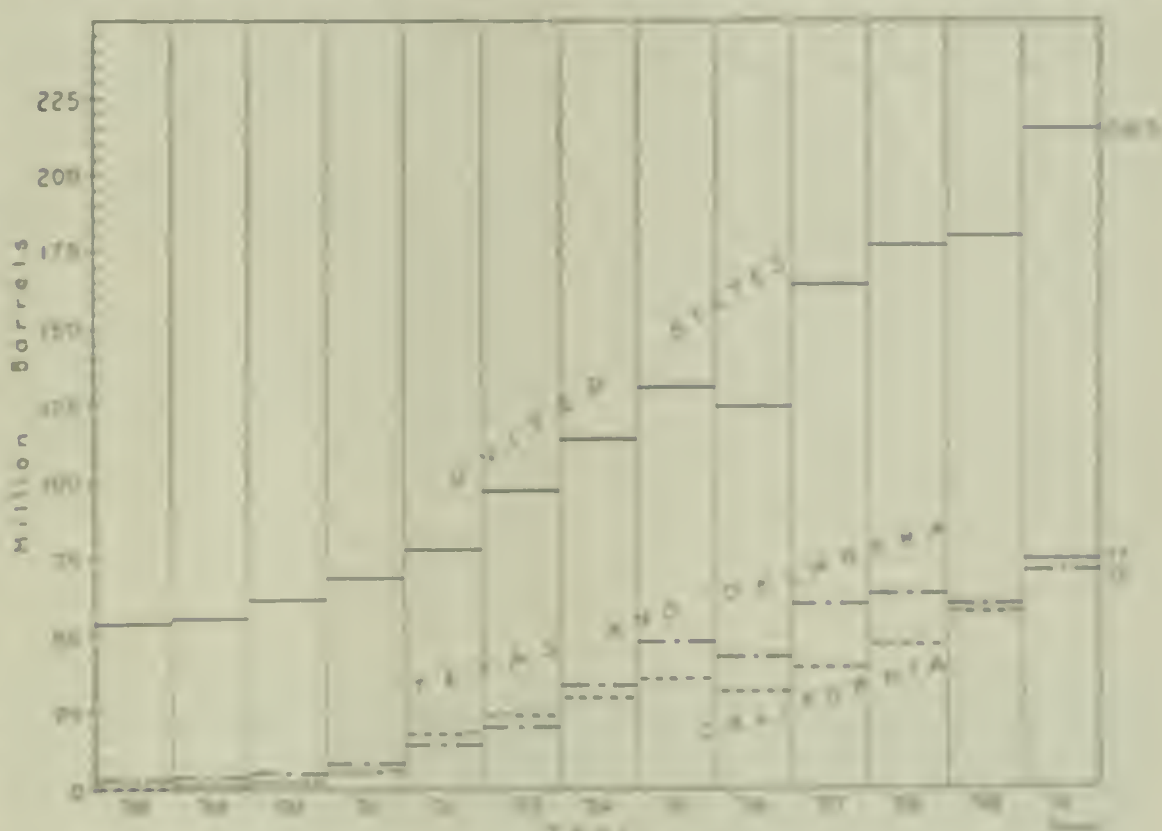
The requirements for the perfect combustion of liquid fuel are as follows: Reduction to a fine spray or complete atomization; bringing it into contact with the proper amount of air; mixture of oil spray and air burned in the furnace of refractory material with room enough to complete combustion before the gases come in contact with the boiler-heating surfaces. The first condition is fulfilled by selecting a proper burner, and the remaining conditions can generally be obtained by making slight changes in, or additions to, the existing furnaces.

As to whether steam or air should be used for atomizing the oil, the decision is usually in favor of steam, because it takes about the same amount of steam to operate the air compressor as it does to atomize the oil at the burner and the additional investment and complication involved with greater possibility of interrupted service is avoided.

Also a flat fan-shaped flame presents a larger surface for heat radiation and uniform distribution of gases than any other shaped flame, and at the same time requires a minimum number of burners per boiler.

Heating of the oil is an aid to economical combustion, and should take place as near the furnace as possible and be carried as high as safety permits, but not so high as to cause the oil to decompose and carbon to be deposited in the supply pipes. If preliminary heating is limited to the temperature of the flash point of the oil used there can be no trouble from these causes.

One of the most important questions in the combustion of liquid fuel is the regulation of the air supply in such a way as to obtain perfect combustion before the gases come in contact with the heating surfaces of the boiler. This can be done with an automatic damper regulator, although its adjustment is rather difficult. It is therefore usually accomplished by hand regulation of the damper when considerable variations in the load take place. This is supplemented by changing the position of the ashpit doors, which are kept closed until a slight tendency to make smoke is noticed in the furnace; or, better, by using an Orsat or continuous CO_2 recorder to determine the position of the damper and the ashpit doors which give best complete combustion under certain constantly recurring conditions.



Production of Oil from 1898 to 1910

Types of Oil Burners

Although thousands of patents have been granted for oil burners or atomizers two general subdivisions of five general classes, as designated by the United States Naval Liquid Fuel Board, cover practically all of the main features of construction. The two general subdivisions are:

Outside mixing: Oil and atomizing agent meet outside the burner.

Inside mixing: Oil and atomizing agent meet inside the burner.

The five general classes included are:

Drooling: Oil oozes out over the steam or air jet.

Atomizing: Oil is swept from the orifice by steam or air jet.

Chamber: Oil mingles with steam or air in the body of the burner and the mixture issuing from the nozzle is broken into minute particles by the expansion of the steam.

Injector: Similar in principle to boiler-feeding injector.

Mechanical spraying: Effected by mechanical means without the use of atomizing agents, such as steam or compressed air.

Method of Installation

In spite of the various principles involved in burner construction, the success of an oil-fuel installation depends not so much upon the type of burner or atomizer used as upon the method of its installation, and the intelligence with which it is operated after the installation is made.

To conform with the underwriters' requirements, storage tanks above the surface of the ground should be placed at least 200 feet from inflammable property and the top of the tanks should be located below the level of the lowest pipe used in connection with the apparatus. When the tanks are located underground they should be outside the building, at least two feet below the surface and 20 feet from any building, with the top of the tanks below the lowest pipe in the building used in connection with the apparatus. Storage tanks should be fitted with vent pipes, [illegible] the level of oil in the tanks, filling pipes, [illegible] for heating the [illegible] water, suction pipes, return or overflow pipes, steam pipes for filling the space in the tanks above oil with steam in case of fire, and suitable manholes for cleaning-out purposes. A suitable strainer should be installed on the suction line between the storage tanks and the oil-pressure pumps. The suction line should slope so that it will drain all oil back to the storage tanks when the pump is stopped and a vent opened. Duplicate oil-pressure pumps should be installed with pump governors and all piping in connection with these pumps should be cross-connected in such a manner that a change can be made from one to the other and repairs made to either without interrupting the service. A suitable oil heater should be installed, so that the exhaust steam from the oil pumps can be utilized to heat the oil before it reaches the burners. A relief valve should also be installed on the discharge line between the pumps and the burners, and provision should be made for removing any condensation from the steam lines to the burners. Automatic regulating devices are desirable for varying the pressure of both the oil and the steam to the burners in accordance with the demand for steam on the boilers.

In a series of tests* on a 604-horsepower Babcock & Wilcox boiler equipped with Hammel burners and furnaces at the Redondo plant of the Pacific Light and Power Company, an efficiency as high as 83.3 per cent. was obtained, and the water evaporated per pound of oil from and at 212 degrees Fahrenheit was 15.81 pounds. The average percentage of CO_2 was 13.2, the excess air 21.2 per cent. and the steam used by the burners 2.15 per cent. The average efficiency for all seven tests, running from 72.7 per cent. up to 195.5 per cent. of rating, was 80.47 per cent., and the average evaporation from and at 212 degrees Fahrenheit was 15.23 pounds.

In tests made at the Ravenswood plant of the New Amsterdam Gas Company, on a 595-horsepower Babcock & Wilcox boiler, equipped with a Peabody furnace and four No. 1 burners, a boiler efficiency of 80.97 was attained, when evaporating 14.61 pounds of water from and at 212 degrees Fahrenheit per pound of oil. The steam used by the burners was 1.54 per cent. of the total steam generated.

Although a fair idea may be obtained of the comparative cost of the two fuels by making certain assumptions in regard to heat values, specific gravity, gain in efficiency, etc., still this will not enable one to figure the saving which could be made by changing from one fuel to the other. The reason for this is that the saving generally depends on other things than the cost of the fuel. The saving in firemen and coal passers, increase in capacity, facilities for fuel storage, advantage of pumping oil over methods of handling coal, elimination of handling ashes, quantity of coal used for banking fires, elimination of smoke and other things, many of which cannot be figured out in advance in dollars and cents, would throw the ultimate cost decidedly in favor of oil. The only way to determine the exact saving is to operate the plant with each fuel for a long enough period to get accurate data on all the items entering into the question.

*The results of these tests are given in the May 9 issue of POWER.

Discussion

D. S. Jacobus: The efficiency results secured in the tests on an oil-burning boiler at Redondo, Cal., represent good practice. Better results, however, than these were secured in tests made on one of the boilers at the same plant preparatory to making a test of the plant. The results of the plant tests, which have already been reported to the society, indicated that a kilowatt-hour was turned out at the switchboard for every 25,000 B.t.u. contained in the fuel oil. In these tests the standard form of Peabody furnace was employed with burners of the outside-mixer type. I intend to submit the results of the tests of the single boiler to the society in connection with an article dealing with boiler and furnace efficiencies.

M. H. Bronsdon: Every test of crude or fuel oil made for me by Professor O'Neill at the University of California showed practically the same calorific value, regardless of its specific gravity or whether or not the gasolene had been removed. The more fluid oils are much less troublesome, requiring much lower pressure to send them through the piping and where the gravity is 17 degrees Baumé or lighter at 60 degrees Fahrenheit they require no warming during the pumping process.

Where oil is used for fuel, perfect combustion may be obtained under all conditions of load with proper installation excepting when the fires are first lighted and the brickwork is comparatively cold. The labor charge is much lower with oil fuel than hand-fired coal, for with oil fuel one fireman can readily care for the fires under 5000 or more horsepower of boilers, provided the boilers are on the same floor level and equipped with feed-water controllers.

Boiler settings and boiler tubes will last much longer with oil than with coal, provided the tubes are kept clean. The flame from the burners should not under any circumstances be allowed to impinge upon the boiler tubes. Extra large combustion chambers below the tubes are especially desirable.

The impression should not be given that by changing from coal to oil fuel the capacity of any boiler plant can be increased from 35 to 50 per cent. In a boiler plant with sufficient draft to burn large quantities of coal, or where the evaporation can be made to exceed, say, seven pounds of water per square foot of heating surface, fuel oil will not increase the capacity 35 to 50 per cent.

Every item and condition of boiler-plant operation favors the use of oil fuel, the price of the oil being the only factor regulating the economical results to be obtained. Its use is clean, safe, reliable and responsive, the only laborious work being that of changing and cleaning the burners and piping. Proper cleaning vats should be provided in a suitable place, as fuel oil is very sticky and odorous.

Experience leads me to favor burners of the type known as "outside mixers," that is, where the oil and steam mix just beyond the tip of the burner. Carbon seldom causes trouble with burners of this type, even where the oil is quite hot before it reaches the burner. There seems to be no practical difference in the efficiency, however, in the use of either "inside-" or "outside-mixer" burners.

When properly installed, there is no danger from storing or using oil fuel. One important requirement is that the tank should be well ventilated to allow the escape of any gas that forms and no flame should be allowed to approach the uncovered storage tank.

In a well designed and carefully operated boiler plant using coal for fuel, where the efficiency is approximately 75 per cent. or better, the use of fuel oil will not change the efficiency materially. In a plant which operates from 20 to 24 hours per day, the standby losses, of course, will be lower with oil than with coal for fuel, due to the fact that there are no banked fires to be maintained under spare boilers, some of which are of use only during the peak-load conditions. Any gain in efficiency is not due simply to the use of oil fuel instead of coal, but rather to better conditions which are maintained with less effort on the part of the operatives, such as the removal of soot from the tubes, cleaner back connections and the fact that the fireman is not fatigued by his labors, but can without any particular effort see that perfect combustion is maintained. The CO_2 recorder becomes a valuable instrument in a boiler room using oil for fuel.

Professor Robinson: It would seem to me that the place where the use of fuel oil would have its greatest economic advantage, would be on steam vessels. There the saving in weight, volume and labor would have a much greater value than on shore. This would make it possible for the steamships to pay a higher price for oil than installations on land. Such being the case, it would seem to have small chance to compete with coal in New England until such time as it shall have been demonstrated that the supply is sufficient to take care of the steamships and leave a surplus for the land plants.

R. C. Monteagle: The question was asked whether there were any vessels running in New England that were burning oil. I do not know of any at present. The "Harvard" and "Yale" were two good examples; they are now on the Pacific coast. When they came out first they were fitted to burn coal and the running time between Boston and New York was 15 or 16 hours, and they almost invariably took over that time. After running a year they changed over to oil fuel, and thereafter had no trouble in making the trip on running time. I was going to ask Mr. Collins if he could not get some more data about the amount of water in fuel oil, as I understand all fuel oil contains a certain percentage of water. In the case of one of the vessels referred to, I happen to know that due to water in the oil in one particular instance, it caused the flame to go out, and as the fireman did not go the rounds properly, the oil kept flowing into the corrugated furnace and overflowed under the fire-room floor. When he finally discovered that the flame was out he stuck a torch into the furnace and immediately there was a puff and fire. If the vessel had not been built of steel it might have been a total loss.

In reply to several individual questions, Mr. Collins stated that the steam required for the oil pumps was about 1.5 per cent. of the total steam generated; this added to that required for atomizing made a little over 3 per cent. As to the presence of water, this is very apt to be present in crude oil, but fuel oil should be free from it. Furthermore, if two or more burners are used, and a slug of water extinguishes the flame in one, the flame from the other will relight it. Referring to the case cited by Mr. Monteagle, Mr. Collins pointed this out as proof that only reliable men should be employed in fire room when oil is used as fuel.

Some Ingenious Engine Room Kinks

By R. O. Warren

Most power plants contain interesting features, some of which would escape the casual glance because their simplicity detracts from their real merit. During a recent visit to the power plants of the Amoskeag mills, Manchester, N. H., the writer saw several devices which were of interest.

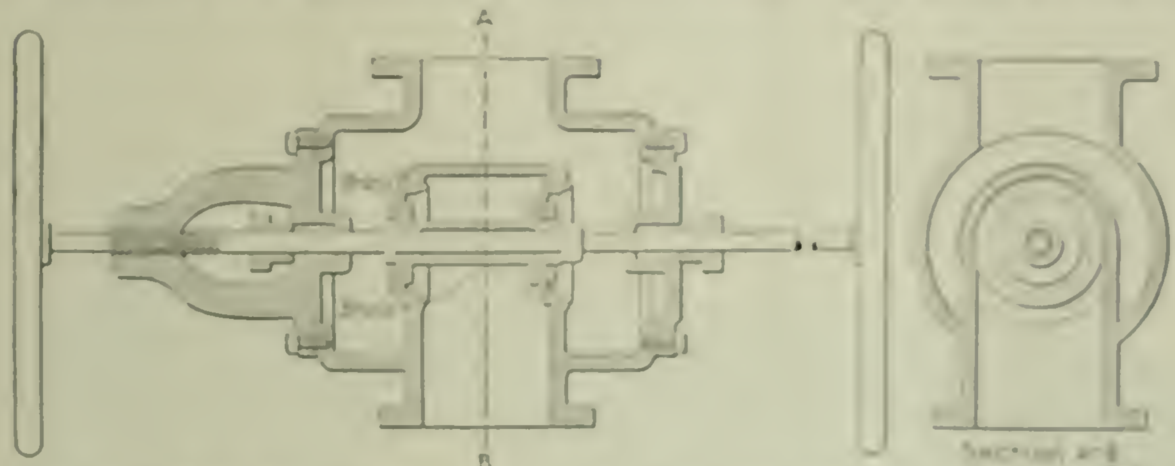


Fig. 1. Sectional Views of Double-wheel-and-stem Throttle Valve

Perhaps one of the most important was a double-stem, double-wheel poppet throttle valve, one of which is used on each reciprocating engine throughout the works. A sectional view of one of these valves is shown in Fig. 1. It consists of the main body containing two double brass seats against which the double poppet-valve disks seat. In addition to this feature the valve stem is made with an extension, as shown. This valve stem passes through the sleeve to which the brass valve disks are secured, each by four [illegible]-inch tap bolts. One end of the sleeve fits against a collar on the valve stem; the other faces against a nut. Both ends of the valve stem pass through a stuffing box, but only one end of the stem is threaded.

The chief advantage of this valve is that the engineer can shut down the engine from either side of the cylinder, a most convenient arrangement in case of a runaway engine. Fig. 2 shows one of these valves in the steam pipe of one of the large reciprocating engines. This illustration also shows an arrangement used to prevent pipe vibration. Before this device had been put in place the pipe vibration was so severe that leakage continually occurred at the joint formed at the straightway valve shown in the vertical pipe.

Fig. 2. Double Throttle Valve and Pipe Brace

Details of the arrangement are shown in Fig. 3. It consists of two saddles, each fitting on each section of vertical pipe, and a distance piece which snugly fits into the hollow place in each saddle. The saddles and distance piece are kept in place by means of two stayrods which are drawn together by two turnbuckles. Each rod is bent around the pipe as shown; the turnbuckles are midway between the two vertical pipes.

While passing an almost empty coal-storage bin, a method of ventilating the coal was observed, which is illustrated in Fig. 4. The bin contains several rows of upright beams, as shown. On two sides of each upright there are fitted saw-tooth projections, each projection forming an air space leading to the main flue, which extends from the bottom to the top of the upright supports.

When the storage bin is full of fuel, the gases and heat generated will escape through the numerous air vents to the top of the building. In this manner spontaneous combustion is prevented to a certain extent. There is one disadvantage; if the coal should once get on fire the ventilating vents would produce an excellent draft and add to the difficulty in subduing the fire.

An interesting method of heating and ventilating the Coolidge mill, the latest addition to the Amoskeag mills, is shown in Fig. 5. The heating apparatus consists of seven old Manning boilers, each 5 feet in diameter and 16 feet 6 inches long, and five larger boilers of the same make, each 6 feet 6⅜ inches in diameter and 19 feet 5½ inches long. These boilers are all placed in a horizontal position and rest on brick piers placed at each end of each boiler. Exhaust steam is carried through a tunnel from an adjacent mill to these boilers, and surrounds the tubes on the outside. The boilers are separated at the end next to the air passage leading to the fans by brick headers, so that the air cannot bypass between the boilers.

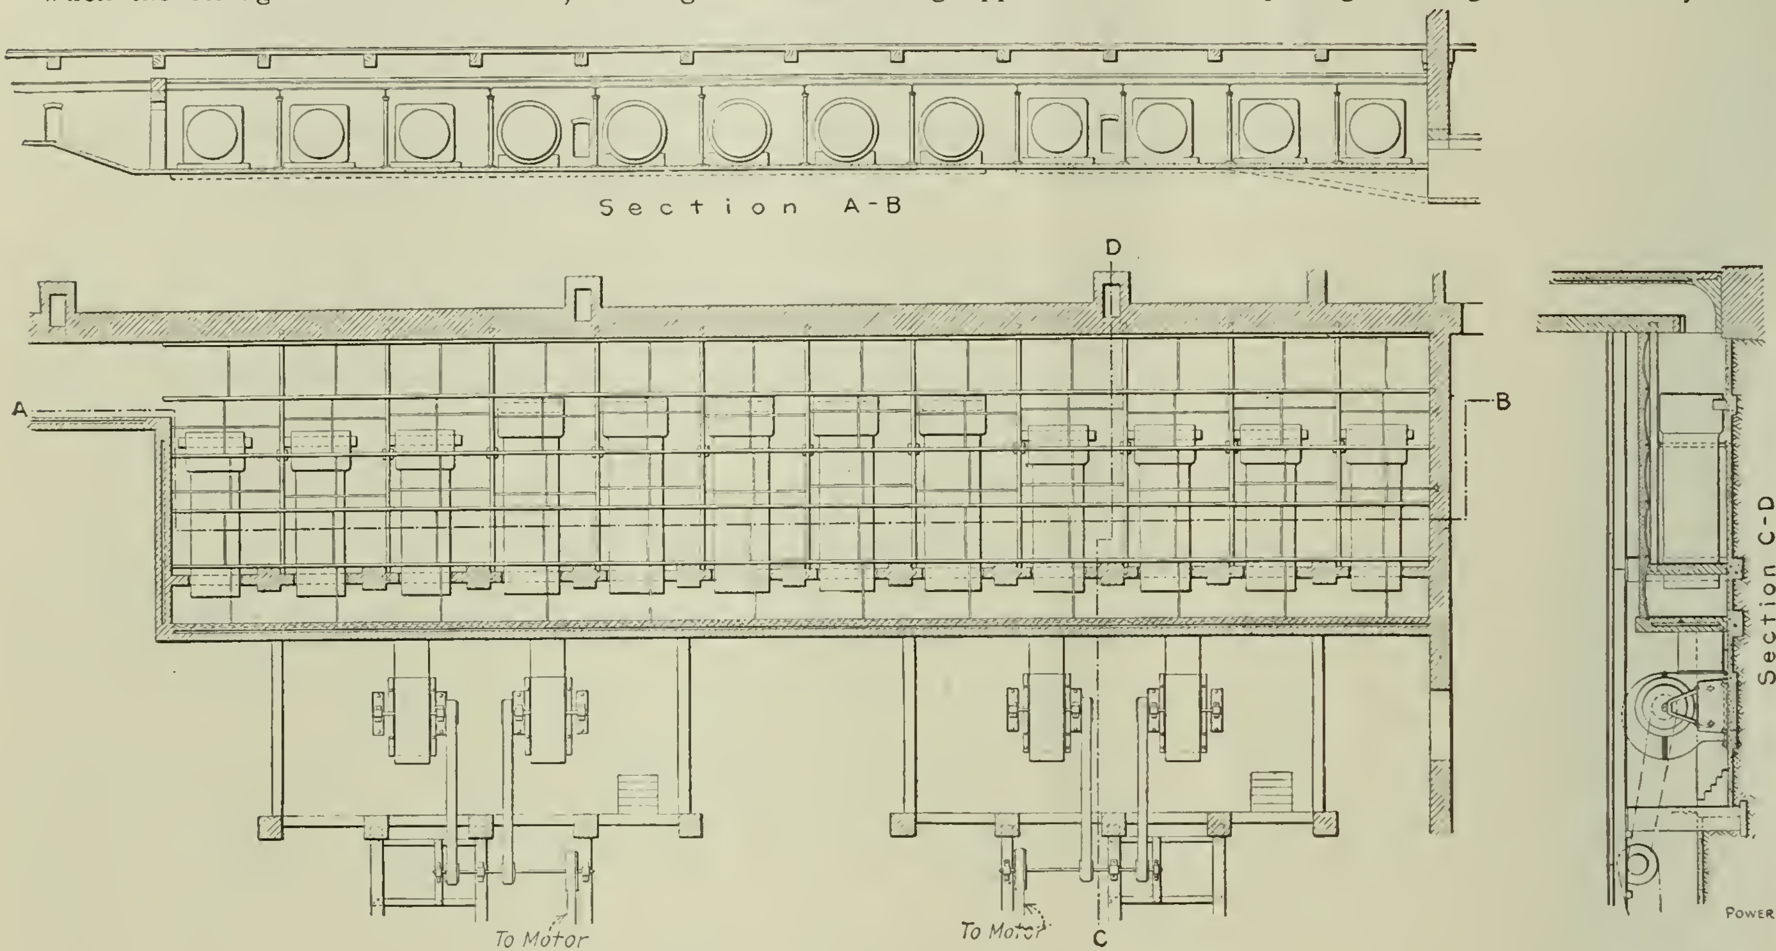

Fig. 5. Arrangement of Heating Boilers and Air Fans

Fig. 4. Showing Construction of Ventilating Chutes

Extending along the front end of the boiler is an air duct which is 8 feet 10 inches high and 4 feet wide. At the rear end of the boiler, connection is made with an air duct which is 5 feet high and 40 inches wide. This air duct runs up to the Coolidge mill, in the basement of which the hot room is located. Another branch leads to a neighboring mill. Two 6-foot fans, placed outside of the wall surrounding the boiler, supply the air for heating and ventilating; each is driven by a 60-horsepower motor. These fans force the air into the air duct at the front end of the boiler and the air passes through the boiler tubes to the other end, where it is allowed to surround the outside shell of the boilers, thus coming in contact with every part of the heating surface of the boiler shell and tubes. The air when thoroughly heated passes to the various rooms in the mills.

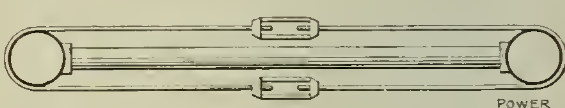

Fig. 3. Details of Saddles and Stayrod Arrangement

By means of this system two large mills are heated indirectly by exhaust steam with very little piping and no radiators. The help that would be necessary to keep them in proper condition is therefore eliminated.

These devices have been put in under the direction of Charles H. Manning, mechanical engineer of the company.

Electrical Department

Especially conducted to be of interest and service to the men in charge of the electrical equipment

Automatic Starting Attachment for an Exciter

An exciter unit that is somewhat out of the ordinary is in operation in the power plant of the Lynn Gas and Electric Company at Lynn, Mass. The unit consists of a 125-volt General Electric dynamo of 75 kilowatts capacity driven by a Curtis turbine at a speed of 2400 revolutions per minute; the steam pressure is 150 pounds per square inch. The special feature of the outfit is an arrangement for starting the unit automatically when the running exciters reach their load limit.

A general view of this unit is shown in Fig. 1. The constructional details of the automatic attachment are shown in Fig. 2; this is a steam-control valve consisting chiefly of a Waters governor with the springs, ball weights, pulleys and gears removed, the only part utilized being the valve body, valve and stem. The valve is inserted in the steam-pipe line upside down and is fitted with a bypass adjusted so that when the main valve is closed a small volume of steam flows through the bypass to the intake end of the turbine; the condensed steam is permitted to drain from the turbine casing through the drip valves, which are always open. This arrangement keeps the steam end of the turbine hot and ready for immediate use. Bolted to the flange of the control-valve body is an L-shaped piece of flat iron *A*, to which a thin piece of wood is attached and this supports an electromagnet *U*, which is energized from the exciter busbars on the switchboard. Attached to the member of the governor which contains the bearing through which the valve stem passes is a U-shaped piece of iron to which the lever *L* is pivoted at *M*. A slot *N* is cut in the lever in which the pin *O* can slide; this pin passes through the valve stem.

A piece of soft steel of the same width as the magnet core and forming an armature for the magnet is attached to the handle, as shown at *P*, and a 28-pound lead weight *Q* is hung on the end of the valve stem. So long as current at the normal pressure of 125 volts passes through the magnet coil, the magnet holds the lever *L* in the position shown, in which position the valve is closed and the turbine inoperative. When the exciter voltage drops seven volts, a relay opens the circuit through the magnet coil and the magnet, being deenergized, is, of course, unable to hold the lever up against the downward pull of the weight *Q*; the latter drops, pulling the lever down and opening the valve, thereby starting the turbine. The rapid descent of the valve stem is prevented by means of the dashpot shown in the sketch. The handle *L* is for closing the control valve, of course, when the turbine is to be shut down.

Fig. 1. Exciter Unit with Automatic Control

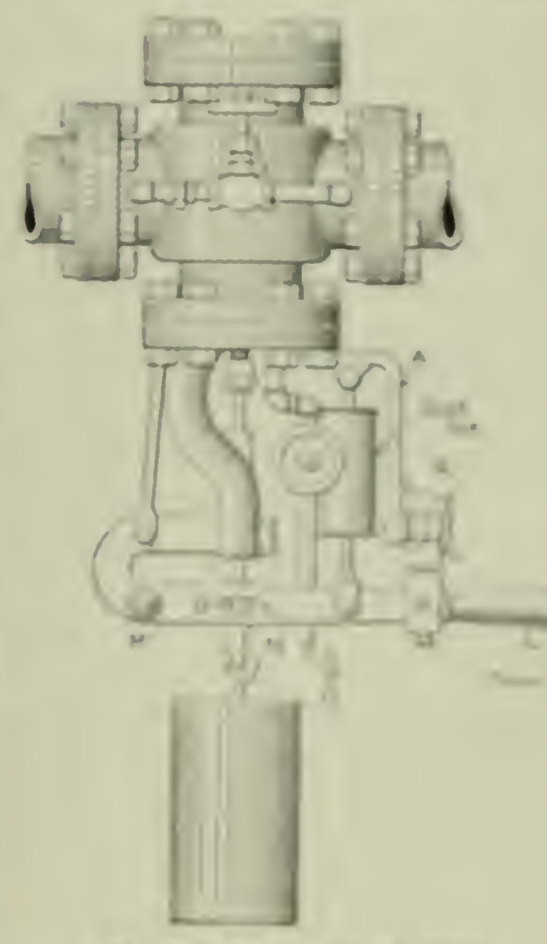

Fig. 2. Automatic Starter

Fig. 3 is a diagram of the master circuit in which the magnet *U* is the one shown in Fig. 2. Normally, when the exciter is not needed, the switch *T* is held closed by the solenoid *S* which is also energized from the exciter busbars. A drop of seven volts weakens the solenoid to such an extent that its plunger drops and opens the switch *T*, thereby "killing" the magnet *U* which has been holding the steam valve of the turbine closed, as described.

The switch *T* has three blades but the middle one is independent of the other two when they are closed. When the handle is pulled, however, it closes all three contacts. The middle blade, when closed, short-circuits the resistor *R* and this strengthens the solenoid *S* sufficiently to enable it to lift the plunger and close the switch *T*. When this has been accomplished, the middle blade is pulled out, leaving the resistor *R* in series with the solenoid *S*, in which condition the latter will just hold up its plunger at normal exciter voltage. The middle blade

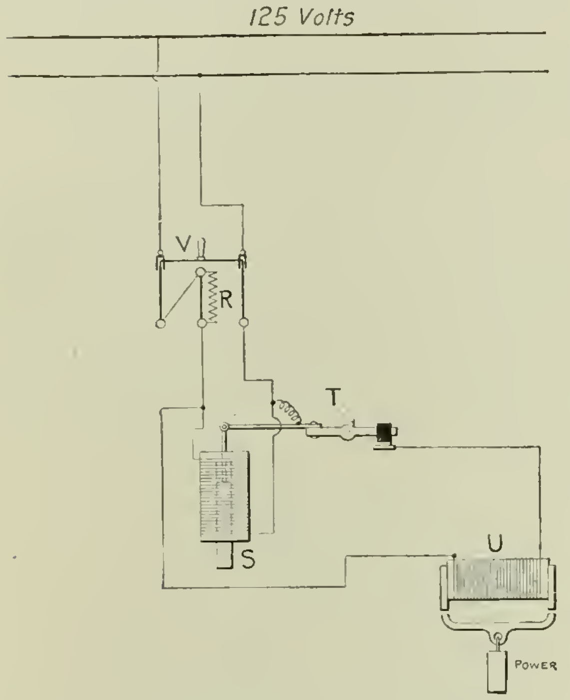

FIG. 3. MASTER CIRCUIT DIAGRAM

of the switch *V*, therefore, serves merely to reset the switch *T* from the switchboard.

An East Indian Postgraduate Technical School

Mr. Tata's Research Institute in Mysore has at last been completed and will begin work next July. Dr. Morris Travers, director of the institute, has issued the following statement:

"The annual guaranteed income of the institute is about 270,000 rupees (about $86,000) which sum should be able to maintain six departments of work. The work at the beginning, however, will be limited to four departments, namely, general, organic and applied chemistry, and electrical technology, these being considered by the council to be of the greatest importance to Indian arts and industries and not provided for in the other post-graduate institutions in the country. Graduates of a recognized university or a similar institution will be admitted as students. The institute does not charge any fees for tuition, though it does not offer any scholarships. The council has decided that the other two departments are to be devoted to pure and applied science, in some branch, but is not in a position to make a definite announcement on this subject."

The institute owes its existence and its magnitude to the princely donation of Mr. Tata and the generosity of the Mysore state. The work has taken about ten years. It aims to provide an institution where technical and scientific research work of a higher order can be undertaken on a large scale in its laboratories and where the students can have a practical insight into such work.

Small Station Switchboards

By Guion Thompson

It is almost universal practice in small plants to display as much switchboard as circumstances render possible. The switchboards are bulky and by some are considered unsightly; also more of a plaything than a necessity. The wiring and apparatus are usually crowded in a mass on the back in order to avoid getting the board too large from the point of view of switchboard advocates. To those who do not admire them, this mass of wiring and apparatus appears inconsistent with the form of energy being handled and seems a departure from the usual rules of spacing and other precautionary methods practised in other branches of the art. The appearance of a generator room is better without a switchboard, as has been demonstrated in the large stations where the boards are placed on galleries. The largest and latest stations are working toward elimination altogether, which appears to be much more in keeping with thorough station efficiency.

The switchboard is only a development of our old-fashioned admiration of mechanism to be manipulated and with which to awe the uninitiated. The apparatus mounted on a switchboard is refined down to the last notch of size and delicacy, all of which tends to detract from its efficiency, as of all the parts of a station equipment the control should be rugged and reliable to the highest degree. A remote-control board may appear complicated, but it is based on simple principles the applications of which do not need to be shaved down to the last degree of delicate construction in order to reduce space and attain convenience. The switch gear and main circuit connections are rugged and of open construction, easily accessible and yet removed from accidental interference by reason of their isolated situation.

The expense of remote-control equipment is considered excessive in small plants but there is no reason why it should cost more than the ordinary switchboard in any station that contains more than a small generator circuit-breaker, switch and voltmeter. For example, in a small plant of two 500-kilowatt water-driven three-phase generators with six outgoing feeders and requiring one attendant on watch, the generator room should contain only the generators, exciters, wheel governors and attendant's desk. The desk should be so placed that while sitting thereat the attendant has full view of the room. The required generator and feeder indicating instruments should be mounted on a small panel along the back of the desk about eight or ten inches high and on the top of the desk, with a clear space in the center, should be the finger switches controlling the main switch gear in the basement, wire tower or other protected location, as conditions may indicate.

Current for the control circuits may be obtained from the exciter busbars and, if it is thought necessary, a small storage battery may also be provided for such use, though there does not seem to be any real need for it because it is quite practical that all switch gear should be inoperative and open when the plant is shut down. All ammeters, voltmeters, wattmeters, etc., should be connected to their operating circuits through transformers and absolutely no main wiring should enter the desk. Wherever the main wiring, switches, etc., are located, they, of course, need not be ornamental but of rugged construction, and wiring connections should be of similar character and generously spaced for easy access and handling.

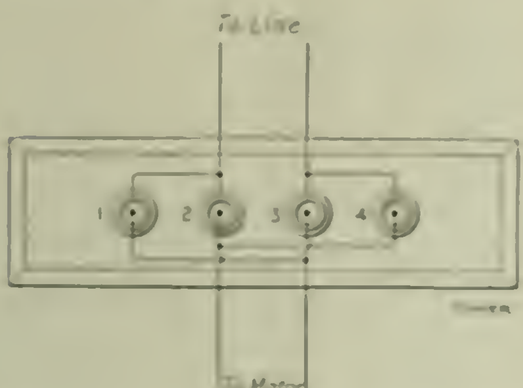
Switch gear, lightning arresters, etc., should be regularly inspected and kept in first-class condition but the station attendant should not be the one to make this inspection. The monotony of continual contact with his surroundings tends to render him oblivious to increase of wear and irregular operation of minor parts; inspection should be made by the superintendent. We know that very few switchboards in small plants are ever inspected beyond a casual glance at the mess at the back and a remark to the operator that he had "better remove that stick," or piece of waste or some other stray object. The first real evidence of anything out of order is usually a display of pyrotechnics and the operator is censured because he is there all the time and ought to know what is going on behind the board as well as in front. With the remote control he has no responsibility for the maintenance of the switchboard and the superintendent, who has, is given an opportunity to perform his duty and to have repairs made without danger of fireworks or shutting down the plant.

In substituting remote control for the old form of switchboard many changes suggest themselves in the methods of treating details. For instance, generator ammeters, wattmeters and field resistors are all local to their respective machines and in a small station it seems consistent and feasible to mount each set of instruments on a pedestal near the machine to which they are connected. The place for the resistor in the field circuit of a machine is adjacent to that machine, with either mechanical or electrical control at the desk. Voltmeters and feeder instruments should be at the desk, with the exception of recording instruments, the proper location of which is the switch room. With a diagram of the main circuits under a glass in the center of the desk the operator can always have a grasp of feeder conditions as changes or additions occur from time to time. The advantage of having the operator familiar with the system outside the station can scarcely be exaggerated.

LETTERS

Substitute for a Double-throw Switch

After installing a 5-horsepower direct-current motor for driving a crab winch through a friction clutch, we found that the weight of the line would not run the winch backward after throwing out the clutch, so we decided to make the motor reversible. Having on hand neither a double-throw switch nor the material from which to construct one, we resorted to the arrangement indicated in the accompanying sketch.



SUBSTITUTE FOR A DOUBLE-THROW SWITCH

We mounted four incandescent-lamp receptacles on a board and connected them as shown. Then we short-circuited the terminals of two ordinary attachment plugs with pieces of No. 12 copper wire and screwed them into the different receptacles according to the direction of rotation required. With the plugs in Nos. 2 and 3 the motor runs one way and with them in Nos. 1 and 4 it reverses.

This arrangement works so satisfactorily that we have decided to leave it in use instead of putting in a switch.

W. S. YOUNG.

Cherokee, Iowa.

An Extension Brush Holder

We have a 150-kilowatt alternator of the compound-wound type and the brushes on the rectifying commutator had always given considerable trouble by sparking and cutting away. They are woven-wire brushes and had to be bent as shown in Fig. 1. As they wore down near the bend we could not get tension enough on them to hold them down on the commutator; then the sparking increased, and the more they sparked the worse they would cut. Besides, the flashing caused a flickering at the lamps due to the variation in voltage. In order to get around the difficulty, I made up a full set of extra brush holders, each consisting of a simple block with two slots through it and two set screws, as shown in Fig. 2. This holder was mounted on the end of a short brush which was set in the regular holder, and a working brush of regular length was clamped in the diagonal slot. The complete arrangement is shown in Fig. 3. This enables

FIG. 1. THE REGULAR BRUSH

FIG. 2. AUXILIARY HOLDER

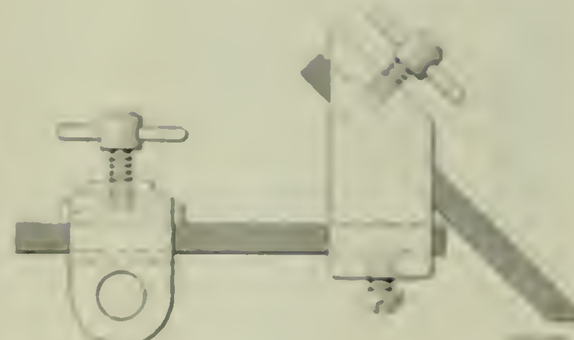


FIG. 3. APPLICATION OF AUXILIARY BRUSH HOLDER

us to keep the spring tension constant and to use up nearly all of the working brush.

Nelsonville, O.

Starting a Large Motor Supplied by a Small Alternator

A factory was newly equipped with three-phase induction motor drive, the power to be furnished by the central station of the city. All the motors started their required load without difficulty except one of 50 horsepower. The customer tried in every way he knew to get this motor started but with no success. It was consequently declared defective and I was sent to locate the trouble. A thorough examination of the motor disclosed no defect except a ground in the rotor squirrel cage, and I knew that this would not necessarily interfere with the operation of the motor. The fuses, transformers and the inside wiring to the motor were found to be in perfect condition. The voltage of the circuit was tested and found to be normal.

Then we decided to give the motor another trial, but before doing this we connected lamps across the three phases in order to find out if there was an abnormal drop in voltage at the time of starting. With two or three men at the belt to aid the motor, the compensator switch was thrown in. The motor hummed, made a feeble effort to start, and the test lights showed extremely low voltage on the line. As the torque of an induction motor varies as the square of the applied voltage, one-half of the normal voltage would give only one-fourth of the normal torque, so it was now no wonder to me that the motor refused to pick up its load.

We inspected the line leading from the power house and found it was large enough to carry the current without any appreciable drop in voltage, and I felt sure that they were not running the voltage down at the central station while the motor was being started. Upon investigation at the power house we found that the current was supplied by a 100-kilowatt alternator, and observing the voltmeter on the switchboard while the motor was given another trial start showed that the heavy lagging current taken by the relatively large motor weakened the alternator field and reduced the e.m.f. to about half the normal voltage.

As a makeshift we tried running the voltage up while the motor was being started; it was run up to 15 per cent. above normal and when the motor hit the line we immediately cut all the resistance out of both the alternator and exciter field rheostats. The busbar voltage was thereby held about normal and the motor speeded up with its load with the greatest ease. This method had to be used in starting this motor until a larger generator was installed.

G. J. KETWILLER.

Anniston, Ala.

The portion of the feed pipe in the boiler should be suspended by short wires from the braces and not be allowed to rest upon or across the tubes. Tubes are sometimes cut through by the continual movement of the feed pipe upon them, due to the pulsations of the feed pump. The pipe should be put together in sections so that it may be removed and cleaned.—ED.

When the belt has become oil soaked and will not stay on the pulleys, a good method of cleaning it is as follows: Coil the belt loosely in a tub of sufficient size, and cover with whiting. Be sure that the whiting gets in between the coils of the belt, and it will be only a short time before the whiting will absorb the oil from the leather. It will then only need to be wiped clean to be ready for further service.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Running a Gasolene Engine with Kerosene

By M. W. Pullen

It is well known that for a hydrocarbon engine to run properly it is necessary that the fuel be finely atomized (preferably vaporized) and thoroughly mixed with the intake air. With gasolene engines and some forms of kerosene and crude-oil engines the problem of obtaining the proper mixture has been solved in a number of ways which are quite satisfactory. With a kerosene engine, vaporization of the fuel is much more difficult than in the case of the gasolene engine, because kerosene is not as volatile as gasolene. If, then, an attempt be made to use kerosene as fuel for an engine normally adapted for gasolene, trouble is likely to arise from failure to vaporize the kerosene.

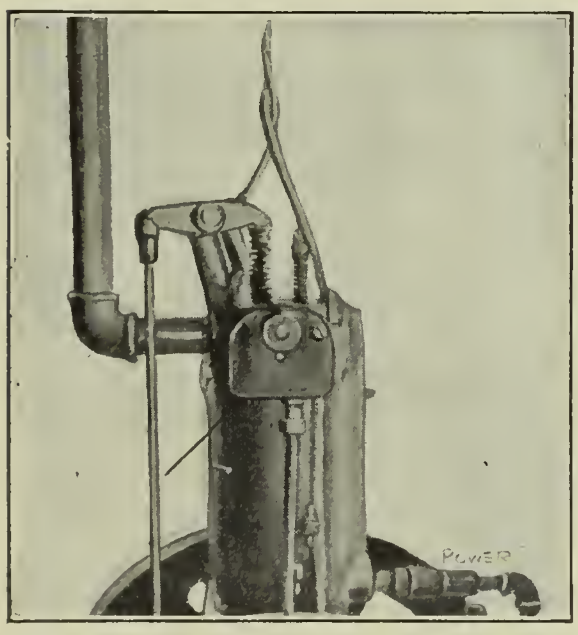

Fig. 1. Gasolene Feeder

This trouble was very noticeable in the case of a small engine which was supposed to be properly equipped to burn kerosene. The engine was fitted with an atomizing mixer very much like that used by the manufacturer for gasolene. Fig. 1 shows the atomizer used for gasolene on the type of engine under discussion; the arrow points to the air-intake opening. Fig. 2 shows a vertical section (not to exact scale) of the device taken at right angles to the needle valve and Fig. 3 a vertical section partly in the plane of the needle-valve axis. It is clear that as the intake air is drawn into the cylinder it sucks a certain amount of fuel through the small nozzle and the two mingle in the short passageway to the cylinder.

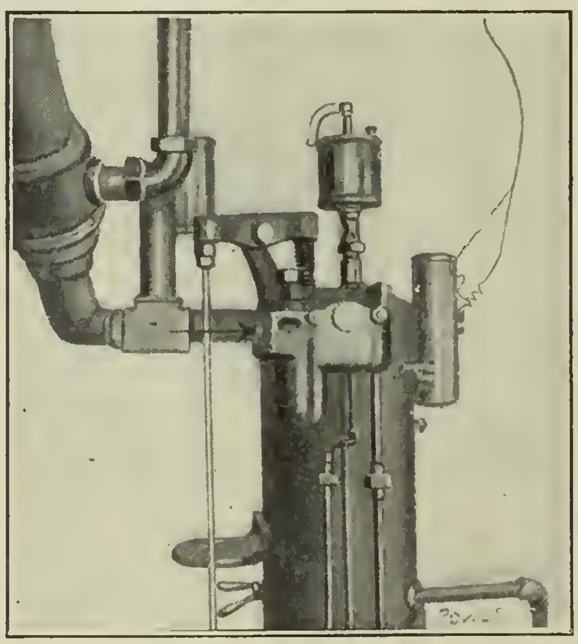

Fig. 4. Kerosene Feeder

Fig. 4 shows the atomizer that is used for kerosene. The similarity in appearance of the two is quite marked, the kerosene device differing only in having the retort at the left. The intake opening is located somewhat differently, however, as indicated by the arrow. The retort, which is the only essential difference between the two types of atomizer, is arranged to be heated with a blow torch in case it is desired to start the engine on kerosene. In this case the large sight-feed oil cup shown just above the needle valve is screwed into an opening directly over the retort; this opening is indicated in the sectional view of Fig. 5. The function of the sight-feed cup is explained later. The portion of the kerosene atomizer which is not shown in Fig. 5 is exactly like the corresponding part of the atomizer represented in Figs. 2 and 3. Vent holes are provided for the escape of the hot gases of the blow torch from the jacket space *J* but they do not show in Fig. 5; one may be seen near the top of the retort in Fig. 4.

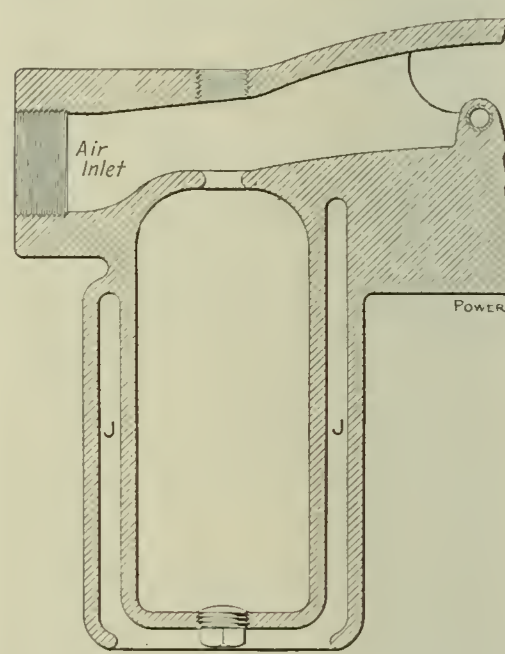

Fig. 5. Section of Kerosene Vaporizer

To start the engine with kerosene, the sight-feed cup is filled with the fuel and the retort is heated at the bottom. When it is hot enough, the cup is opened and the kerosene drops down into the retort, where it is vaporized. The kerosene vapor rises into the air passage and mixes with the air drawn into the cylinder by the suction stroke of the piston and the ordinary cycle of operation

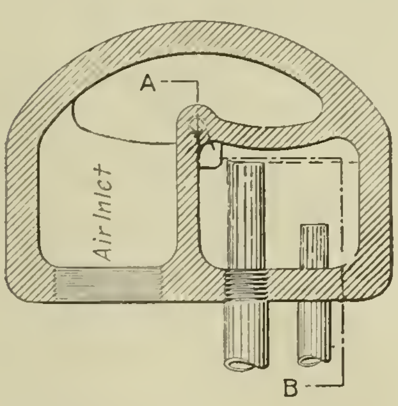

Fig. 2

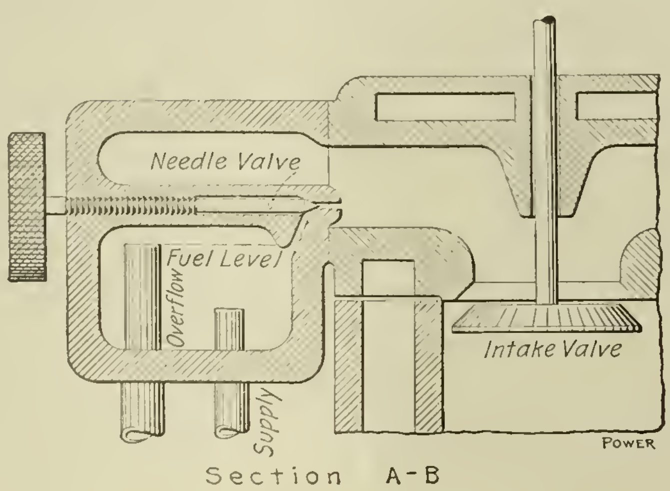

Fig. 3

Sections of Gasolene Feeder

started. After the start the needle valve is opened, the oil cup shut off and the kerosene is thereafter fed to the engine in exactly the same way that gasolene is fed in the gasolene atomizer. The retort, of course, goes out of use until another start is made.

If there is gasolene at hand the sight-feed cup may be mounted in the position shown in Fig. 4 and the engine started by allowing gasolene to feed from the cup into the air passage of the atomizer, whence it is swept up by the air and forms an inefficient mixture but one good enough for starting. After the engine has run for a few minutes, the gasolene is shut off and the needle valve opened; regular operation on kerosene follows. This latter method of starting is much handier than the former, and if it be used the retort is unnecessary, a simple gasolene atomizer being sufficient as far as running is concerned. No provision is made for vaporizing the kerosene; it is simply atomized by the nozzle.

The engine with the kerosene (retort) feeder gave trouble almost from the time

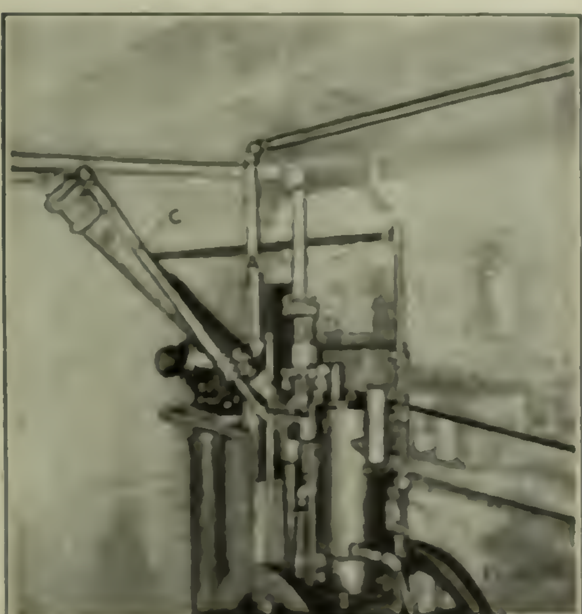

FIG. 6. INTAKE-AIR HEATER

it was put into operation. It used a great deal more fuel than it should, even when the needle valve was regulated to give the least amount of fuel that would enable the engine to run smoothly.

The second trouble was in lubrication. The engine, as will be noted, is vertical with a closed crank case, being oiled by the splash system. The hight of the oil in the crank case was noted daily and each time it was necessary to *draw off* oil instead of adding more; the amount drawn off was greater than the amount added by the oil cup which was supposed to keep up the supply. Then, again, the oil worked out through the main bearings and getting on the flywheels it spattered two streaks on the floor and ceiling of the room.

The cause of the lubrication trouble was not discovered for some time. However, it became necessary to draw the oil all off about a month after the engine was set up, and the oil was saved with the idea of using it again. It was noticed that it had a peculiar appearance, was very thin, and did not feel very smooth between the fingers. A close examination showed that it was a mixture of cylinder oil and kerosene, mostly kerosene.

From this discovery it became evident that the kerosene was not being fully burned and that some of the unburned part of it worked down into the crank case; perhaps a good share of it went out through the exhaust port.

In Fig. 6 is shown the remedy adopted. A jacket of 3-inch pipe fittings was put on the exhaust riser, which is of 1½-inch standard iron pipe, and the intake air was led through it. The air comes from out-of-doors through the small vertical pipe *A*, entering the bottom of the heater *B*. The air then rises along the hot exhaust pipe and out at the top by way of the pipe *C*, which leads down to the atomizer. The heated air serves to help vaporize the kerosene.

It is now necessary to add oil to the supply in the crank case and, what is more important, the kerosene tank does not have to be replenished nearly as often as before with the same engine load. No exact data as to the saving can be given, but it is estimated that with the heated air only about three-quarters as much fuel is used as when the engine was supplied with cold air.

Steam Engineers for Gas Power Plants

BY CHARLES O. HAMILTON

"Whom have you picked out to take charge of your power plant?" is the way I generally bring up the matter of attendance in going into details with a gas-engine buyer. I am not likely to say "engineer"; it's mighty apt to start something.

After explaining the need for attendance and the buyer understands the matter, it is only natural for him to say, "How will my present steam engineer answer?" This is a most natural suggestion. Why not the present engineer?

Unfortunately, the engineer himself in many cases has made his selection as the gas engineer a bad move for his employer. The reasons may be many, but foremost is the prejudice that he has cultivated for the gas engine. He would be out of harmony with gas power; until he had weaned himself from his first love and formed an attachment for the new power he could not hope to succeed. The chances are that he has opposed the purchase of the gas plant and his personal feeling prejudices the builder against trusting him to operate the engine.

Even though he had taken a broad-minded position, advising fairly on such points as were put up to him during negotiations, there might be still many things which would make his selection as operator of the plant seem inadvisable. Chief among these objections is usually the fact that unless he has been more progressive than the average engineer he has not equipped himself with any knowledge of gas-engine operation, having assumed that if he should ever be called upon to operate such a plant his knowledge of steam engines would enable him to step in and make good immediately. He is apt to scorn A, B, C instructions and the need of his making-over that is requisite to change from steam- to gas-engine operation.

A good steam engineer has a great many points to recommend him. He is not afraid of the noise and the moving parts of an engine, whereas a man of other training would be timid until he became used to the surroundings. His training has made him thoughtful and watchful of details; he does not forget to do the little things. He has self-reliance and presence of mind in an emergency—a most valuable asset. He knows the plant, knows the ins and outs of everything, probably having installed or renewed a good part of it if long in his position. To have been a successful steam engineer he must have been of good habits. He must have been something of a mechanic in order to keep his plant in shape.

Every one of these things counts in his favor as a gas-engine operator, but if he is prejudiced against gas power or has been so indifferent that he has made no study of its peculiarities, the favorable points will not suffice to make him eligible.

Steam engines and gas engines are both machines for converting heat into mechanical energy. But aside from this function there is mighty little similarity. They are decidedly unlike in operation. Conditions in the steam cylinder are materially different from those in the gas cylinder because steam differs, of course, from flame. Steam exerts a fairly even continuous pressure on the working parts; gas pressure starts with an explosion and diminishes rapidly; it is also intermittent. Lubrication, packing, valve conditions, are entirely different. Even the bearings require different handling and adjustment. The control of the fuel and ignition have no correspondent at all in handling steam.

The steam engineer served a long time to learn steam-engine operation. The gas engineer, to be equally proficient, must serve and study too.

The ordinary steam man usually begins his gas-engine apprenticeship by far underestimating his need for special knowledge and training, and is inclined to feel that changing to gas power is a step downward. The fact that he has been "it" in the old plant often leads to a resentful, obstinate, overwise bearing in receiving instruction regarding the eration of the gas engine. Starting up looks so easy in the hands of the erecting engineer that he assumes there is nothing to it. He despises suggestions of a routine, preparing to start and stop.

When anything goes wrong, he will hark back to his old plant and when he cannot figure it out he blames the gas engine. He will make about as ridiculous mistakes in his new work as an inexperienced man would make with steam—mistakes he would laugh at in a steam engineer, yet he does not see the joke when we laugh at his bungling with the gas engine.

When we find an old steam engineer who is wise enough to know that he does not know about gas power and really wishes to learn, there we find an ideal candidate for a gas engineer.

The gas engineer in Europe must make his engine perform well up to its possibilities or lose his standing as a mechanic. It is so in this country with steam engineers, and eventually it will be so with gas-engine operators.

There is another feature that steam men do not always like. The medium-sized gas plant, say, of 20 to 200 horsepower, using natural gas, city gas or gasolene, will not require over two hours' time out of the eight, nine, ten or eleven hours which the operator puts in. (In this time estimate I am considering a plant where the engine is belted to a line shaft.) If a suction-gas producer is used, another hour will be sufficient to care for that. Consequently, the gas engineer must occupy himself for the greater part of the day with other work.

Here, again, we are apt to find the steam man with his hair rubbed the wrong way. Where there is any auxiliary machinery, such as dynamos, pumps, compressors or a heating system, to take up his time he is satisfied, but when the spare time must be put in at some regular work, like running a lathe or other production machine, he is apt to buck, and rather naturally, because this usually forces him to learn two trades, gas engineering and machine-tool operation. Under such circumstances, the steam engineer is at a disadvantage compared with a man taken from some machine in the shop, who willingly masters the gas engine as a side line to running his regular machine. But there are hundreds of industrial establishments in which working at a distinct trade in addition to running the power plant is not necessary. Only the ordinary kind of mechanical work, such as the care of belts, shafting, hangers, etc., is required. Here the steam man ought to shine if he would take the proper interest in gas power.

There is a growing demand for competent men in this line of work. We know it from the continual efforts made by engine buyers to hire our field men and experts away from us to take charge of their power plants.

What I have written here is not intended as an argument for or against the steam engineer in the gas plant. It is intended merely to tell some facts which I know to exist, some facts that are not always quite apparent to the people who buy engines and those who run them.

I do not know that the average steam engineer wants to take hold of a gas plant such as might be bought to replace his steam plant, but if he knew the possibilities for more money—and that is what most of us work for—I should think he would be anxious to do so. My experience indicates that the man who can successfully operate a gas-power plant and make himself of real service in his spare time will easily earn at least 25 per cent. more money, with shorter hours and cleaner work, than he could get in the average steam plant of the same horsepower. Perhaps he would not get it at the start, but why should he expect it? He is learning a new trade then.

Essential Factors in Making Producer Gas

Bulletin No. 7, just issued by the Bureau of Mines, describes the results of some interesting investigations, made by J. K. Clement, L. H. Adams and C. N. Haskins, of the processes that take place in a gas producer. One of the chief objects of the work was to determine the effect of temperature upon the proportion of carbon monoxide obtained. In experiments made by Mr. Clement at the Norfolk plant of the United States Geological Survey, it had been found that the temperature in the generator varied greatly in different parts of the fuel bed. In order to ascertain the conditions of temperature most favorable to efficient operation it became necessary to determine the temperature required for the formation of carbon monoxide and hydrogen.

The investigations described in the bulletin demonstrated that a very high temperature is necessary for the maximum production of carbon monoxide from carbon dioxide and carbon. Other conditions, however, are against operating the decomposition zone of the fuel bed at extremely high temperatures—much above 1300 degrees Centigrade (about 2400 Fahrenheit). A very hot fuel bed means that the gases will leave the generator at a high temperature and thereby lower the efficiency of the producer unless the heat of the gases could be used for generating steam or preheating the air blast. High temperatures also favor clinkering. In the application of the results of these experiments to commercial producers and furnaces it will be necessary, of course, to consider the other questions which are involved.

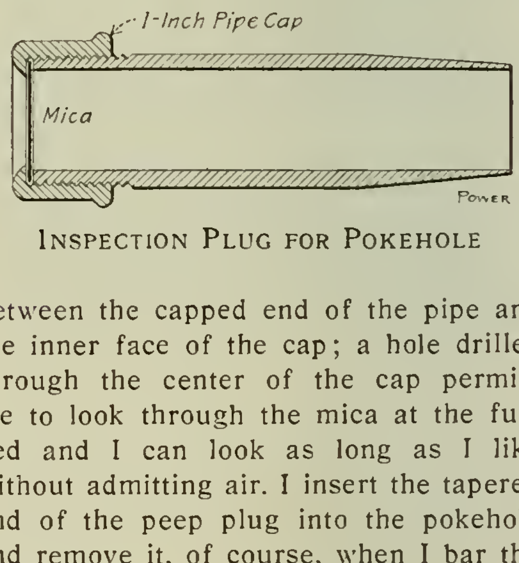
The investigations also demonstrated that the higher the velocity of the gas through the fuel bed and the thinner the bed, the smaller will be the percentage of carbon monoxide formed; also, the greater the supply of air to a given depth of bed, the smaller will be the percentage of this gas formed.

The use of large amounts of steam is inconsistent with the realization of high temperature, and is, therefore, to be avoided. Moreover, on account of the large percentage of carbon dioxide that is formed when a relatively large quantity of steam is used, it is doubtful if a real gain in efficiency is obtained.

CORRESPONDENCE

An Airtight Peephole

For a long time I followed the common practice in the operation of gas producers of using the opened pokeholes as peepholes for inspecting the condition of the fuel bed, wishing all the time that some other way could be devised. Finally I hit upon the simple arrangement illustrated by the accompanying sketch and now I never need to open a pokehole to the air except for actually poking the bed. The arrangement shown consists of a piece of 1-inch pipe 6 inches long, capped at one end and slightly tapered at the other, with two sheets of mica clamped



INSPECTION PLUG FOR POKEHOLE

between the capped end of the pipe and the inner face of the cap; a hole drilled through the center of the cap permits me to look through the mica at the fuel bed and I can look as long as I like without admitting air. I insert the tapered end of the peep plug into the pokehole and remove it, of course, when I bar the fuel bed.

N. A. LEE.

Hawley, Minn.

A 63-ton shafting has recently been placed in the engine room of the Sharp Manufacturing Company's mills in New Bedford, Mass. To move the huge piece of metal from its bed on a flat car to its position in the engine room required the work of ten men and two large steam road rollers for two days. A cylinder weighing 29 tons had previously been placed in position.

Just because you do not get a raise in pay every few months is no sign that you are not appreciated. Things might have been worse. You might have got fired.

Inspirator Troubles

Some years ago I had trouble with an inspirator. The conditions under which it worked were severe and different from what the device was designed to work under. It received its water supply under a head of about 45 pounds; the water pipe was the common supply for two power pumps, and the steam supply came from a main that supplied two air pumps and a duplex steam pump.

As long as the steam pressure would be kept up to 140 or 150 pounds per square inch, the inspirator would work properly, but as soon as the pressure dropped, as it would through the night, trouble would be experienced. In starting the inspirator, it would only run a few minutes and then break. The trouble was with the water supply. The inspirator was made to lift water, and when doing so works satisfactorily with widely varying steam pressure.

With the inspirator connected to a water supply under pressure, the valve on the suction pipe should be throttled until just the right amount of water is admitted; otherwise the inspirator may break. In starting up under such a condition the steam should be turned on first; then open up the water-supply valve a little and draw over the starting lever, for, when lifting the water, it can easily be determined if there is too much or too little. It is a matter of rather nice adjustment, depending on the steam and water pressure, but after a few trials one can judge the right amount of opening the suction valve needs.

North Cambridge, Mass.

Flywheel Worked Loose

One morning, after I had started a 12x12-inch automatic high-speed engine, my attention was arrested by a loud grating noise. When the governor "came out" the noise stopped, but it was succeeded by a rapid pounding. I shut down and as the governor "went in" the pounding ceased and the grating began.

I found that the governor was rubbing against the eccentric oil guard, which was caused by a loose and shifting flywheel. I could think of no easy way to shift the wheel back to place, so I tightened the set screws in the hub and started up again. This time there was no pounding and the engine ran very well all day. The wheel was about ½ inch out of position on the shaft and this drew the eccentric out of line with the valve rod. Putting the wheel back into position was a difficult matter, for it was a side-crank engine and the flywheel and armature were so close to the main and outboard bearings that there was not enough room for the usual make of jacks.

During the day I made two jacks by sawing a 2½-inch cast-iron bar in 3-inch lengths. I drilled and tapped them for a ⅝-inch set screw, shown in the accompanying illustration. I also made a clamp to fasten to the shaft. The clamp contained two set screws which were to be used for gripping the shaft after the clamp bolts had been tightened as much as possible. With the clamp in position on the shaft, the base of each jack was placed against the clamp ends and the heads of the set screws were placed against the hub of the flywheel. I then loosened the set screws in the wheel hub and with a small monkey wrench began to screw out on the jacks. Presently the wheel began to move and in a few minutes it was back in place.

I then took some putty and plastered it all around the shaft close to the hub and after removing one set screw out of the hub I poured in a solution of sal-ammoniac and water and allowed it to stand until the next morning. The clamp and jacks were then removed, the engine was started up and no trouble has been experienced since.

The object of using sal ammoniac was to rust the wheel and shaft together.

Jacks Used to Force Flywheel Into Place

Some Power Cost Figures

Some interesting figures on the cost of producing power in a plant which sells its exhaust steam for heating during the winter months have recently been reported. These figures refer to the plant of the Wells Power Company, of Milwaukee, Wis., the power plant of which is an outgrowth of a small isolated plant installed to furnish power and heating for several neighboring buildings in the center of the business section of the city, and at the present time furnishes power and exhaust steam for heating to customers within an area of 2½ square miles.

When the original isolated plant was outgrown a new plant was built to be operated in parallel with the former, each plant being situated in the basement of a mercantile block. The old plant had a capacity of 550 kilowatts and 900 boiler horsepower. The new plant at present contains 1000 kilowatts in generators and 1524 horsepower of boilers, and there is provision for eventually more than doubling this capacity.

During the year ending July 1, 1910, the total generated output was 1,561,410 kilowatt-hours, of which 1,275,400 kilowatt-hours were sold to outside consumers, the remainder being used through the company's buildings. Based on the kilowatt-hours sold, the total earnings were $0.097 per kilowatt-hour, divided into $0.056, earned by the sale of electrical power, and $0.026 credited to heating; the remaining amount represents miscellaneous income. Against this earning the total expense charged, which includes depreciation and taxes, amounted to $0.075, giving a net profit of $0.022 per kilowatt-hour.

In order to furnish a real basis for comparison with isolated plants and central stations, it is more logical to take the figures for kilowatt-hours generated rather than the amount sold. On this basis the figure for total earning per kilowatt-hour are $0.079 against a total expense of $0.062.

In considering these results allowance must be made for the fact that, owing to the location of the plant and the impossibility of obtaining the large quantities of water necessary for condensing without undue expense, it is necessary to operate this plant noncondensing in the summer time as well as during the winter when exhaust steam is used for heating. If it were possible to run condensing during the warm weather, the total expense figures would undoubtedly be materially lessened.

H. M. Wilcox.

Boston, Mass.

Smoke Preventers

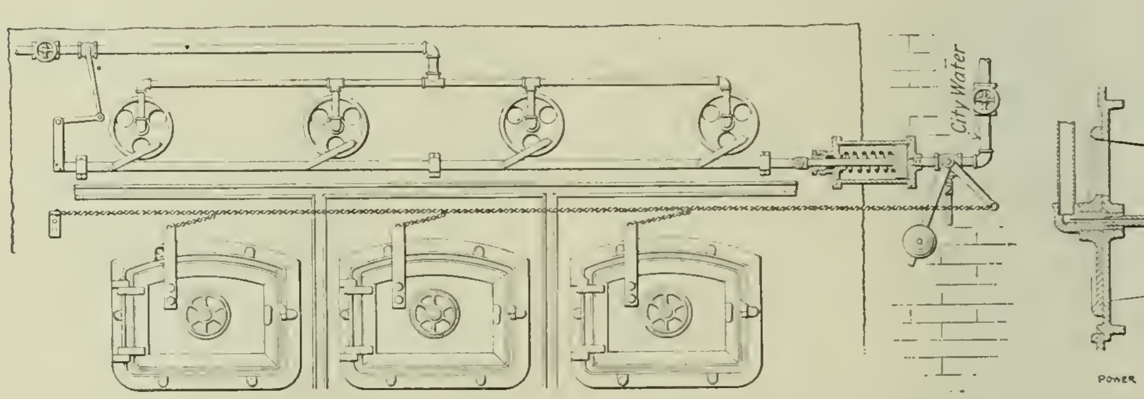
I carried out several experiments some years ago with a so called smoke preventer, the principle of which was to admit steam and air over the fire while the volatile gases were being distilled. The fronts of our boilers were badly cracked. The doors were each 24 inches wide by 20 inches high, and considerable air was admitted when firing and cleaning the fires, causing a serious reduction in steam pressure as the load carried was very heavy.

Patterns were made and a new front with three doors each 18x14 inches was cast and put on one of the boilers. After this was done it was noticed that the stack of the boiler with the remodeled front smoked for a longer period after each firing than the boilers with the old-style front, which was believed to be due to the new front being tight and shutting out the air over the fire.

It was then decided to put on a steam-jet smoke consumer, which was done by piping steam to the inside front wall. A ¾-inch supply pipe fed the ½-inch branch pipes, which were fitted with nozzles made with a very thin, wide opening, in order to spread the steam over the entire fire. This device was tried on one of the old-style fronts, steam being turned on as soon as the doors were closed after each firing. On trial it was found that with the jet on and doors closed the black smoke was reduced to nearly one-half of what it was without the jet, and still better stack results were obtained with the fire door slightly open; the coal consumption was also increased and the feed valve was opened about one turn more to make up for the increased evaporation, due to a hotter fire with better draft rather than more complete combustion.

As this device depended upon the fireman for operation, it would either be left on all the time or not turned on at all.

These results lead to a second experiment on a larger scale with a more complete and automatic device, which is shown in the illustration and was applied to the new front. It consisted of four draft plates 7 inches in diameter, fastened to the boiler front, through which holes were drilled to correspond to the openings in the plates. A hole equal to the area of the opening in each plate was also made through the front brickwork and pitched slightly downward, so that the air and steam would tend to strike the bridge-wall about 2 feet over the fire. Superheated steam was admitted through the ⅛-inch nozzle placed through the center of each plate, which also acted as a bearing on which the plate could revolve.



Control of Steam Jet As Attached to the Front of the Boiler Setting

The draft plates and the butterfly valve in the steam line were operated by a cylinder 4 inches in diameter by 8 inches in length, and closed by a heavy spring on one side of the piston in the cylinder. Water under city pressure was admitted to the cylinder through a three-way valve which was opened as the chain was pulled when opening the fire door; when the door was closed, the three-way valve was closed by a weight and the water gradually drained out of the cylinder through a ¼-inch pet cock.

Steam was superheated by means of 12 feet of ¾-inch pipe placed crosswise of the boiler over the tubes. Both steam and air were gradually shut off by the action of the spring in the cylinder, and could be regulated to close in from 1 to 10 minutes, the duration of the steam blast being determined by trial, the idea being to diminish the amount of steam and air as the volume of volatile gas was decreased. A globe valve was placed in the steam and water lines in order to make changes and cut out at cleaning times.

This boiler was tested in comparison with another boiler fired alone and on another stack. Smoke was greatly decreased over that coming from the other stack without the jet, and better results were gained by having the fire doors open about 2 inches for three minutes after firing and also by firing alternately one-half of the grate at a time, which led to the conclusion that the plates were too small.

I had no CO_2 recorder, so I do not know whether the percentage of CO_2 was increased or not by the use of the "consumer," but, in every case when the device was turned on, the water tender gave the feed valve an extra turn open, and also several more barrow loads of coal were used per day, which led me to believe that the capacity of the boiler was increased, and the clinker was more brittle and easier to get out.

In order to observe the decrease in smoke, the device was left closed until the dense, black smoke was rolling out of the top of the stack, and then put on, the result being that the smoke instantly changed to light gray, and, if the steam jet was shut off again, black smoke would again issue from the stack.

These boilers were worked at full capacity and on a very poor draft. The coal was bituminous run-of-mine, containing about 13,500 B.t.u. and 15 per cent. ash; therefore, it was necessary to fire very light and often, or about every 5 minutes, using not over four small scoops at each alternate firing. In this plant is also another battery of water-tube boilers with the same kind and size of grate, but set in a dutch-oven furnace, the arch being 8 feet long and about 4 feet high in the center. Firing the same amount of coal in the same manner in this type of furnace gave a much cleaner stack than was possible with either the steam jet alone or combination of air and steam with the ordinary furnace.

I believe that the "smoke consumer" shown herewith, properly designed and set in a dutch-oven furnace, will not only produce a clean stack, but will increase the capacity of the boiler and give a high per cent. of CO_2 and better combustion.

The results obtained with the different types of furnaces and methods of firing are given herewith, and in each case the boiler was run at full capacity and fired in the same manner and by the same fireman.

The figures correspond to the numbers used in the Ringelmann smoke chart:

Boiler and furnace	Average Per Cent. of Time for Each Condition					
	No. 5	No. 4	No. 3	No. 2	No. 1	Clear
Sterling boiler, dutch-oven furnace, no jet or air over fire, No. 5 boiler	5	15	25	10	25	20
"Smoke consumer," Fig. 2, in operation on No. 4 boiler	10	15	20	20	25	10
Boiler with smoke consumer cut out	25	30	10	5	0	0
Boiler No. 3 with steam jet, Fig. 1, cut in, old front	20	20	20	20	15	5
Boiler No. 3 with steam jet cut out, old front	40	25	25	10	0	0

No. 4 boiler was equipped with the new three-door front when the test was made. It will be seen from the above table that No. 4 boiler, with the new front with air and steam shut off over the top of the fire, also with the original style of front as shown in column five, never showed a clean stack.

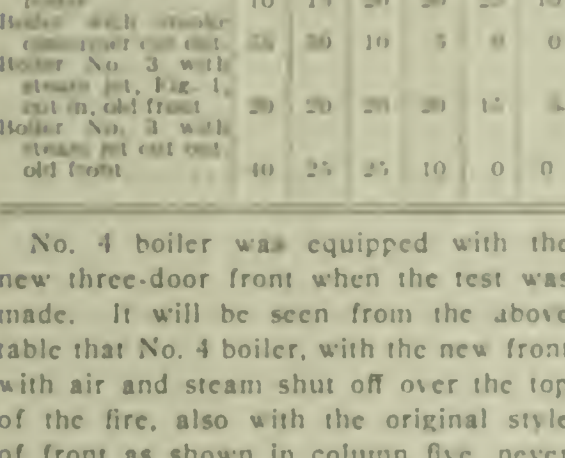
Regrinding a Safety Valve

It was necessary to grind a pop-safety valve so I began to think up a convenient method of turning the valve, which was not made fast to the stem and was threaded for a 1¼-inch pipe in the center.



Valve-grinding Device

I, therefore, made the tool shown in the illustration. The square shank end was cut from an old bit and a short piece of 1¼-inch pipe shrunk on the round end. A thread was then cut on the end of the pipe and a 1¼x1½-inch bushing was screwed on it. The whole was then screwed into the valve.

A bit brace was used to turn the valve disk on its seat. The valve was then readily ground in.

This tool will often come in handy as any size of bushing may be used.

Howard R. Taylor.

Norwich, Conn.

Babbitting Bearings

Most all of the so called anti-friction metals are composed of an alloy of two or more metals, such as copper, tin, antimony, bismuth and lead. Babbitt metal, however, has come to mean a metal containing any part of these metals, the base being chiefly lead.

Twenty-four parts of antimony and 76 parts of lead appear to be the proper mixture of the two metals, because 24 parts of antimony seems to be the maximum amount that will unite with lead to form a complete alloy. Considerable care is necessary in preparing these alloys because the melting temperatures of the component metals are so different.

Most engineers are aware that old babbitt metal after having been used and remelted a number of times loses its fluidity and becomes more and more pasty the more it is used until it will not make a sharp, smooth casting. This is due to the rapid vaporization of the more volatile metals and the oxidation of other metals of which the babbitt may be composed. When babbitt metal has reached this condition it is practically worthless but it can be restored to its normal fluidity, to a certain extent, by the addition of a small amount of lead. Pieces of old type metal would be more beneficial than lead as, owing to its composition, it not only restores the normal fluidity, but will improve the quality of the babbitt in general.

There are numerous ways of babbitting a box or journal. One very good way is to level and line up the shaft by putting small cubes of wood under it in such a position that they may be taken out after the babbitt has been poured, thus leaving small pockets for the oil under the shaft. These pockets will get full of oil and in case the journal begins to heat, due to a stoppage of the oil feed, etc., the oil from these pockets will work up to the bearing and thereby protect it from any very serious damage.

A good way for babbitting bearing for small shafts is to wrap common writing paper around the shaft and fasten it with coarse twine. The babbitt will run more smoothly by coming in contact with the paper covering than when coming against the cold surface of the shaft, although the shaft may have the chill removed by means of a blow torch before pouring the babbitt. The paper and cord method is preferable as the thickness of the paper will compensate for the slight shrinkage of the metal so that it will not be necessary to do as much scraping as would otherwise be the case.

If the twine is properly wound around the shaft, care being taken not to allow the twine to extend to the end of the box, but leaving it terminate in a complete circle about ½ inch from the end of the bearing, the oil will not run out at either end of the bearing. The ends of the bearing must be filled with something to prevent the metal from running out while pouring. This may be done by placing a pasteboard washer on the shaft up close to the end of the bearing and packing all small interstices with putty or soft clay paste. Then the bearing may be poured and a good bearing obtained.

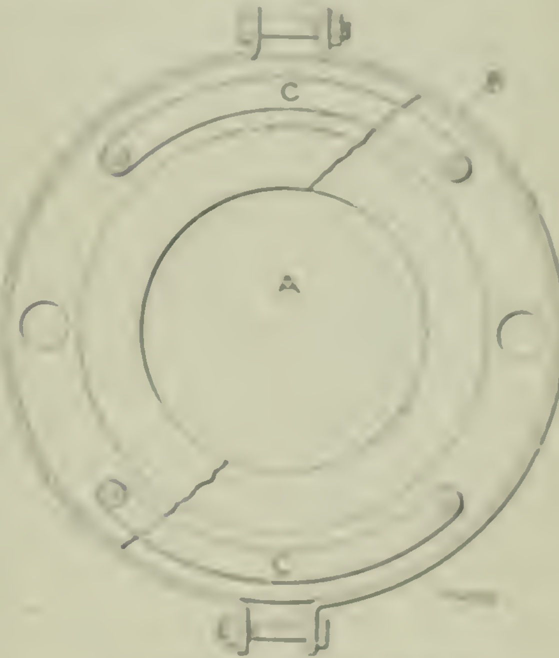
Repairing a Broken Pump Gland

A 12 and 8 by 14-inch pump of the pot-valve center-packed type had a cracked gland, as shown at *A* in the illustration. As a new gland could not be



Repaired Pump Gland

procured within two weeks, and as the pump had to be ready for the line for the peak load, I made the repairs as follows:

I got some ⅜x1-inch stock and made a strap to go around the outside of the flange, as shown at *B*. By drawing up on the bolts the gland was held together. Then I made two clamps, as shown at *C*, out of some ⅜x¾-inch stock, and drilled a 1⅛-inch hole in each end so that the clamps would fit over the studs. These clamps were fitted to the top and bottom studs, which enabled setting up the packing and prevented leakage.

When packing pumps of this type, care should be taken that all the old packing is taken out and that the plunger is central in the stuffing box. If the plunger sags and there is more clearance at the top, a tack screw put under the plunger or rod, whichever it may be, will equalize the clearance around the plunger in the stuffing box.

I find that by soaking the packing in oil over night and putting it in both short it gives better results and wears better.

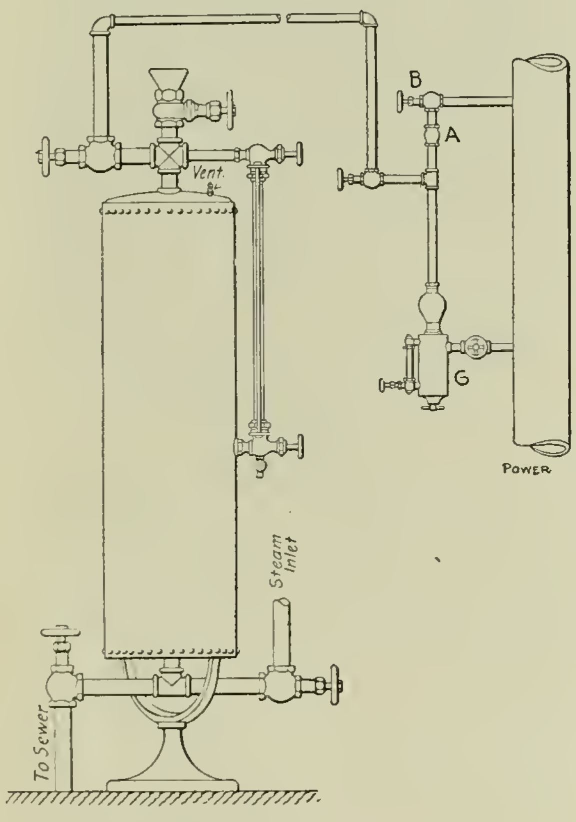
Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

A System of Lubrication

About three years ago I rigged up an oiling system in the plant where I am employed similar to the one described by Charles P. Weaver in the March 28 number of POWER. I connected the system up as described by Mr. Weaver with the addition of a check valve in the oil pipe close to the reservoir, which prevents any oil from returning to the reservoir when pressure is off. I provided a funnel similar to that shown in Mr. Weaver's sketch, through which to fill the reservoir. My reservoir contains enough oil to last six



MR. WEAVER'S OIL RESERVOIR

weeks, at the end of which time I find that I have quite a job refilling the reservoir.

As every engineer knows, cold cylinder oil has cold molasses beaten to a frazzle when it comes to slowness, and in handling any quantity of it he is quite likely to get his hands and clothing soiled, besides consuming a lot of time. To avoid this annoyance I ran a 1¼-inch pipe from the top of the reservoir to the oil barrel, entering the barrel at the bung and extending the pipe to about one inch above the bottom of the barrel. I put a union in this pipe 3 inches above the barrel and a globe valve just over the union, so that an empty barrel can be easily removed and a full one substituted. The oil barrel is set on skids about one foot higher than the bottom of the oil reservoir.

When the reservoir needs refilling I simply close the steam or water inlet to the reservoir, open the outlet to the sewer and open the two valves in the pipe between the reservoir and the oil barrel. The water runs out at the bottom of the reservoir and pulls the oil out from the barrel, filling the reservoir with oil as fast as the water runs out. We do not have to handle the oil at any time. The pipe from the barrel to the reservoir should be filled with water or oil to start the outfit, which is simply a siphon. If no air is allowed to get into this pipe it always works; but to fill the tank quickly when the plant is running, I have a ½-inch pipe running from the bottom of the reservoir to my condenser, with a valve close to the condenser. This pumps the water from the reservoir and fills it with oil in a very short time.

The Point of View

The front-page editorial of the April 18 issue of POWER gives a good suggestion to engineers as to how they might make their work more interesting. A man can do much better work when he takes a genuine pleasure in what he is doing than when only working to put in time so as to be able to draw a salary. However, the engineer is not always to blame, for while there are men who would not do the right thing no matter how fairly they are treated, there are some men who would be of use if they were rightly handled.

Take, for example, the young man commencing to learn the business and suppose he gets into some plant where the chief engineer is a man who thinks that everybody is trying to get his job and therefore is afraid to teach the young man anything of real value. Then there comes the time when the engineer is in need of an assistant. The young man does not get the job, for he has not been trained properly for it. So he is told that he does not know anything and never will know anything. How does he feel? How would any man, with a spark of pride, feel? Would he not be pretty much discouraged? A man treated like this may never rise above an ordinary helper. He has been spoiled at the outset. If any of the firm should inquire about him, the chief will say he is no good, so they fire the boy and hire somebody else. If it had been the case of a machine which had cost a hundred dollars or so, there would have been an investigation to fix the blame.

In my opinion, the average man who starts out to learn a trade has, if not the right view, the right spirit, and it is up to the man he is working for to develop him so that he may be valuable to others and himself. The beginner often believes that every man is an expert in his line and that each one is doing his best; but how rudely he is "brought to earth" when he finds that 90 per cent. of his fellow workers are just mediocre workmen.

Some years ago, I read an editorial in an engineering paper on the statement of an engineer who refuted the fact that an employer did not buy proper supplies for his plant. At the time it had not been my opportunity to see much of the methods employed in steam plants, so I thought this editorial unusual; now I know better. Anybody with experience knows that firms that buy the best supplies on the market are in the minority. I know of a plant belonging to one of the largest corporations in New England which buys a cheap grade of packing intended for 75 pounds pressure and uses it on superheated steam at 135 pounds. The chief can get nothing better. This tends to spoil his "point of view" somewhat.

As it is true that the engineer often considers his work a dull, monotonous drudgery, it is also very true that he is not wholly to blame. The layman is looking from a wrong "point of view" which cannot take in all the things that the engineer sees. If a fireman should call himself an "industrial chemist" in the hearing of some employers and some chief engineers, no matter how good a workman he may be, they will say that he is crazy and will fire him out of the plant. If he happens to be a young man, it will alter his "point of view" somewhat.

I claim that many engineers would take great pleasure in their work if they were allowed to do so by their employers. It will be found that those who are the most successful are those who are appreciated by their employers. This gives them added confidence and an opportunity to expand and develop in knowledge.

G. H. KIMBALL.

East Dedham, Mass.

Constant Receiver Pressure

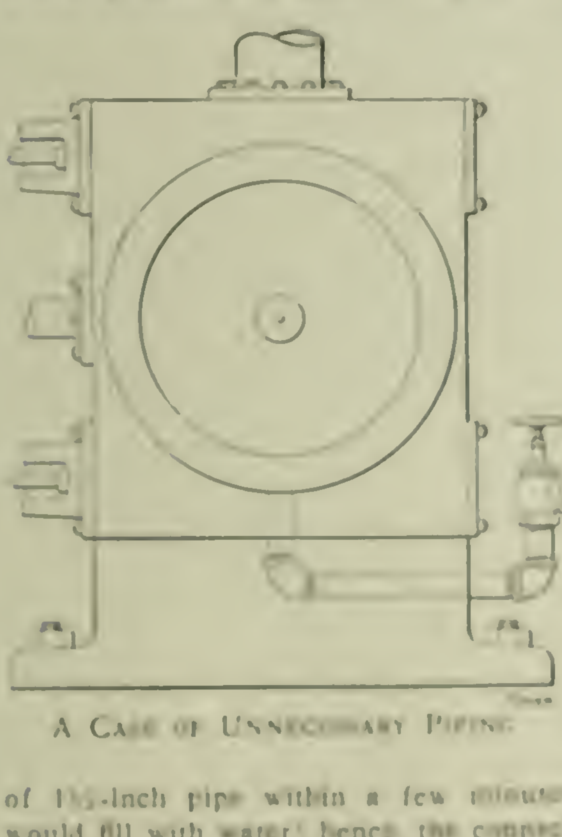
W. R. Beard, in the March 28 issue, gives it as his opinion that the cylinders of a compound engine should each do the same amount of work, and that it is better to maintain a constant receiver pressure under all loads.

In my opinion the receiver pressure should be such that the governor will revolve in its highest plane regardless of whether one cylinder does more work than the other or not. The engineer's problem is to keep the wheels turning with as little coal as possible, and it goes without saying that with the shortest cutoff in the high-pressure cylinder the steam consumption will be least.

Exeter, N. H. L. JOHNSON.

Unnecessary Clearance Loss

Under the above heading in POWER of April 25, S. Kirlin writes of the extravagant steam consumption of a four-valve engine equipped with relief valves and connected as shown in the accompanying illustration. I fail to see how this would affect the economy. The 3 feet



A CASE OF UNNECESSARY PIPING

of $1\frac{1}{2}$-inch pipe within a few minutes would fill with water; hence, the connection would add nothing to the clearance space, excepting the little space cleared after excessive pressure has opened the relief valve.

I take exception to Mr. Kirlin's method for two reasons: First, in a four-valve engine it could not be placed near enough to the end of the cylinder, if tapped into the bottom, to do any good during the period of compression, when it is most needed; second, it is likely to give trouble by leakage at the connections, after being used a few years.

I would much prefer to have relief valves tapped directly into the counterbore, through the side of the cylinder. This custom is adopted by most engine builders and gives universal satisfaction. If Mr. Kirlin placed his relief valves in an inverted position underneath the cylinder, he would find adjusting and repairing a disagreeable job, unless the cylinder was overhung and placed some distance above the floor.

GEORGE R. WILLIAMS.

Findlay, O.

Will an Isolated Plant Pay?

There has lately been much discussion of the above query in the columns of POWER. As I have had some experience with the encroachment of the central station upon the field of the operating engineer, I will add my quota to the general debate. Personally I am of the opinion that even diminutive isolated plants pay; and where they do not compare favorably with purchased power, I believe the fault to lie in the ignorance and stupidity of the attendant engineers. Some years ago I was hired to care for a 25-kilowatt motor which the central station had installed to supplant a little 20-horsepower Atlas slide-valve engine. The old engineer was afraid of electric power, and the superintendent of the mill was blissfully ignorant as to its simplicity and imagined that he had to have an experienced central-station man to operate the machine, which, by the way, was an old Edison bipolar motor, whose only apparent imperfection was a tendency of the commutator and the adjacent bearing to heat up. It ran, otherwise, very nicely; and the power soon became popular with management and operatives alike.

But early one morning the motor stopped; something was wrong with the transmission lines; and over the telephone came the cheering news that the power would be shut off for the rest of the day. Now the mill was behind with its orders, and a delay of even one hour's duration would be seriously felt. If all prospective patrons of power stations could have heard our manager's vehement denouncement of the service that day, it would not now be necessary to propound the above interrogatory caption.

To change from the motor to the engine took some little time, for additions had to be spliced to the main belt, and several pulleys had to be changed; but I was elated at the prospect of running the little engine, though I had up till then never seen it in service. They said that she had a habit of lying down on her job, but I was confident that I had located and eliminated its "book worm," for, while working with it when it lay idle, I had discovered the eccentric advanced so far that the port was over half open for lead. And my suppositions as to the performance of the engine were verified; it bore its load as steadily as the motor had carried it, and at a less expense. I am unable at this late date to give comparative costs of operation in detail, but I do remember well that the saving for the first month was $[illegible], for it was the means of bestowing upon me my first case of swelled head in engineering.

But the point I started in to illustrate and impress upon the reader is that the central station could never have endangered the engineer's job in this mill, had the engineer himself been competent. Hairs may be split as to the proper method of balancing charges, interest, etc., but it should not be forgotten that the engineer is the man who is responsible for the largest items of expense—such items as cannot be juggled by the central-station experts. If a plant is already installed in a building and the engineer loses his job through the crowding out of the central station, I am of the opinion that he deserves losing it. An excellent idea for those who would fight against the encroachments of the central station would be to unite into a society, and vote to levy assessments for the support of experts, whose duty it shall be to visit such plants as are threatened, and make sure that the encroachment is not warranted by the incompetency of the operating engineer.

Saxonville, Mass.

Holly System for Draining Manifold

In answer to the question asked by Mr. Bopp as to the practicability of the Holly system for draining a manifold collecting drips from separators, reheaters, etc., I wish to say that the Holly system will work if Mr. Bopp will connect a $1\frac{1}{4}$-inch equalizing pipe from the header to the receiving tank or manifold, if it is large enough to be used as a receiver.

The riser should be $1\frac{1}{2}$- or 2-inch pipe, depending on the amount of condensation, and the separating tank should be 35 feet above the water line of the boilers. A check valve should also be placed at each boiler in the return line. The turns in the riser should be made by long bends and all valves should be gate or straight way. The vent pipe from the separating tank should be ½-inch with a good valve near the lower end and should connect with the exhaust pipe or heater. At the present time I am in charge as engineer in a plant using the Holly system under conditions similar to those outlined by Mr. Bopp.

Binding "Power"

I am much interested in the methods used by many in binding copies of POWER. This is how I do it. I got my idea from our daily report-sheet file. One day while in the superintendent's office I saw several catalogs which were made up of loose sheets and bulletins placed in substantial covers and held together by two pins or keys passing through the covers and through the holes in the back margin of the leaves. I found several sizes. Some, however, were just the size for such papers as POWER, *Practical Engineer, American Machinist* and other magazines of like dimensions. I selected a set of covers to fit POWER. Before binding the papers, I removed the covers, binding wires and advertising matter. Then I took the pages of reading matter out of each issue that I most desired to save, and punched holes in the back margin, using a templet and belt punch. I put them in place and then tightly bound them down.

As the book was made up of several magazines, I could not use the page numbers as printed, but numbered them from 1 to 700, which was the size of my file. An index was made of the names of the articles and their page numbers, and they were grouped under such heads as New Power Plants, Boiler Management, Boiler Tests and Testing Apparatus, Pumps, Condensers and Connections, Engine Design and Theory, Engine Management, Power Plant Management and Economical Operation, and Gas Engines. Some articles which contained matter coming under more than one head were listed under two or three heads. The list was then typewritten and pasted inside the front cover. The cost of this file was nothing except a little time. It is easily worth $5, perhaps more. A slip of paper pasted on the front cover gives the dates of the first and last number the file includes. My file covers six months.

One objection to binding the whole magazine is that where several papers are taken, there are often articles which are nearly the same, so that the file contains much duplicate matter. Such a method makes a bulky file and handling for reference difficult. I file only those articles which present a new thought or new phase of a subject or one that is of especial interest. Selections from several magazines makes quite a large volume. After reading the articles, I mark those I wish to save and mark their classification. Then when I am ready to do the binding I take the paper apart and remove the pages marked. These loose-leaf binders can be bought for a nominal sum, but I would advise going to the superintendent first. While there are very few dull pages between the covers of such magazines as POWER, *Electrical World, Practical Engineer* and others of the same nature, I do not like to waste time looking through several bulky volumes to find something on a certain subject.

J. CASE.

Hyattsville, Md.

Belt Lacing

In the February 28 number, Thomas Clark asks for information on belt lacing, and as there have not been many replies, I submit the following for his consideration:

Some of the sketches and descriptive material below I have written up in the past, and some of the illustrations shown I have copied from sketches found in a power-plant office in this city. None of the methods shown are considered fancy lacing, but for durability and efficiency they are all right.

The lacing shown in Fig. 1 is known as the hinge joint. It is all right to use on small pulleys at high speeds. Heavier work demands a joint of which Fig. 2 is an example. In making the joint shown in Fig. 2, lace the outside holes first; the pulley side of the belt will show four short and three long straight lines. Fig. 3 is a good all-round joint; the lacing is started at *A A* and finishes at *E E*.

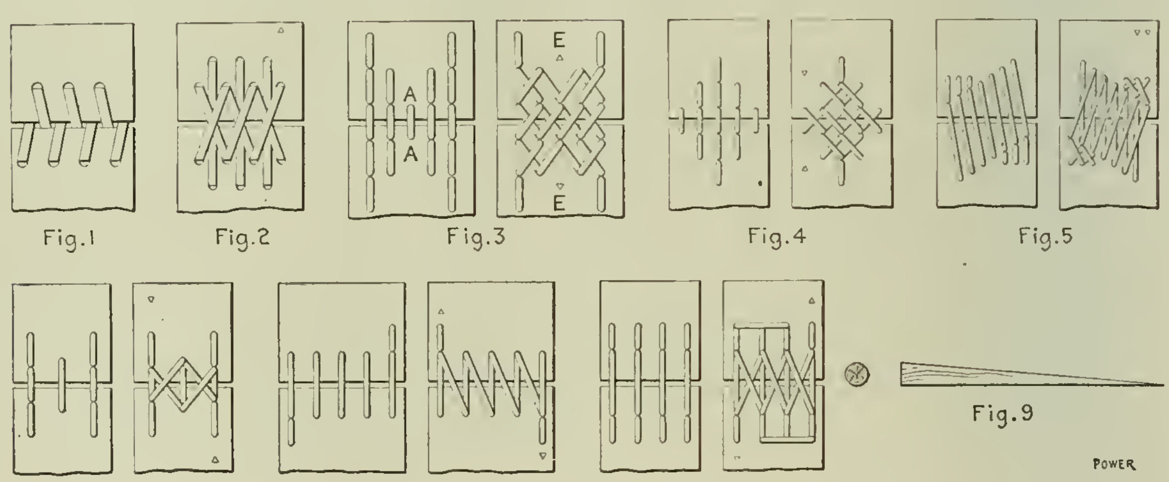

Fig. 1 Fig. 2 Fig. 3 Fig. 4 Fig. 5 Fig. 6 Fig. 7 Fig. 8 Fig. 9

Fig. 4 is often used and Fig. 5 is generally used on quarter-turn work. For small belts running at average speeds, use the method shown in Fig. 6. Figs. 7 and 8 are methods used for light and heavy work.

Fig. 9 is a valuable tool to have on hand when lacing belts. If the lace hole is too tight, it is an easy matter to insert the point of the tool in the hole and start the lace through, and if the tool is used carefully, it will not injure the belt.

Belt ends should be cut off squarely and the holes punched exactly opposite each other; the first row on one end should be opposite the first row on the other end, and so on. Many prefer to cement belt ends instead of lacing, but this has the disadvantage of rendering the taking up of stretch or slack a difficult matter.

JAMES E. NOBLE.

Toronto, Can.

Stopping a Pound

C. B. Smith's article in the April 25 issue on the reduction of lead and compression, induces me to tell how I increased the output and decreased the coal consumption.

Some time back I was employed in a plant which had one 26x48-inch single-eccentric noncondensing Corliss engine running 90 revolutions per minute. I was told when I took charge that the engine was very much overloaded and that it had a very loud pound but that I was not to let that worry me as there had been two men from the factory trying to locate the cause but had gone away in disgust.

The boilers carried 125 pounds of steam and whenever the steam went below 115 pounds the engine would hook up and the feed from the mill would have to be removed until 125 pounds could be maintained. The engine is five years old and has had two new crank pins.

I applied my indicator and found that the compression started when the piston had made two-thirds of the stroke, which carried it up to about 75 pounds. I cut the compression down one-half but still the pound was not affected. It could be heard for a block around. I had several indicator experts come out to take cards and they all claimed that the conditions could not be improved.

I noticed that the higher the boiler pressure the louder the knock, but still I thought the indicator showed a good admission line. I decided something must be done, so I gave my steam valve enough lap to let the piston travel about one inch before the valves opened. This stopped the pound instantly and the engine began to run as smooth as any engine in the city. The load that it previously carried with 125 pounds of steam can be carried nicely now with 100 pounds. Today the engine pulls the same load with a one-quarter cutoff that a three-eighths cutoff would not handle when I took charge. Thus by removing the compression the engine developed considerably more power.

Some Argument Figures

When a central-station man undertakes to prove that an isolated plant has really no excuse for existence, or an isolated-plant man starts in on an exposition of central-station iniquities, or a gas-engine man presents a few "representative" comparisons with steam, or a—well, when figures are dug up by anybody in support a commercial contention those figures nearly always have a weird, unnatural aspect. The old, old characteristic of zealotry comes right to the front with forefeet stuck deep in the sand and hind feet combatively elevated. Sometimes, of course, the figurer has a forlorn hope to defend and his plight seems to demand heroic measures, but in many cases the bare, unbolstered truth is ample and would be infinitely more effective than a strained version.

An instance of the latter sort of "case" is printed in a recent number of the National Electric Light Association *Bulletin*. A storage-battery man, obviously with a view to presenting an invulnerable argument for the electric truck as against the gasolene truck, puts the cost of charging the battery at one cent per kilowatt-hour. Now, although that figure may be correct for the specific truck and generating plant to which he referred, we all know perfectly well not only that one cent per kilowatt-hour is not a representative figure but that there are not a dozen charging stations in the entire country that can generate their energy at that cost, let alone sell it for that. Where, then, is the sense in quoting this rate in a letter purporting to present a general comparison? The electric truck has so many real advantages over the gasolene-motor truck for use within the radius of any city in this country and the operating costs of the two are so nearly alike that a discussion of the latter is a waste of time and a forced favorable showing for the electric is more harmful than otherwise.

An amusing manifestation of inconsistency was made recently by our esteemed contemporary, the *Electrical Review and Western Electrician*. In an effort to show that isolated-plant costs are higher than central-station rates, the *Review* said editorially that a certain isolated plant powered by three gas engines of forty horsepower each showed the woefully high operating cost of something like three or four cents per kilowatt-hour. Some of the figures on which this contention was based were absurdly high and unrepresentative, but the amusing feature of the case is that the *Review's* editorial assertions and assumptions were completely refuted by the report of a producer-gas-power central station published in the same issue with the editorial. Although the isolated plant of one hundred and twenty horsepower could not get its cost below three cents, the central station, which was of only eighty horsepower capacity, easily showed less than two cents per kilowatt-hour!

The explanation is simple. The fixed charges and fuel cost ascribed to the isolated plant were abnormally high, whereas the fixed charges for the central-station plant were too low and the costs of administration, of transmitting power to the consumer and of keeping lines in condition were ignored.

An Uphill Fight

It is always desirable to know the actual cost of power being delivered from any plant. The advantages to be derived from this knowledge are too obvious to require explanation. It is frequently the lack of this information in convenient form which enables the central station to take over the plant and reduce the importance of the installation to one required merely for heating.

On the other hand, many a winning fight has been conducted using well arranged operating records as an argument, the significance of which the owner could not fail to appreciate. When the matter is one merely of dollars and cents, it is not so very difficult for the well informed engineer to carry the fight into the enemy's country and present his side of the case with some show of success.

There is another feature in this controversy, however, against which the operating engineer finds himself well nigh powerless to contend. This is one of high finance and does not relate to the actual money involved in any equal situation, but has more to do with the influences which control the different concerns requiring power. Moneyed men have affiliations which are not apparent on the surface; they play billiards at the same club, they go hunting and fishing together and have associations which result in mutual benefit to their concerns and which influence them to make decisions than is the outsider would indicate poor business judgment.

There is a group of buildings in the business district of a Western city, all taking central-station current and paying from five to eleven cents per kilowatt-hour. The chief engineer of this property, a capable man, has repeatedly brought to the attention of the owner that concentrating the several different heating plants necessary to take care of these buildings and generating current at a central point, using the exhaust steam for heating, would result in a net saving of twenty thousand dollars a year, but this has had no effect.

It would seem to the ordinary individual that the owner, although already a multimillionaire, could afford to take the trouble to pick up this extra money. It may easily be possible, however, that he can well afford to pay twenty thousand dollars a year for the privilege of sitting in the same game with the financial powers that be, the benefits of this being far greater (to him) than any petty saving which might accrue from changes recommended in his power department.

Against this sort of competition the operating engineer is working under a serious handicap. It illustrates the necessity of being wide awake in every respect and emphasizes the importance of having every scrap of available information at hand, ready to use at the proper time.

If the engineer knows, he has a chance. If he does not know, he is lost.

Slovenly Language and Salary

As we have said before, it is neither necessary nor to be expected that an engineer shall be a shining literary light or even a polished writer or speaker. It *is* important, however, that engineers should use language which means what they intend it to mean and refrain from inflicting upon more careful people a mongrel jargon unworthy of the intellect of a scavenger's assistant. Electrical engineers and artisans appear to be more reckless in this respect than other technicians. A common specimen of inaccuracy is the use of the word "kilowatt" alone when "kilowatt-hour" is meant. This is not inelegant, of course; it is merely an indication of either ignorance or carelessness. A kilowatt is very far from being a kilowatt-hour; it has to exist exactly sixty minutes before it represents a kilowatt-hour. It is highly probable that every reader of POWER knows that simple fact. It is almost as probable that many of them would unhesitatingly say that the cost of "current" is so many cents "per kilowatt," which is absolutely devoid of intrinsic meaning. Such a statement is usually understood by those familiar with the sloppy habit of speech, but that is no excuse for it. Current is neither power nor energy and power is not energy and has no value until it is combined with time to make energy. A similar carelessness characterizes references to horsepower, the word being used alone when "horsepower-hour" is meant.

The haphazard use of the word "field" is another common cause of confusion and mental irritation. In electrical engineering the word has exactly one meaning, no more. A field magnet is not a "field"; neither is a magnet coil, nor is a yoke ring, nor yet the exciting current. Nevertheless, all of these are frequently referred to as the "field" by men who either ought to or do know better. Both of these editorial pages could be filled with such citations.

Now there is no direct relation between exactness of speech and earning power, except in literary work. But there is a very strong indirect relation in all other kinds of skilled work. A man who is careful in one respect is very likely to be careful in others and, although it is not at all probable that the mere avoidance of the class of errors just referred to will produce an immediate increase in salary, it is almost certain that cultivating the habit of accuracy—not hair splitting—will ultimately increase one's value to his employer. A certain electrical engineer has a knowledge of his particular branch of the science that should enable him to earn a very large salary. The fact is, however, that he is so slovenly in the application of his knowledge that other men who have less are drawing larger salaries because of their greater accuracy. The inaccuracy of this man is reflected in his every utterance; "power" is always "current" with him; "reactance" is "self-induction," and everything about a machine except the armature and bearings is referred to indiscriminately as the "field"—and so on, down the whole list.

Absurdities of a School of Finance

The school of finance and commerce attached to one of our large universities requires neither scientific nor engineering knowledge from its students at entrance and does not teach either of these branches in its courses. It is, therefore, astonishing that last December the school required each student to separately select a manufacturing plant and make a series of reports thereon.

The first report was to be a careful study of the power plant, its installation, cost of production and cost of distribution, involving a number of drawings and a careful discussion of the suitability of the power equipment for the particular plant, comparing it with other possible sources of power.

This was to be followed by a second report dealing with the raw material, its storage and handling. A third report was to relate to superintendence, organization, management, labor payment and inspection, the students to suggest improvements and give reasons therefor. A discussion upon storing, shipping and selling the finished product was next in order, and, finally, a report was to be made upon "cost keeping."

The average student taking this course has no conception of foot-pounds; he could not define a horsepower, and would be unable to distinguish between boiler, engine and electrical horsepowers. He has probably never heard of a B.t.u. and knows absolutely nothing about the burning of fuel and the cost of power production. He has never installed a power plant; knows nothing of its power, and has not had sufficient experience to estimate depreciation. Yet his teacher, advancing these tasks, believes these facts can be obtained by merely "observing" and asking a few judicious questions.

How can an untrained mind observe fuel costs, capital costs, repairs, etc.? These are not elements of observation, but matters of experience and operation. Moreover, to whom shall the student address "a few judicious questions"? If he obtains any information at all, is he sure that his information is correct, and how can he check it? As to cost keeping, even though he has access to the books and accounts of a particular plant, it would require many weeks for him to go over the vouchers, for, say, the past year, and ascertain whether or not the accounts were properly and correctly kept. Yet this student is to advise as to the adaptability of the system of bookkeeping and to make suggestions as to improvements.

Such a course is incongruous and serves as a testimonial to the impracticability of those responsible for it. If certain schools would confine their efforts to the fields which they can legitimately cover and not attempt things out of their sphere, technical education would be better served and there would be fewer instances of its being subjected to ridicule by the practical man.

If a man tried to sell a 1000-horsepower Corliss engine for five hundred dollars, any of us would naturally ask him what was the matter with it. Why do not all of us do that when another man offers to sell cylinder oil at eleven cents a gallon?

When you reach the conclusion that you are too big for your job, it is a safe plan to take a vote and see how nearly unanimous that opinion is before you shake the dust of that job off your feet and tackle a bigger one.

After all is said and done, do you really believe there is any good excuse for a modern dynamo or motor to spark at the brushes? We don't.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Bucket Pump Defined

What is a bucket pump?

B. P. D.

A bucket pump is one in which the water passes through the piston as in the common house pump or as in the vertical single-acting jet-condenser air pump.

Vacuum in Simple and Compound Engines

Which requires the higher vacuum, a simple or a compound engine?

S. C. E.

There is no difference in the requirements except as regards economical operation, but it is customary to carry a higher vacuum with a compound than with a simple engine, as it is believed that it is more economical not to employ so high a vacuum in simple engines on account of the difference of temperature between the entering and the exhaust steam in the simple engine, which is much greater than in the low-pressure cylinder of the compound engine and nullifies the gain of a reduced back pressure by initial condensation.

Flared Tube Ends

Why are the tube ends of water-tube boilers flared instead of being beaded?

L. H. F.

Tubes are flared because it is easier, cheaper and just as effective as beading for the purpose intended.

Variation in Air Pump Piston Speed

Why does the piston of an air pump start off fast and slow down near the end of the stroke?

P. C. V.

In the independent steam-operated direct-acting air pump the cylinder at the beginning of the stroke contains a little water and also air at the pressure existing in the condenser. At the beginning of the stroke the piston meets with little resistance and, until the air is compressed to nearly atmospheric pressure, the motion of the piston is rapid. As the pressure in the cylinder rises the speed is reduced and is slowest as the water and the air are being forced out through the discharge valves.

Hydrostatic Test and Yield Point

If the bursting pressure of a boiler shell is 600 pounds per square inch and the yield point is one-half the tensile strength, what hydrostatic pressure would it be safe to apply? What is the rule for finding the yield point?

H. T. P.

If the bursting pressure is 600 pounds per square inch and the yield point is at one-half the tensile strength, then yielding will begin at 300 pounds pressure per square inch. With a factor of safety of five, the working pressure will be 120 pounds, and the hydrostatic test pressure applied 50 per cent. above the working pressure, or 180 pounds, 120 pounds below the yield point, is presumably safe. There is no rule for determining the yield point or elastic limit as it is called. It can only be determined by experiment.

Steam and Air Pressure

If a 4-inch air pipe should be connected to a 4-inch steam pipe with 110 pounds pressure in the air pipe and 100 pounds pressure in the steam pipe, what would happen?

J. J. H.

The air, if the pressure were kept at the original pressure, would force the steam back to the boiler whence it came and increase its pressure to that of the air unless relieved by the blowing of the safety valve.

High-speed Engine Valve Setting

If the valve on a high-speed automatic engine is out of adjustment, how may it be reset?

E. C. M.

In most high-speed automatic engines the only valve setting the engineer can do is that of adjusting the length of the valve stem. The valves are set by lead, which means that the lead is made right for each end of the cylinder. Usually a little more is given on the head than on the crank end.

Gas-engine Efficiency

What is the heat efficiency of a producer-gas engine of a few hundred horsepower?

W. T. McN.

From about 22 to about 27 per cent., according to size and condition.

Steam Table Difference

In the last edition of "Kent's Pocketbook" the value for the latent heat of steam at 212 degrees Fahrenheit is given, in a table compiled by Marks & Davis, as 970.4 B.t.u. The value of 966 is the one I have seen most frequently used. Which is the correct value? Which value is used in engineering work where accuracy is desired?

C. D. H.

Recent investigation has shown that the total heat of saturated steam as given in the old tables was too low, and both the Marks-Davis and the Peabody tables have been revised in accordance with the new values. The Marks-Davis tables are used in this office. Peabody's new value for the latent heat of steam at 212 degrees is 969.7, the difference between this value and that given in the Marks-Davis tables is largely due to the fact that Professor Peabody uses for the value of the B.t.u. the amount of heat necessary to raise a pound of water one degree at 62 degrees, while Professors Marks and Davis use the average amount of heat required to change a pound of water one degree through the entire range from 32 to 212.

The Best Size of Wire

How can I determine the best size of wire to use in a long power circuit?

C. T. McK.

From the purely mathematical point of view, the greatest economy is obtained when the value of the energy lost in the line annually is equal to the interest and depreciation charges against the cost of the line. There are practical considerations, however, which cannot be ignored. If the drop in the line is excessive, the voltage regulation at the far end will not be satisfactory, induction motors will not operate properly and it will be difficult to attain satisfactory results from incandescent lamps because of the variations in candlepower. If the line is an addition to an existing system, the question of regulation takes first place; if it is a question of laying out a new transmission line or building the feeder system of a new plant, maximum operating economy comes first, because the matter of regulation in such cases can usually be provided for by means of special apparatus. The interest and depreciation on such apparatus should be added to that on the line in figuring the maximum economy conditions.

Refrigeration Department

Principles and operation of ice making and refrigerating plant and machinery

Capacity of Ammonia Compressors

By F. E. Matthews

Since the efficiency of ammonia compressors is subject to wide variations, both through diversity of design and diversity of operating conditions to which the same machine is often subjected, the efficiency of the individual compressor should be determined under its own operating conditions. This can be accomplished most accurately by determining the quantity of refrigerating fluid actually passing through the system and comparing this amount with the apparent amount computed from the displacement of the compressor.

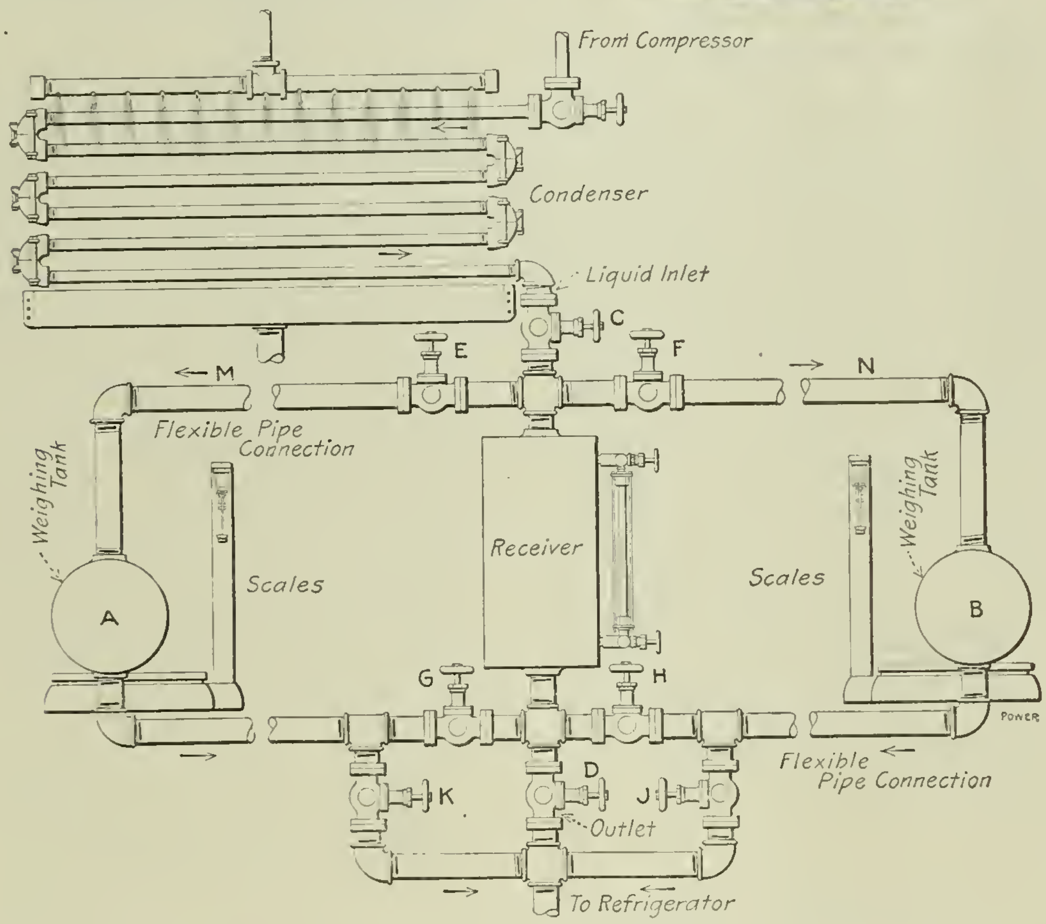

Fig. 1. Arrangement of Piping for Weighing Ammonia

The best way for determining the amount of liquid refrigerant is to weigh it. Fig. 1 represents a condenser, a pair of weighing tanks and their connections. For testing, crosses are inserted in the inlet and outlet lines, and valves and additional pipes are attached as indicated. When using the weighing tanks, the outlet valve *D* is closed or blanked off and, as the valves in the new connections are closed, the liquid refrigerant collects in the receiver. The weighing tank *A* is filled by opening valves *E* and *G*, after which valve *G* is closed and the gross weight of the tank and its contents is determined. The weight of the refrigerant is then found by subtracting the net weight of the tank and the liquid in the bottom connections. While the liquid in tank *A* is being weighed, tank *B* is supplying the cooler through valve *J*. Alternate filling and emptying of the two tanks allow the operation of the plant to proceed without interruption. When employing this method for weighing the refrigerating liquid, it is necessary that the pipes connecting with the weighing tanks be sufficiently long to insure flexibility to the system. The liquid level should never be allowed to rise to the pipes *M* and *N*, as any liquid other than that vertically over the drums will not be weighed correctly.

Assume that a test has been conducted under standard conditions and it has been determined that *X* pounds of anhydrous ammonia are evaporated per hour. The number of heat units required to cool a pound of the liquid is

$$S\ (t_1 - t_2) = 1\ (90 - 0) = 90\ B.t.u.$$

The heat units available from the evaporation of one pound of ammonia are

$$R_{B.P.} - S\,(t_1 - t_2) = 555.5 - 90 = 465.5\ B.t.u.$$

The amount of anhydrous ammonia required per ton per minute is

$$\frac{200}{R_{B.P.} - S(t_1 - t_2)} = \frac{200}{465.5} = 0.42964\ pound$$

which is equivalent to 25.778 pounds per hour or 618.7 pounds per day of 24 hours; where

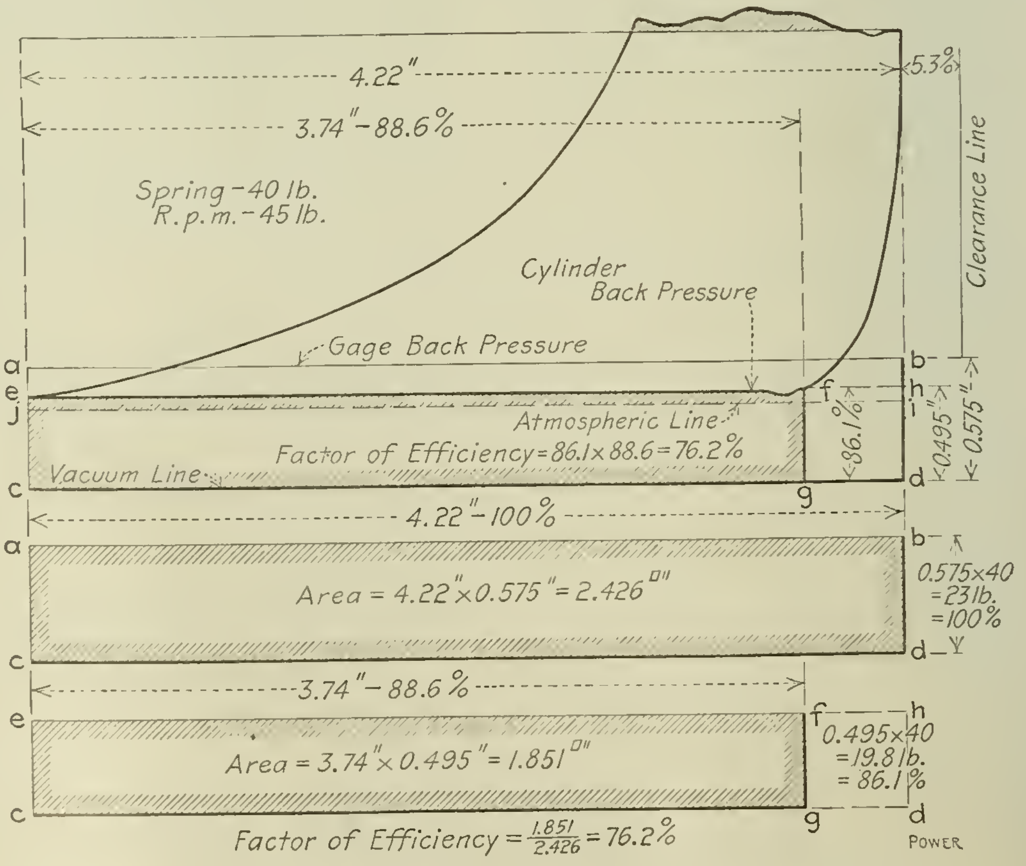

Fig. 2. Graphical Method for Determining Efficiency

[illegible]

S = Specific heat of liquid ammonia;
t_1 = Temperature of the liquid ammonia;
t_2 = Temperature of the ammonia vapor corresponding to a back pressure of 15.67 pounds gage;
$h\,p\,l$ = Latent heat of vaporization of ammonia at back pressure, in this case zero degrees Fahrenheit;
200 = Number of heat units per minute corresponding to one ton of refrigeration per 24 hours.

If, for example, it is found by test that 3000 pounds of liquid ammonia per hour pass through a refrigerating system, the compression unit of which is a 10x18-inch double-acting compressor running at 45 revolutions per minute under standard conditions, the cooling effect produced is found to be

$$\frac{3000}{25.[illegible]} = 116.17 \text{ tons}$$

The capacity apparently developed is computed from the displacement per minute of the compressor piston. This is represented by the expression

$$D = \frac{\frac{\pi}{4} \times d^2 \times l \times 2 \times [illegible]}{1728}$$

$$D = \frac{0.7854 \times [illegible] \times [illegible] \times 2 \times 45 \times [illegible]}{1728}$$

$$= 163.13 \text{ cubic feet}$$

per minute, where

D = Piston displacement in cubic feet per minute;
d = Diameter of piston in inches;
l = Length of stroke in inches.

The cooling effect per cubic foot of ammonia gas passed through the compressor is found from the expression

$$C = \frac{h\,p\,l - S\,(t_1 - t_2)}{V}$$

$$C = \frac{[illegible] - [illegible]\,([illegible] - [illegible])}{[illegible]} = [illegible] \text{ B.t.u.}$$

where,

C = Cooling effect per cubic foot of ammonia;
V = Volume of one pound of the ammonia gas passing through the compressor, cubic feet.

Hence the apparent tonnage capacity is

$$\frac{D \times C}{200} = \frac{163.13 \times [illegible]}{200} = [illegible] \text{ tons}$$

Obviously, the efficiency of the compressor can be approximated by dividing the probable cooling effect, as determined by calculation based on the properties of the liquid, by the tonnage computed from the apparent displacement per minute in cubic feet, as calculated from the dimensions of the compressor, hence,

$$E = \frac{[illegible]}{[illegible]} = [illegible] \text{ per cent.}$$

In the majority of cases the tonnage capacity of the system is required with reasonably close accuracy, but it is often impracticable to weigh the ammonia. In such cases a somewhat less accurate estimate of the efficiency of the compressor can be made with the assistance of an indicator. For all practical purposes the weight of ammonia gas may be considered proportional to its absolute pressure, and within narrow limits the amount of refrigeration represented by a cubic foot of ammonia gas will likewise be proportional to its absolute pressure. From this it follows that anything tending to reduce either the number of cubic feet of gas that a compressor handles or lower the pressure at which it is handled, proportionately reduces the capacity of the compressor. Graphically this is illustrated and the actual amount of the reduction in capacity is determined as follows:

Having taken an indicator diagram, such as that shown in Fig. 2, draw the lines *a b* and *c d* representing, respectively, the actual back pressure in the suction pipe, as indicated by a gage, and the line of absolute vacuum. Next, determine *f*, the point at which the suction valve first opens to admit cold gas to the compressor cylinder. This point is the intersection of the admission line *e f* and the reëxpansion line forming the heel of the diagram. Draw a vertical line *f g* through this point and other vertical lines *e c* and *b d* through the ends of the diagram. These horizontal and vertical lines form two rectangles. The larger one *a b d c* incloses a smaller one *e h d c* which, in turn, is made up of two still smaller rectangles *e f g c* and *f h d g*.

In the case under consideration the cylinder back-pressure line *a b* scales 4.6 pounds above the atmospheric line *j i*, making the absolute back pressure within the cylinder approximately 19.6 pounds. The observed suction pressure in the suction line is 8 pounds gage or approximately 23 pounds absolute, of which the 19.6 pounds is 86 per cent. This means that on account of the fall in back pressure, in passing through the suction valves and pits in entering the compressor cylinder, each cubic foot of gas represents only 86 per cent. as much ammonia by weight, as it would had no resistance been encountered and the cylinder back pressure had been 23 pounds, the same as in the suction line.

The diagram shows that the compressor from which it was taken had excessive clearance. Due to the reëxpansion of the high-pressure gases remaining in the clearance spaces, the opening of the suction valve is delayed until the piston has reached point *f* in the suction stroke. Cold returning ammonia gas can enter the compressor cylinder only during the time the piston is passing from *f* to the end of its stroke. The full length

of the diagram represents the full stroke of the piston and a displacement of 100 per cent. of the full volume of the cylinder. In this case, however, 11.4 per cent. of the volume is occupied by reexpanding hot gas which reduces the amount of cold gas that can enter the compressor to 88.6 per cent. In other words, the actual displacement of the compressor in cubic feet is only 88.6 per cent. of the apparent displacement, based on the cylinder dimensions only.

Now, the 88.6 per cent. of the gas discharged weighs only 86.1 per cent. as much as indicated by the pressure gage on the suction line, so that the number of pounds of ammonia actually discharged by the compressor was only 88.6 × 86.1 per cent. of what would be discharged by a compressor in which there is no clearance or resistance offered to the gas in passing through the suction valves.

Graphically, the length *a b* of the large rectangle *a b d c* represents the compressor cylinder volume, and the hight *b d* the absolute suction-gas pressure in the return line outside the compressor. The product of *a b* and *b d*, or cubic feet and weight per cubic foot—since the weight of a gas depends upon the absolute pressure—represents the apparent displacement per stroke in pounds.

The length *e f* of the small rectangle *e f g c* represents that part of the compressor-cylinder volume filled by the cold gas; and the hight *g f*, the absolute suction pressure within the cylinder. The product of *e f* and *g f* represents the *actual* displacement per stroke in pounds, or the apparent displacement minus the reëxpanded hot gas represented by the rectangle *f h d g*.

The displacement efficiency of the compressor is represented by the ratio of the area of the small to the large rectangle and will be found to be numerically equal to 70.2 per cent, regardless of the units employed in measuring the areas.

$$\frac{4.74 \times 0.405}{4.[illegible] \times 0.475} = \frac{1.851}{2.4[illegible]} = 76.2 \text{ per cent.}$$

or using pounds to per cent.

$$\frac{[illegible] \times 88.6}{[illegible] \times 100} = 76.2 \text{ per cent.}$$

The apparent number of cubic feet of ammonia gas discharged per minute by a 19x38-inch double-acting compressor running at 45 revolutions per minute has already been found to be 501.15. If it is found, by the indicator-diagram method just described, that the displacement efficiency is 70.2 per cent., the actual number of cubic feet discharged will be

0.762 × 501.15 = 427.50 *cubic feet*

which, multiplied by the number of British thermal units of refrigeration represented in each cubic foot of ammonia gas actually displaced gives the total cooling effect of the machine expressed in British thermal units per minute. This quantity divided by 200 reduces the capacity to tons per 24 hours. Under standard conditions the number of British thermal units per cubic foot was found above to be 51.50, and, under standard conditions, the tonnage capacity of the compressor under consideration when operating at the determined efficiency of 70.2 per cent. is

$$\frac{501.15 \times 0.762 \times 51.50}{200} = 1[illegible] \text{ tons}$$

per 24 hours.

To expedite the figuring of capacities, not only under standard but also under other conditions, the accompanying tables of constants have been derived. To determine the tonnage capacity of a double-acting compressor of any size operating at any piston speed and under various conditions of head and back pressure it is necessary only to substitute appropriate values from these tables in the following equations.

Since 200 B.t.u. per minute is the equivalent of one ton per 24 hours, the tonnage capacity *T* of a compressor will be equal to the number of cubic feet of gas *D* actually displaced per minute multiplied by the number of British thermal units of cooling effect *H* available per cubic foot of gas actually displaced, divided by 200. But the actual displacement is equal to the apparent displacement *D* (figured from the dimensions and speed of the machine) multiplied by *E*, the displacement efficiency of the compressor, which may be assumed either from knowledge of the design, calculated from the indicator diagrams or determined by weighing the liquid refrigerant according to the method already described. Expressed as an equation, this becomes

$$T = \frac{DHE}{200}$$

or since $\frac{200}{H}$ represents the cubic feet required per ton

$$T = \frac{DE}{\text{cubic feet required per ton}}$$

but

$$D = \frac{[illegible]}{[illegible]} = [illegible]$$

$$\text{[illegible] piston speed [illegible]}$$

from which the displacement can be computed readily when the diameter of the cylinder and the piston speed are known. The piston speed of a double-acting compressor of a given length of stroke, when operating at a given number of revolutions per minute, may be determined directly from Table 1.

It is also obvious that the apparent displacement is equal to the displacement per foot of piston travel multiplied by the number of feet of piston travel per minute. Table 2 gives this displacement per foot of piston travel, and Table 3 the number of cubic feet of ammonia that must be actually displaced per minute by the compressor to produce refrigeration at the rate of one ton per 24 hours.

Example: The capacity of a 19x38-inch double-acting compressor of 78.15 per cent. displacement efficiency operating at 45 revolutions per minute under 180 pounds head and 10 pounds back pressure is

$$T = \frac{\left(\begin{array}{c}\textit{Piston speed from}\\ \textit{Table 1} = 285\\ \textit{feet per minute}\end{array}\right) \times \left(\begin{array}{c}\textit{Apparent displacement}\\ \textit{per foot of piston}\\ \textit{travel from Table 2}\\ = 1.[illegible]\ \textit{cubic feet}\end{array}\right) \times \left(\begin{array}{c}\textit{Displacement efficiency of compressor} = [illegible]\end{array}\right)}{\textit{Cubic feet per minute per ton per 24 hours from Table 3} = [illegible]} = [illegible] \text{ tons}$$

A Case of Frosting

Of two vertical single-acting inclosed-crank-case ammonia compressors, one gives trouble by frosting all over the base of the crank case and water jacket; the other does not frost. A [illegible]-inch pipe with a valve connects the base of the compressor that frosts to the suction line. The valve is left open to prevent the accumulation of pressure in the crank case which forces the oil out through the shaft stuffing box. If the boxes run tight enough to prevent this, it heats. The frost melts off when the valve is closed. What causes the trouble? Does the high-pressure gas get by the piston into the base?

It would appear that liquid ammonia is entering the base of the frosting compressor through the pipe connecting the base to the suction line. This would happen if the connection is made into the bottom of the suction line and the system is so operated that the latter is covered heavily with frost at the point where the connection is made. A small amount of liquid ammonia is sufficient to keep the base of a machine frosted over for a long time, as the absorption of heat through the heavy cast-iron walls is slow and the coating of frost offers still further resistance.

The necessity of running with the valve in the connecting line open is probably due to leakage of high-pressure gas by the piston into the base.

A new set of piston rings carefully fitted might help some, but the better remedy is to so place the equalizing pipe from the base to the suction that any liquid running at the bottom of the pipe cannot drop into the base of the machine. The equalizing pipe is absolutely necessary.

It may be that the suction line to the other compressor is so located that the liquid cannot reach it. If the equalizing line to the second compressor is attached in the same way, the liquid would also drop into the base of this compressor and cause frosting.

New Power House Equipment

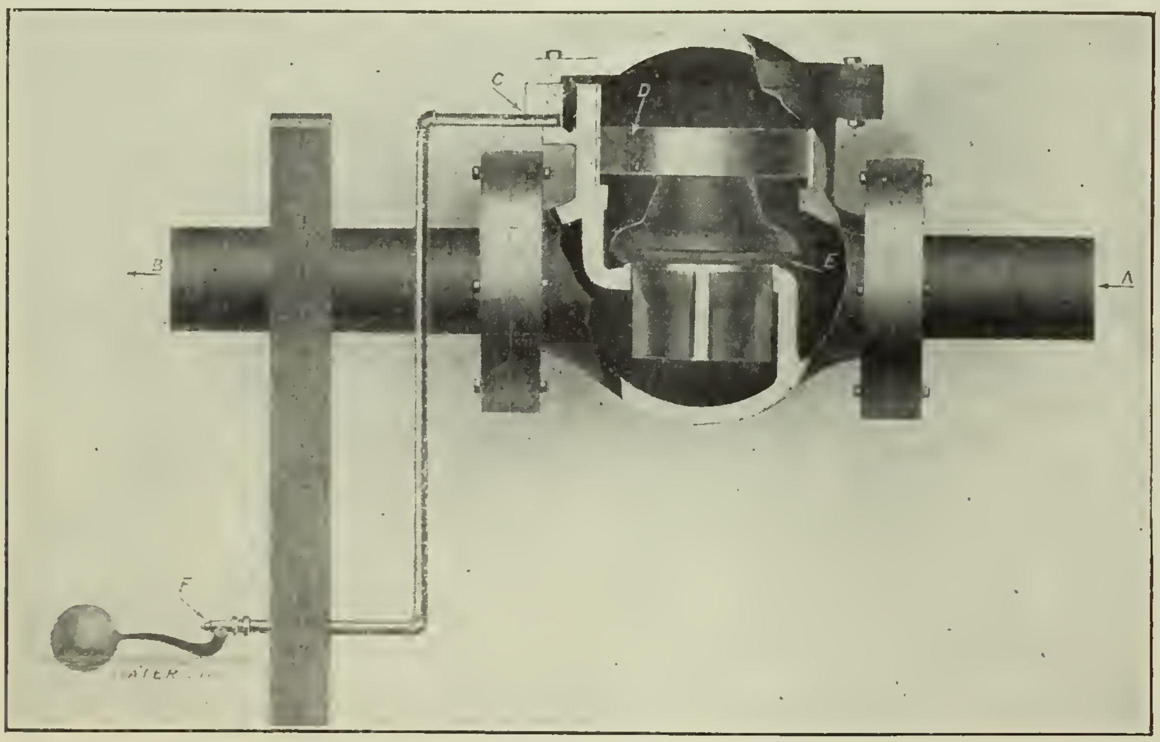
What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

"Hydromatic" Water Valve

The "Hydromatic" water valve consists of a cast-iron body, a cast-iron cover plate and a brass plunger which is made in two parts. The lower part is screwed into the upper and holds a rubber ring *E*—or where required for hot water, a lead ring—which seats in the valve body, making a tight shutoff when the plunger is down.

The brass plunger travels in a brass bushing, and is fitted into it with a piston fit, requiring no packing. Small tapered holes *D* are drilled into the top of the plunger with a capacity for building up head pressure according to the size of the valve. Into the head of the valve above the plunger is tapped a ¼-inch hole, and from this a ¼-inch pipe leads to a pilot valve *F*, at the water level. This valve is controlled by the operation of a seamless-copper 5-inch float.

When the water in a tank reaches the required hight shown by the location of the pilot valve, the elevation of the float closes the valve and shuts off the vent through the ¼-inch pipe. A head pressure is thereby built up through holes in the top of the plunger, strong enough to force the plunger down and shut off the flow of water through the valve. As water is withdrawn from the tank, permitting the float to drop, the pilot valve *F* is opened and the head pressure on the plunger is released just enough to permit the flow of water to restore sufficiently the required level in the tank. The water entering at *A* and passing between the rubber ring and valve seat, passes down around the ribbed valve to the outlet.



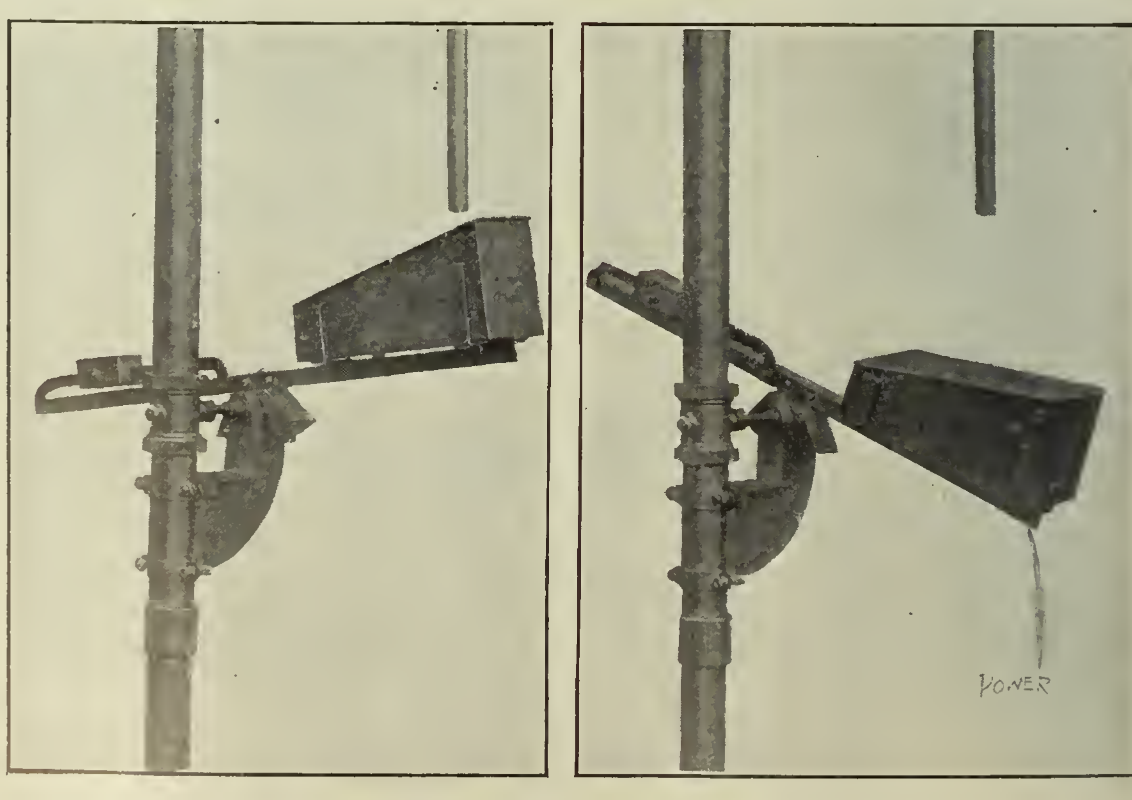
Showing Details of the Hydromatic Water Valve

The valve is very sensitive in its action and permits a small inflow of water or a large inflow of the total capacity of the intake pipe, according to the amount of water withdrawn from the tank.

This valve can be used for maintaining water level in tanks, vats, laundry tubs, cisterns, open feed-water heaters, water towers and for a quick opening or closing of a large water main. This may be accomplished by closing the valve in the ¼-inch pipe, which instantly shuts off the flow of water in the main pipe; the opening of the valve in the ¼-inch pipe instantly starts the flow of water. The shutoff valve in this ¼-inch pipe may be placed any distance from the hydromatic value, as long as the hight of the ¼-inch pipe above the hydromatic valve does not create a water pressure per square inch greater than that exerted by water in the main pipe. This device is manufactured by the Cleveland Steel Tool Company, Cleveland, O.

Miller Automatic Water Controller

This device has been designed to economically handle the distilled water in an ice plant and assists in making pure ice, free from oil and the objectionable red core. The device is illustrated and its action described herewith. A small amount of waste water from the skimmer fills the pan, causing it to drop down a few inches and rotate the valve stem, thus opening the valve.



Showing Automatic Water Controller in Two Positions

A shaft is made to slip on over the end of the valve stem (locked there by a pin and slot), and also serves as a pivot on which the rocker arm rotates. On one end of the rocker arm is an adjustable weight and on the other end a small pan with a hole in the bottom near the outer end. This allows the water to flow from the reboiler into the storage tank.

After the water in the reboiler has been lowered an inch or so, the pan returns to its normal position by the action of the counterweight.

This closes the valve, which remains closed until the reboiler is again full and goes to skimming, thus causing the hot distilled water to stay in the cooling coil long enough to get the full benefit of the cooling water. The process is repeated every few minutes.

The device is free from complicated mechanism and can be installed anywhere between the reboiler and the storage tank and keeps the water sweet and the ice clear.

It is manufactured by L. G. Miller & Sons, 237 Gordon street, Jackson, Tenn.

Bradford Automatic Valves

The principle upon which these valves operate is perhaps most clearly shown in the section of the nonreturn boiler stop valve, Fig. 1. Upon a spider fixed in the valve passage is carried a hollow stationary piston. Upon this piston slides freely a cylinder carrying the valve. The space inside the piston is connected to the boiler side of the valve seat through the port shown, and a small screw valve, the chisled head of which is accessible from the outside of the valve body, is provided to control the passage. The valve is not attached to the valve stem, the flattened end of which simply bears upon the top of the cylinder upon the valve disk.

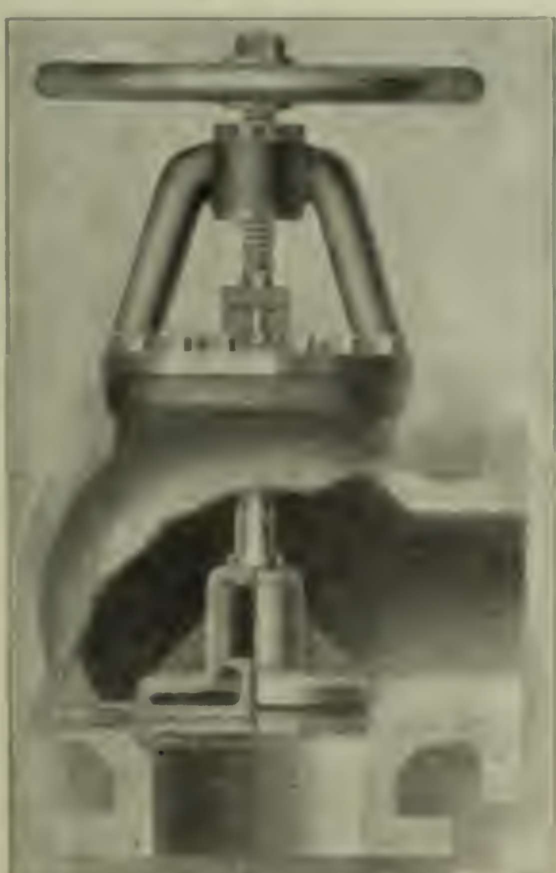


FIG. 1. BRADFORD AUTOMATIC NONRETURN BOILER STOP VALVE

When the stem is withdrawn the full boiler pressure inside the piston causes the valve disk to follow the stem upward, opening the passage for the flow of steam upward through the valve and into the main. Should the flow be reversed, as in case of an accident to the boiler, the valve will be carried to its seat by the backward flow, but will be prevented from slamming by the cushioning action of the steam in the cylinder, which, escaping slowly through the controlled passage, allows the valve to settle quietly to its seat.

In Fig. 2 is shown a protector valve, used to shut off automatically the flow

FIG. 2. BRADFORD PROTECTOR VALVE

of steam from a boiler or battery of boilers in case of a break in the main beyond. The valve is normally held open by the system of compound levers, but in case the velocity of the steam exceeds the normal by a predetermined amount, about 2000 feet per minute for the usual case, the force of its impingement upon the saucer-shaped attachment hung to the valve disk will carry that disk to its seat. The pressure upon the top of the disk will be reduced by the expansion of the steam in the cylinder, and the controlled entrance of steam to this chamber will allow the valve to seat quietly. The same principle is shown applied in a combined atmospheric-relief and back-pressure valve in Fig. 3. Here steam at the low pressure, or air in the case of an atmospheric relief, is admitted to the cylinder and by expansion holds the valve from slamming in the case of closing or by its compression in the case of sudden opening, and by its resistance to change of volume prevents chattering at any phase of the valve's operation.

In addition to the controlling feature the compensating chamber forms a central guide of ample area for the valve disk, even when used in a horizontal position. The chamber is bronze lined, and the seat is of government bronze and

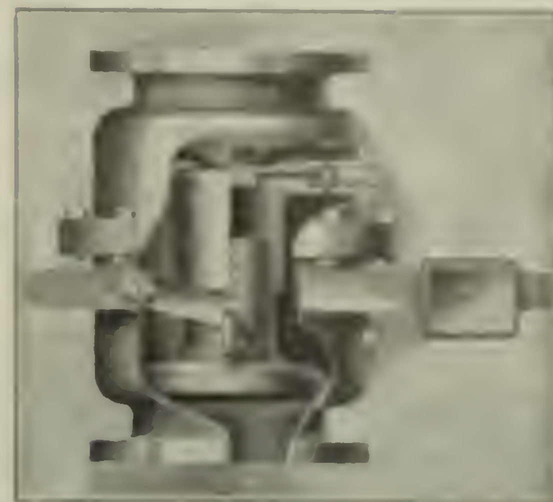

FIG. 3. COMBINED ATMOSPHERIC RELIEF AND BACK-PRESSURE VALVE

interchangeable. They are made by the Jno. B. Perkins Company, 141 Milk street, Boston, Mass.

Perolin Boiler Compound

This boiler compound has no chemical action on the water, but works its way through the cracks in the scale and along the metal of a boiler until the scale drops off and the boiler metal is coated with a film of the compound, to which, it is stated, no scale-forming sediment of any kind can cling.

The compound does not dissolve the scale, but only removes it from the iron so that it can be blown out through the blowoff or washed out when cleaning boilers. It also holds the scale-forming sediment in solution.

Water does not contain the same scale-forming sediment throughout the year, but continually changes with the season, climate and locality, but iron throughout the world is always the same. Therefore, there is a constant, known quantity with which to deal and the manufacturers have, it is said, developed a compound which is drawn to the heated iron and which mechanically removes the old scale and prevents the formation of new scale.

The compound is in the form of a thick liquid, and can be easily fed into the boiler either into the suction line or directly into the hotwell, and fed to the boiler by an injector or pump.

This compound is manufactured by the Eagle Oil and Supply Company, 104 Broad street, Boston, Mass.

Quite a few steam plants have gone out of business, but the general scheme is still working day and night.

Institute of Operating Engineers in Chicago

Since the first of the year there has been in process of formation a Chicago branch of the Institute of Operating Engineers. Monthly meetings have been held in the rooms of the Western Society of Engineers and the movement is now well under way. At the last meeting, which was held May 2, it was decided that there would be no further monthly meetings until the fall, when a vigorous campaign will be conducted and a systematic course of lectures arranged for, all having a bearing on the problems which the operating engineer must solve in his everyday work.

The Chicago organization will be known as the T. J. Waters branch. Mr. Waters was a prominent operating engineer of Chicago and was for many years chief engineer of the Board of Education. He made a special study of heating and ventilating problems and his work in this connection received honorable mention at the Paris Exposition.

Officers have been chosen as follows: P. J. Fleming, branch chairman; W. L. Jackson, lecturer on plant operation; I. J. Bent, lecturer on educational subjects; O. Monnett, secretary-treasurer. Address of the secretary, 1214 People's Gas building, Chicago.

Heating Boiler Explosion Kills Two

Two men were killed and one injured, probably fatally, when a low-pressure sectional boiler exploded in the basement of the supply house of the Union Electric Light and Power Company, St. Louis, Mo., May 4, at about 9 o'clock at night.

The men had gone to the subcellar to get some wire and, according to the advices received, found that the boiler was highly overheated, due to lack of water. One of the men opened a valve in the water-supply pipe and when the cold water struck the cast-metal sections an explosion followed.

The low water was caused by some derangement of the return pipes of the heating system. The night watchman discovered that the water of the return tank of the system was overflowing, instead of returning to the boiler.

Details regarding the exact nature of the stoppage of water have not been obtainable at this writing.

Remains of Heating Boiler Which Killed Two Men

The Electrical Engineers' Pacific Coast Meeting

The Pacific Coast meeting of the American Institute of Electrical Engineers was held at the Hotel Alexandria, Los Angeles, Cal., on April 25 to 29 inclusive. Seven business sessions were conducted at which the various papers arranged for by the committees were presented and discussed.

On Tuesday afternoon an excursion was made to Redondo beach, where the party inspected the power plant of the Pacific Light and Power Corporation. On Wednesday a trip was taken to Pasadena and up Mount Lowe over the spectacular trolley route. On Friday an all-day trip was made to the Mill Creek power plant of the Southern California Edison Company, about eight miles from Mentone in San Bernardino county. A purely pleasure trip was made on Saturday to Catalina Island, starting from Los Angeles at 9:50 a.m. About 300 members and guests were registered.

PERSONAL

George W. Stetson, New England agent for various manufacturers of power-plant equipment, is now located in the Oliver building, room 510, Boston, Mass.

Fred S. Hickey, formerly with the Anchor Packing Company, has associated himself with the Dearborn Drug and Chemical Works, as salesman for their feed-water treatment and lubricants, in the loop district of Chicago.

On the evening of May 3, Col. E. D. Meier, president of the American Society of Mechanical Engineers, addressed a joint dinner of the local members of that society and the Providence Association of Mechanical Engineers at the West Side Club. These two organizations have recently affiliated and Colonel Meier's address was based upon this action.

Prof. F. R. Hutton, who is now president of the Industrial Safety Association, also addressed the meeting, speaking on safety appliances.

W. M. White, formerly of the I. P. Morris Company, of Philadelphia, has become associated with the Allis-Chalmers Company as manager and chief engineer of the hydraulic-turbine department. During the past ten years, Mr. White has been closely in touch with hydraulic-turbine development in this country and for the past five years has had entire charge of the designing for the I. P. Morris Company, in which position he has designed the hydraulic machinery for some of the largest installations in the country. These include such notable plants as that of the Hydraulic Power Company and the Toronto Power Company, of Niagara Falls, the Great Western Power Company, of California, the Washington Power Company, of Spokane, Wash., and the Shawinigan Falls Power Company, of Montreal, Can. Mr. White also designed some of the large centrifugal pumps for the New Orleans drainage system and those that supply the water for the city of Duluth.

POWER

NEW YORK, MAY 23, 1911

ON several occasions this page has been devoted to attempts to impress upon the engineer the necessity for keeping complete operating and cost records.

If our preaching has borne some fruit, we are gratified, but we do not intend to stop at that; we intend to keep right on as long as there is a chance of getting converts to the cause.

Complete records serve a twofold purpose: they show wherein improvements can be made, and they represent the facts in *black* and *white* by which the engineer can disprove the claims of the central-station solicitor.

If it is found to be costing more to generate power than it should, then there is something wrong with the equipment or the operation; otherwise the class of service is such as to legitimately belong to the central station field. Whatever the cause the records show where it is located, and the owner knows exactly where he stands.

While assuming this attitude, we are not insensible to the fact that many engineers are seriously handicapped through lack of the proper facilities for making and keeping complete plant records. This is strikingly shown in the following incident, which is perhaps typical of many others:

The engineer of a small plant put in a requisition for a recording wattmeter, and in the course of a few days was summoned to the manager's office. Upon entering he was greeted with the following remark:

"What is the meaning of this requisition? The company has spent $15,000 to install this plant, which is thoroughly uptodate, and we do not propose to spend any additional money on a lot of frills. If you cannot get results with the plant as it is, we shall be compelled to find someone who can."

The question naturally arises—what can an engineer do under such circumstances? Obviously, the answer will depend largely upon the personality and the resourcefulness of the engineer.

Had a consulting engineer made this recommendation, the chances are ten to one that it would have been accepted without being questioned.

Why, then, was not the operating engineer equally successful in his dealings with the manager?

It is because the consulting engineers, as a class, have gained a certain prestige with their clients. A similar prestige belongs to the operating engineer. It is within his reach and he can gain it by taking advantage of his opportunities.

Again, there are many plants not supplied with measuring instruments, upon which the central station is looking with eager eyes. In most cases the central station is anxious to put its own instruments upon the boards of such plants, in order to be in a position to offer an attractive rate.

In such cases, the engineer, if he is making good, should have no hesitation in granting them permission to install the instruments; in fact, he should welcome it, as it affords him an opportunity to know what his plant is doing. Of course, he should take his own readings and be sure of the constants of the meter. With these data he can figure for himself the cost of producing electrical energy.

Novel Method of Supporting Stack

By Cadwalder Evans, Jr. *

When it was decided to increase the hight of the steel stack of the Stevenson building in Pittsburg, it was found that the corner column of the building would not support the additional weight; hence a steel tower was constructed and the new section of stack supported from it on a cantilever.

There has recently been completed for the central power plant of the Oliver estate at Pittsburg, a difficult engineering feat in an addition to the smokestack, as shown in the accompanying illustrations. This plant supplies all of the Oliver properties, including the Oliver building, a 25-story office structure, the McCreery & Co. store, a 12-story building, and a number of smaller buildings, with electric lights, steam heat, elevator service, refrigeration and compressed air, and is large enough to take care of any addition which may be made to the property, including the projected Hotel Oliver.

The plant is located in the basemenqt of the Stevenson building annex, and contains 3220 boiler horsepower. As originally constructed, the stack was a self-supporting steel structure 10 feet 6¾ inches outside diameter, rising through one corner of the building to a hight of over 221 feet above the boiler-room floor and 80 feet above the roof of the building, terminating approximately on a level with the fifteenth floor of the Oliver building, from which it is distant about 200 feet.

The gases from the stack caused considerable discomfort to the tenants above the eighteenth floor in the Oliver building; hence, it was decided to raise the stack. The first plan called for a symmetrical steel tower about the present stack but it was found that the corner column of the building was not heavy enough to carry the load, so the present overhung structure was decided upon. This consists of a steel tower 83 feet 9 inches high supported on four of the building columns and carrying the new stack on a cantilever. The tower is 25 feet 4 inches by 21 feet 5 inches in section and the center of the new stack overhangs the tower by over 6 feet. The new part of the stack is 124 feet high, making the total hight of 345 feet 8⅝ inches above the boiler-room floor and 323 feet 8⅝ inches above the ground.

*Superintendent of central power plant of Oliver estate.

FIG. 1. NEW STACK IN PLACE WITH 18-FOOT SECTION OF OLD STACK REMOVED

The new stack is entirely self-supporting, is lined with vitrabestos 2 inches thick and has an inside diameter of 7 feet 8 inches, which is 2 feet 6 inches smaller than the old part. The details of erection were very ingenious and comprised: First, the erection of the steel tower to its total hight, which brought it 6 feet above the top of the old stack; second, an 18-foot section of the old stack was removed and lowered to the ground, complete with its lining; third, a smoke-tight 12x12-foot wooden box with side walls 8 feet high and open at the top, was erected 14 feet above the reduced stack. This afforded a shield from the smoke in which the men were able to work while putting up the lower sections of the new stack. After this was completed, the temporary box was removed and most of the smoke was drawn through the 18-foot open gap. The top section of the old stack was then hoisted back into place in one piece and the extension joint between the old and the new sections was packed, thus completing the job.

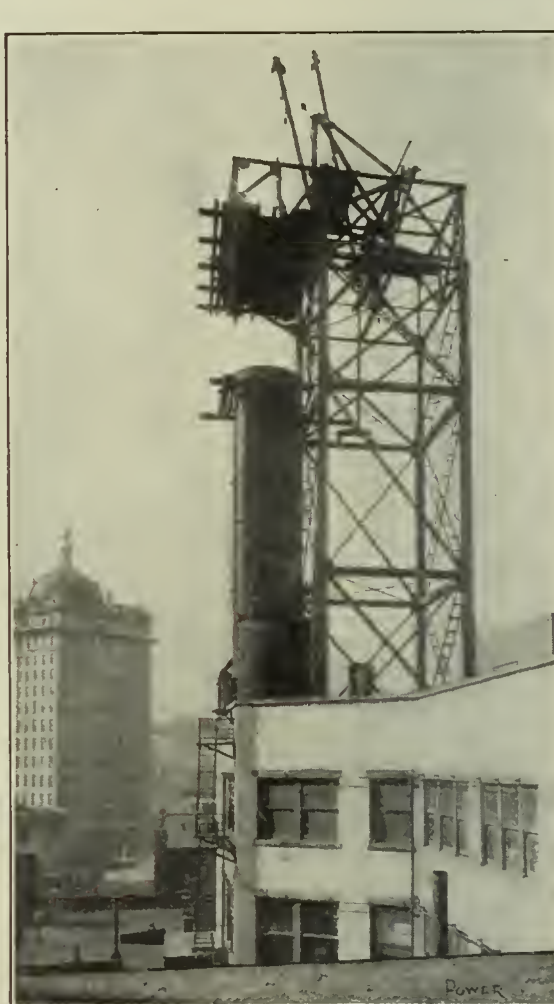

FIG. 2. TOWER IN PROCESS OF CONSTRUCTION

Real Cause of a Flywheel Explosion

By Hubert E. Collins

In 1907 the flywheel of a high-speed engine in the Hotel Knickerbocker, New York City, burst and caused considerable property damage. Facts were withheld at the time but information brought out in the preparation of a damage suit led to the conclusion that a dry link pin bound the governor and the engine ran away.

On March 1, 1907, at about 4 p.m., the flywheel burst on No. 3 engine in the Hotel Knickerbocker, New York City. The explosion of this wheel caused considerable property damage, and a barber was quite badly injured by a piece of the wheel coming through the floor of the barber shop where he was sitting in a chair. The fragment of the wheel passed so close to the barber that he lost his balance and fell through the opening in the floor into the engine room below.

Steam pipes were broken and the engine-room force performed acts of valor in stopping the havoc caused by the explosion.

An account of the accident, which was necessarily brief, as all information was refused, appeared in POWER at the time. The facts as here stated were brought out in the preparation of the damage suit of Dominicis versus Astor and Reegan. Dominicis is the name of the injured barber; Astor, the owner of the property, and Reegan, the lessee.

The same day the accident occurred, experts were called in to learn the cause of the accident, and found the governor wheel wrecked, which was the principal damage to the engine.

When the fragments were put together, it was found that one of them in the fracture had uncovered a flaw which appeared as in Fig. 1. This flaw extended around the rim for a distance of about two feet, gradually dwindling down to nothing from the proportionate size shown.

When the parts were reassembled, the wheel had the appearance indicated in Fig. 2. This sketch shows the location of all the fractures, and, of course, the moving parts of the governor and eccentric were stripped from the wheel. One of the stops for the weight arms was broken off.

Joint *B* was completely disrupted, one flange being broken into four pieces and the other one being cracked from the bolt holes out. On this joint one bolt was sheared on one end, one had both ends broken off, and one bolt was intact. There were three bolts to each joint, which were machined in the body 2½ inches to fit drilled holes in the flanges. The flaw began at the point indicated in Fig. 2 just below the flange of joint *B*.

It was contended by some that the flaw was the primary cause of the accident and this was given first consideration. The principal dimensions of the wheel were as follows: Outside diameter, 90 inches = 7.5 feet; mean diameter, 86.5 inches = 7.2 feet; revolutions per minute rating, 180; rim velocity in feet per minute, 4211; rim velocity in feet per second, 70.6; cross-sectional area of rim, 87 square inches; cross-sectional area of flaw, 3.8 square inches; cross-sectional area of rim through flaw, 83.2 square inches; weight of rim, 6130 pounds.

The strength of the rim through the flaw was first considered and, using the following formulas and process, the factors of safety were found:

$$\frac{r^2 \times D \times W}{5870} = \text{Total centrifugal force} = t$$

$$\frac{t}{6.28} = \text{Total force at two sections (tensile force)} = f$$

$$\frac{f}{a} = \text{Pounds pressure per sq. in. of cross-section}$$

In which

a = Area of cross-section;

r = Revolutions per minute;

D = Mean diameter;

W = Weight.

Now D = 7.2 feet, W = 6130, r = 180 and a = 87 − 3.8 (flaw) = 83.2 square inches. Substituting these values in the above formulas gives the following results:

$$\frac{180 \times 180 \times 7.2 \times 6130}{5870} = 243,614 \text{ lb.} = t$$

$$\frac{243,614}{6.28} = 38,792 \text{ lb.} = f$$

$$\frac{38,791}{83.2} = 466.2 \text{ lb. pressure per sq. in. of flaw}$$

Cast iron in flywheels can be safely allowed a tensile strength of 15,000 pounds and on this basis the factor of safety on centrifugal force is in this case

$$15,000 \div 466.2 = 32.1$$

As this increases or decreases in proportion to the square of the velocity, the factor of safety on the speed is

$$\sqrt{32.1} = 5.6$$

Or, in other words, the speed could reach

$$5.6 \times 180 = 1008$$

revolutions per minute to reach the limit of safety if the rim is considered alone, through the flaw section.

As a matter of fact, the joint of the wheel is much weaker than at the above section. In considering the strength of the joint, the cross-section of the rim without the flaw will also be considered. By referring to the data of this wheel, the pounds pressure per square inch of the rim may be computed and found to be

$$38,791 \div 87 = 445$$

As this design of wheel has only one-quarter the efficiency of a solid wheel, the allowable stress is

$$15,000 \div 4 = 3750 \text{ pounds}$$

The factor of safety on centrifugal force is

$$3750 \div 445 = 8.4$$

The factor of safety on speed is

$$\sqrt{8.4} = 2.9$$

It can be seen by this that the strength

FIG. 1. SECTION OF FLYWHEEL RIM

of the rim containing the flaw was much stronger than the bolts.

That the joint did not fail in any other way than would be expected from excessive speed is shown first by the appearance of the assembled fragments shown in Fig. 2. Referring to this figure it may be seen that joint *B* failed first, then the opposite section of rim from arm to arm containing the other joint left the wheel and the other parts followed these.

Prof. Charles H. Benjamin in his valuable papers in Volume 20, page 250, and Volume 23, page 168, of the Transactions of the American Society of Mechanical Engineers gives conclusive data on the manner in which wheels of this type fail. In every case the failure occurred in the same way as in the wheel in question.

Professor Benjamin tested wheels of 15 to 44 inches in diameter and made of

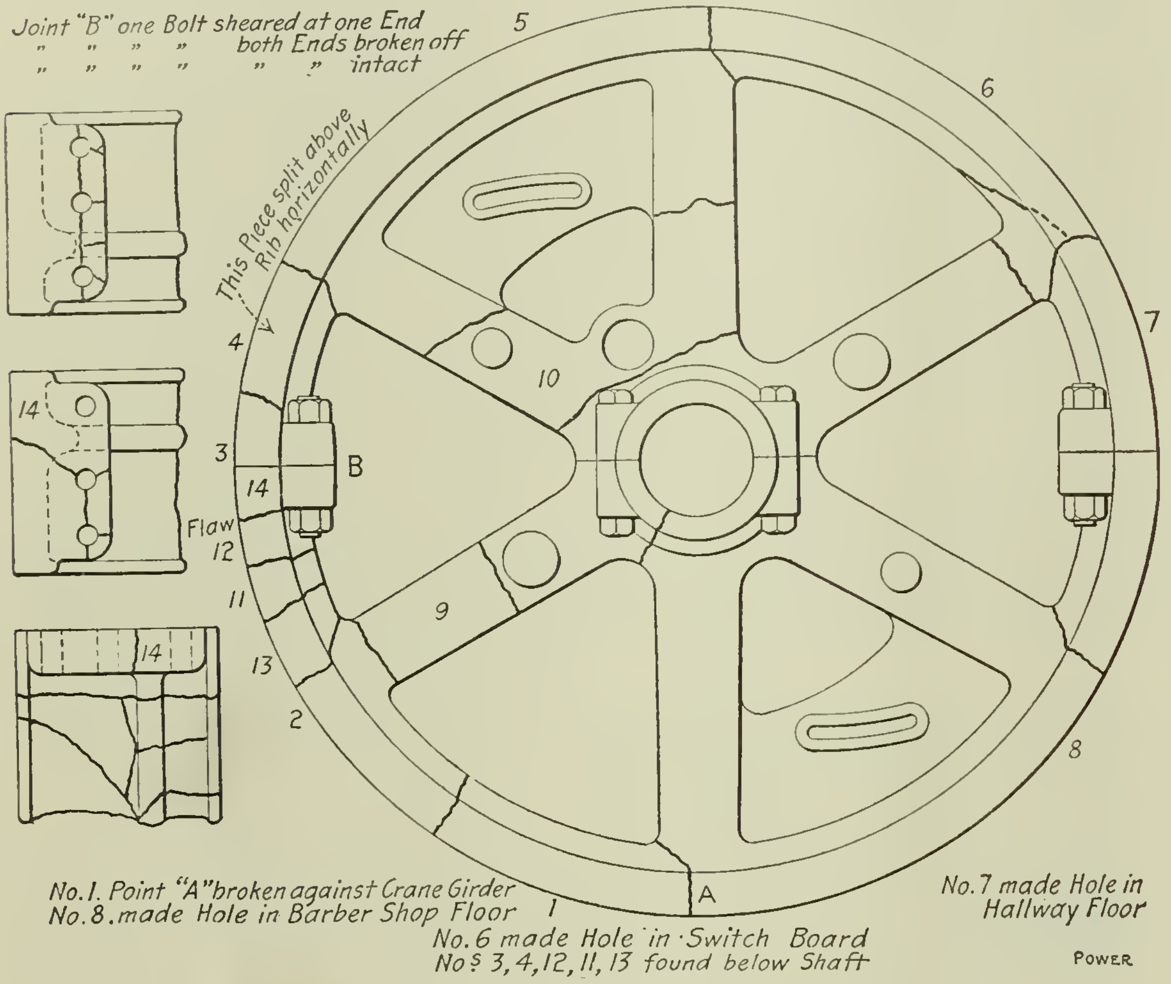

Fig. 2. The Broken Wheel Reassembled

closer iron than the average. He found the tensile strength of the iron to be 19,000 pounds, but on larger wheels it is safer to allow 15,000 pounds, as was done in considering this wheel. He also found the maximum and minimum rim velocities at the bursting point to be 196 and 184 feet per second, respectively, that is, the highest and lowest velocities at which any of the wheels in his tests let go. These tests verify the fact that the wheel in question was well within the limit of safety at its rated speed.

The acceptance test also brought out the fact that the engine was governing within its rated percentage as evidenced by speed tachometers, and the valves were covering the steam ports properly, as shown on the indicator diagrams. The diagrams show that with the throttle wide open and no load, the initial pressure in the cylinder was 29 to 30 pounds less than the steam pressure in the pipes and with full load the drop from steam pressure to initial was 2.5 pounds.

Real Cause of Accident

Having disposed of the flywheel probability, the real cause of the accident may be investigated. Fig. 3 shows the governor and wheel of this engine. The accident stripped the wheel completely from the shaft, and after the parts were assembled it was found that the link pin *A* was scored and cut and some of the brass from the link bushing had fused to the steel pin. This pin is shown in detail in Fig. 4. Where this brass fused to the steel it left little ridges of metal. By referring to Fig. 3, it may be seen that the two weight-arm links *B* and *C* are made fast to the eccentric by pin *A*. This pin passes through one end of each link. These links are brass bushed, and on the inside of the link next to the eccentric were found the plain marks of threads. Pin *A* made up tight in the boss of the eccentric against the shoulder *A*,

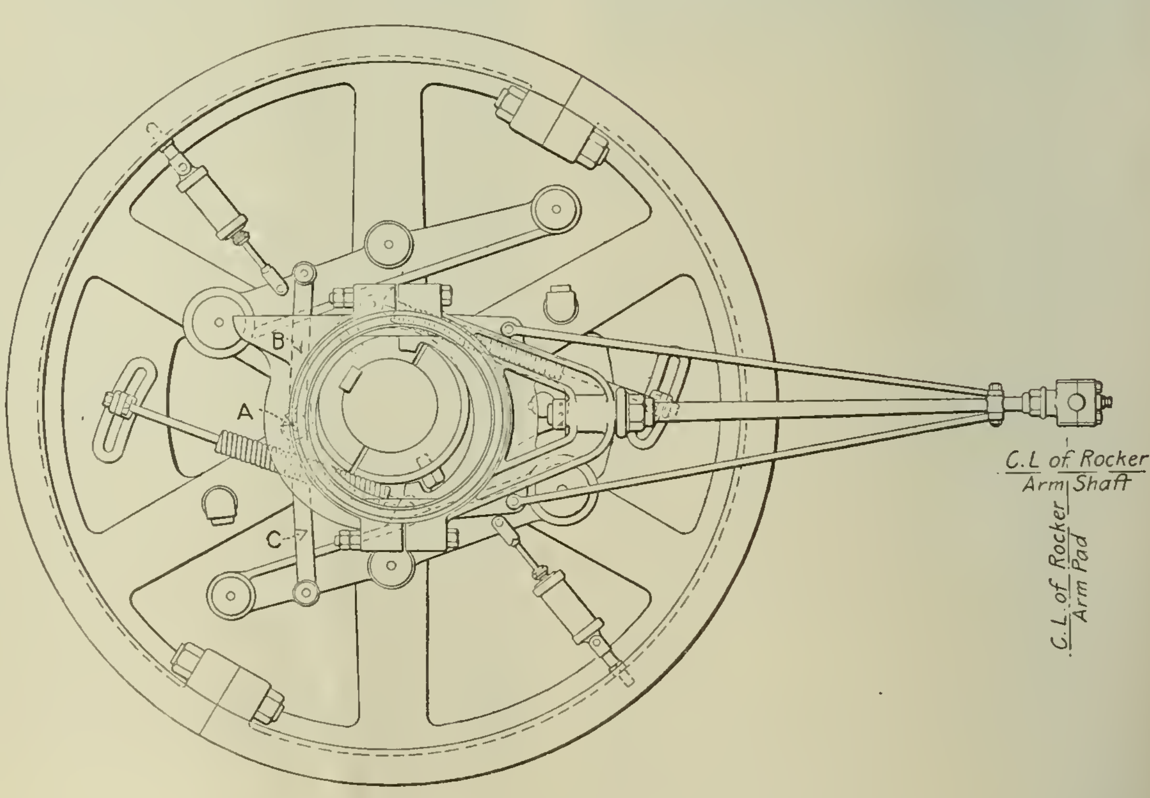

Fig. 3. The Governor and Wheel as They Appeared Before the Accident

Fig. 4. This made it self-locking. The two link ends fitted the large end of this pin.

This engine had been put in service at 2 a.m. on the day of the accident and was in service continuously up to the time of the accident, close to fourteen hours. No trouble was noticed until a few seconds before the accident, when a heavy pound started in the governor and then the engine suddenly speeded up, the generator making an ever increasing screeching noise. The engineer on watch started for the throttle and before he could reach it, the wheel exploded.

The evidence showed that the link pin was dry and had run hot. This had

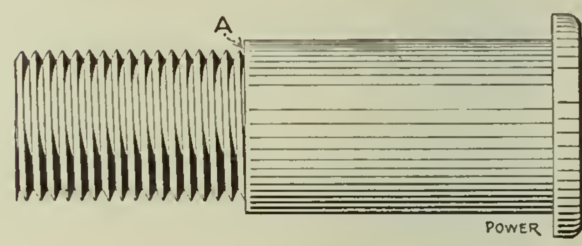

Fig. 4. Link Pin Which Caused the Accident

loosened the pin from the eccentric by pinching it, and the movement of the governor had gradually worked it loose until it was still holding by two or three threads; but there was still room enough for the inside link to pound on the threads between the shoulder *A*, Fig. 4, and the eccentric boss. That it did so pound is shown by the plain marks of threads on the inside of the bushing on the link. The pin was long enough in the thread to still hold and allow this.

This was when the pounding occurred a few seconds before the explosion. Then the most plausible theory is that the pin was pulled out of line enough to bind the governor and cause it to stick and let the engine run away.

Some criticism was made of the fact that this pin had no lock nut. On the contrary, there was no need of such, as it locked against the shoulder.

The final conclusion as to the primary cause of the accident was that "the pin was dry."

A Turbine Driven Roller Mill

A 750-horsepower Parsons turbine, designed to run at 2000 revolutions per minute, is geared to run the mill at 70 revolutions. A 100-ton flywheel takes up the shock of the mill.

The rolling-mill field, looked upon as one of the last and most secure strongholds of the reciprocating engine, has been invaded by the steam turbine. An installation at the Calderbank steel works of James Dunlop & Co. was the subject of a paper recently presented to the West of Scotland Iron and Steel Institute by A. Quintin Carnegie, of the Parsons Company.

About the time that the Parsons were experimenting with the "Vespasian," upon which it will be remembered the speed of the turbine was reduced to that of the propeller through gears, the question of the motive power for the new rolling mill was up, and it was proposed to use the exhaust steam from the existing mill engines for electrically driving the new mill through a low-pressure turbine. Calculations showed that a flywheel already on hand was large enough to permit the rolls to be operated with an almost constant load on the driving engine, and the idea of substituting gearing for an electrical reduction between the turbine and flywheel shaft presented itself. The electrical transmission would cost something like 15 per cent. in transformation losses, whereas the frictional loss, including that of the bearings of the gearing, would not be over 1½ per cent., while the gearing involved a much smaller investment.

The turbine, of which the accompanying section, Fig. 2, is reproduced from *The Engineer* and the halftone view, Fig. 1, from *Engineering*, is of the Parsons mixed-pressure type and runs at 2000 revolutions per minute, either with exhaust steam at a pressure of 10 pounds per square inch absolute, or with live steam direct from the boilers at a pressure of 60 pounds per square inch above the atmosphere. The two throttle valves are connected to the governing mechanism by means of steam relays and are arranged so that preference is given to the use of exhaust steam. When the supply of exhaust steam is insufficient, the balance required is automatically supplied by the high-pressure valve, the distribution of the load between high-pressure and exhaust steam being effected by the decrease in speed. In order to prevent air from being drawn in when there is a shortage of exhaust steam, a small device is provided, which causes the low-pressure throttle to close whenever the exhaust steam falls to nearly atmospheric pressure. The blade areas are so proportioned that the full load may be carried with atmospheric pressure at the first row of low-pressure blades, the high-pressure blades in this case running idly in steam of atmospheric

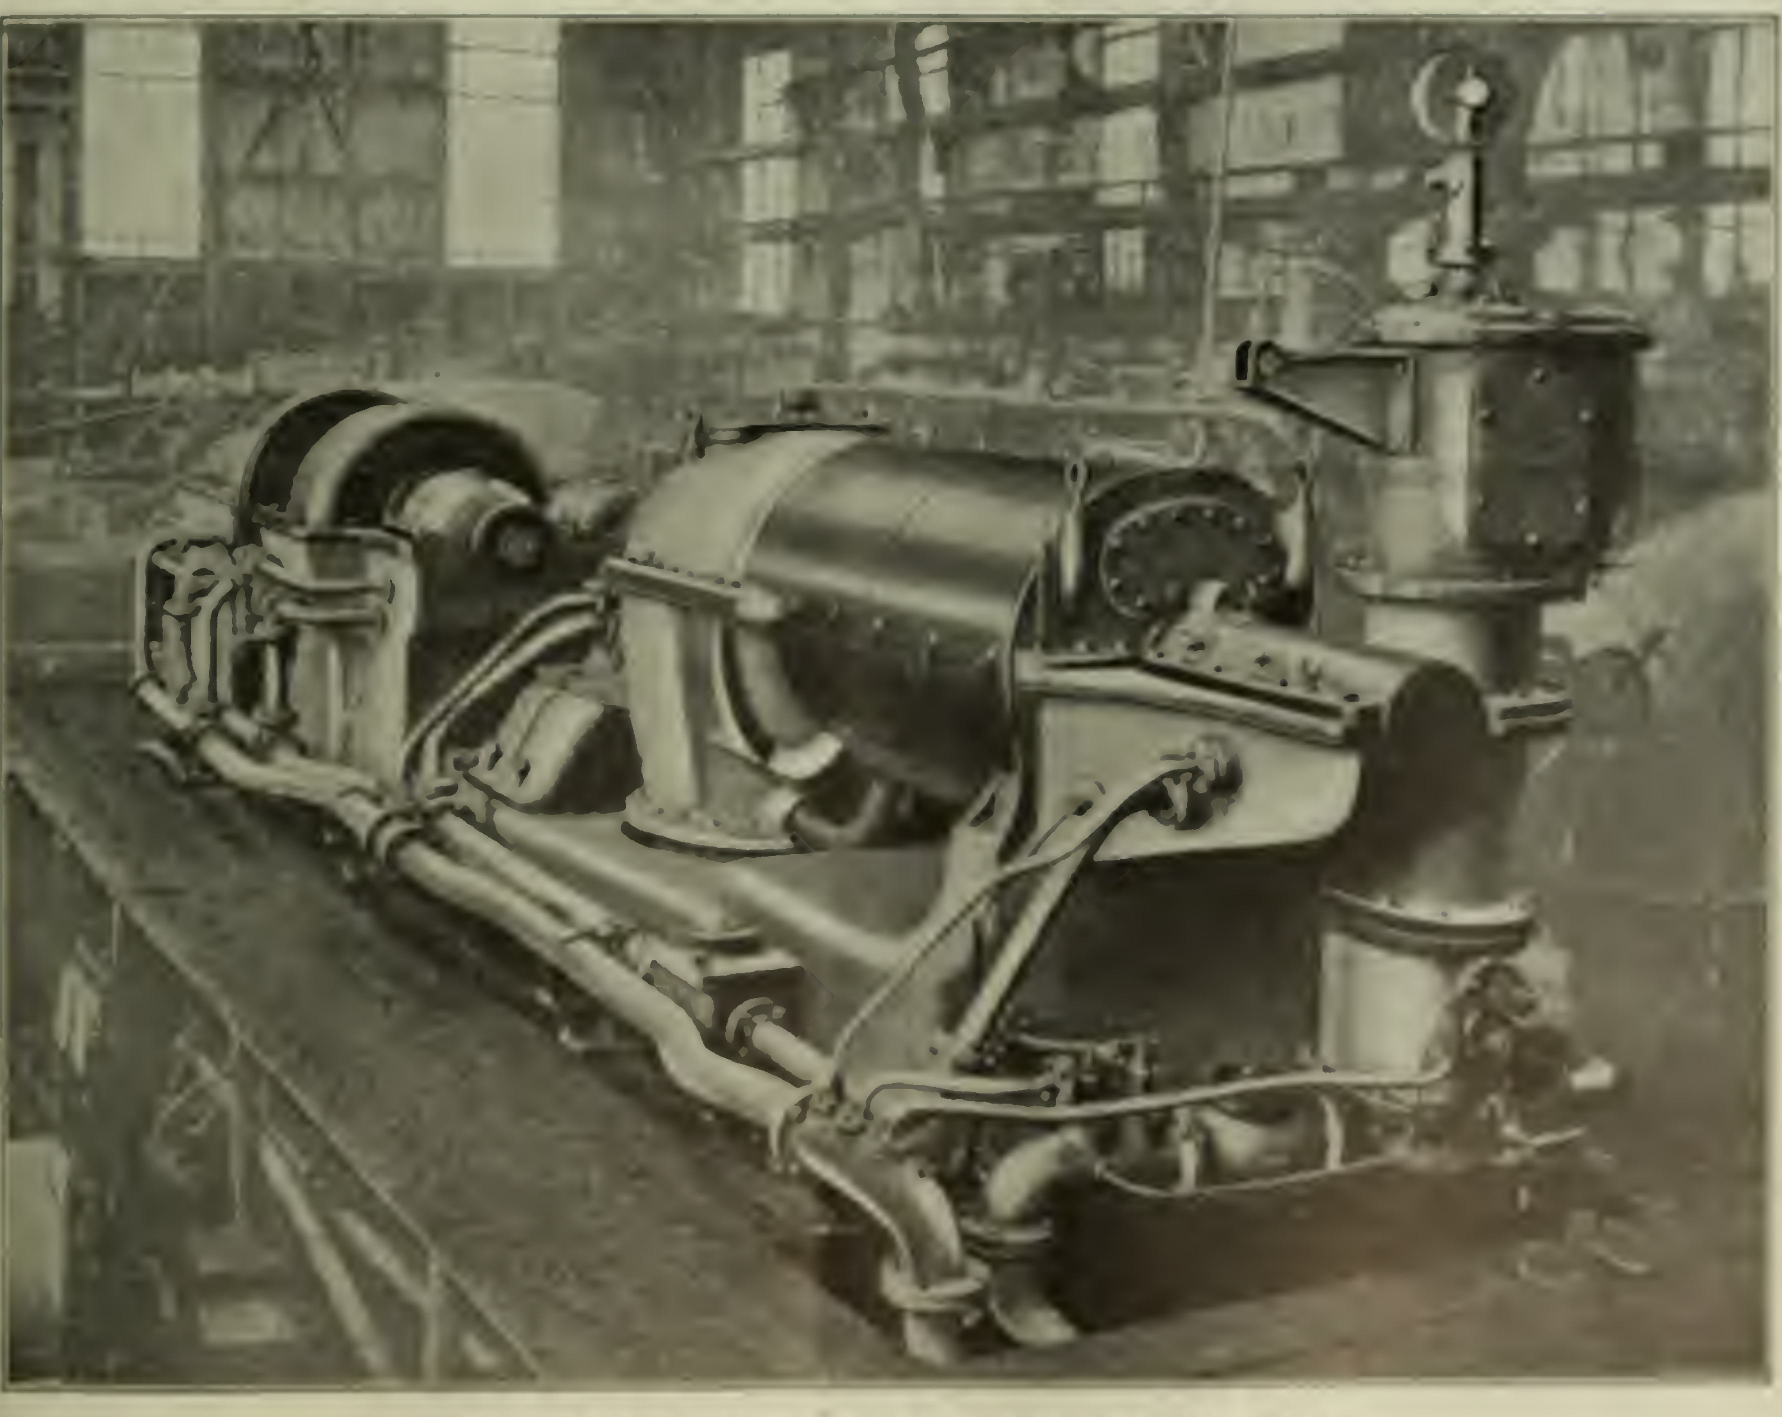

Fig. 1. Geared Turbine for Rolling Mill, Live Steam End

pressure. When the whole load is taken by high-pressure steam, the pressure in the first row of low-pressure blades falls to about eight pounds absolute, so that the smaller quantity of steam is still able to fill the blades and maintain an efficient velocity ratio. Full power from the turbine may be obtained from either source of steam supply or a mixture of the two.

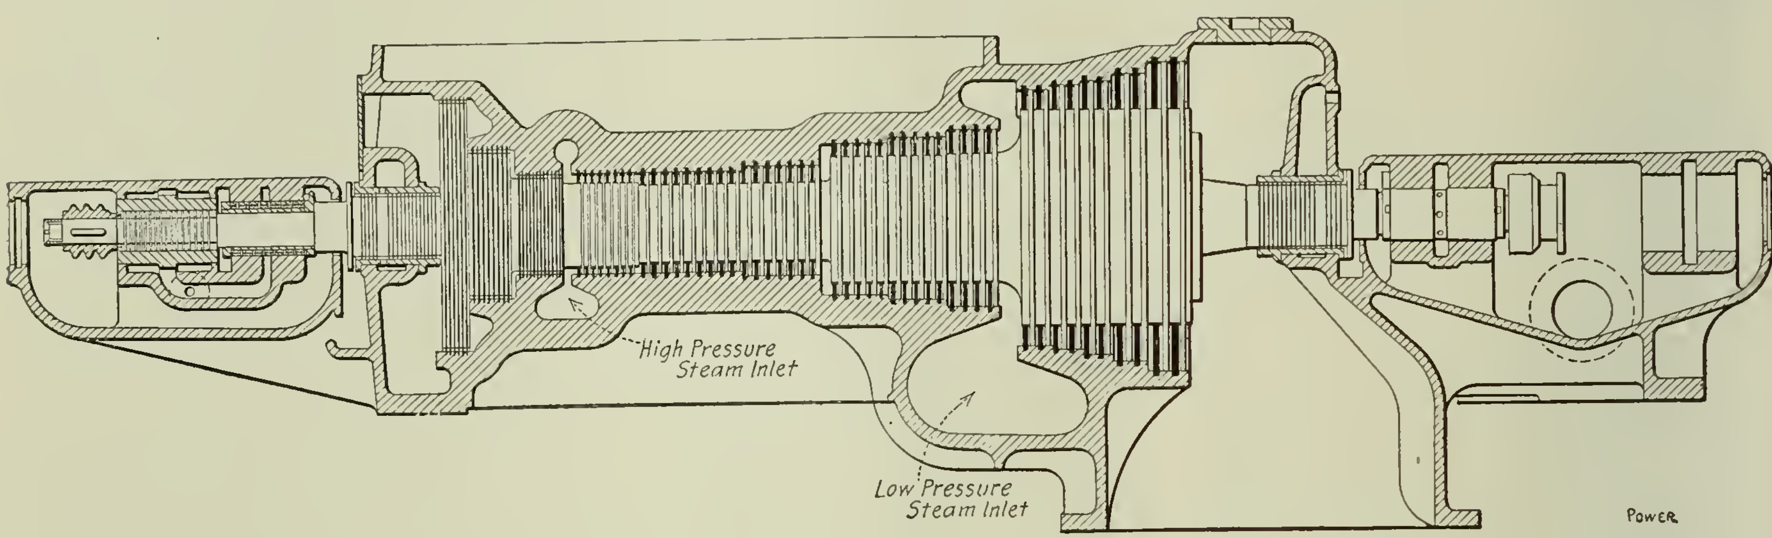

Fig. 2. Longitudinal Section of Turbine

The turbine was designed to develop 750 brake horsepower, and this has been found to be ample. The mill runs at 70 revolutions per minute, the turbine at 2000 revolutions and the intermediate shaft at 375 revolutions. The high-speed pinion is formed solid with its shaft and is made of chrome-nickel steel. The pitch-line diameter is 7.143 inches, and there are 25 teeth, 3½ inches diametrical pitch. The wheel into which it gears has 131 teeth and is 37.429 inches in diameter, with a total face width of 24 inches. The second reduction gear has a mild steel pinion, with 23 teeth, 2 inches circular pitch. The pitch circle diameter is 14.912 inches, and it gears into a wheel of 80.848 inches diameter, with 127 teeth. The total face width of the low-speed gear is 16 inches. The double helical teeth are at an angle of 23 degrees with the axis of the shaft. Both pairs of gears are placed in cast-iron gear cases with white-metal bearings for the shafts. Oil is pumped into the bearings under a pressure of from eight to ten pounds per square inch by a pump driven from an extension of the governor shaft, but the oil for the gearing is delivered by a separate pump driven from the intermediate shaft by means of a Reynolds silent chain. This pump draws oil from settling chambers in the bottoms of the gear cases and sprays it continuously onto the teeth. The level of the oil is kept sufficiently low to be quite clear of the bottoms of the wheels. The arrangement of the gear is shown in Fig. 3 herewith, also reproduced from *The Engineer*. Couplings of the flexible type are fitted between the turbine and the high-speed pinion shaft, and also between the first and second reduction gears. These allow for small errors in the alinement of the shafts, and also give the necessary end freedom for expansion of the turbine shaft.

Together with its shaft the flywheel weighs nearly 100 tons. It is carried on two adjustable gun-metal bearings, each 22 inches in diameter. One of these bearings forms part of the lower-speed gear box. The low-speed gear wheel is keyed directly on to the end of the flywheel shaft and is overhung from its bearing. The flywheel, which is of cast iron, is in two portions, connected with the usual shrunk links. The external diameter of the wheel is 23 feet. Since the stored energy in the flywheel is about 20 times that of the turbine and gears, it is evident that the latter are subjected to a small fraction of the shock due to the rolling mill. The flywheel shaft is connected to the main pinion of the mill by a pair of wobbling couplings. One of these is of cast steel, while the other is of cast iron, of such section as to allow its breaking in the event of any undue strain on the mill. Four of these couplings are said to have broken in one afternoon.

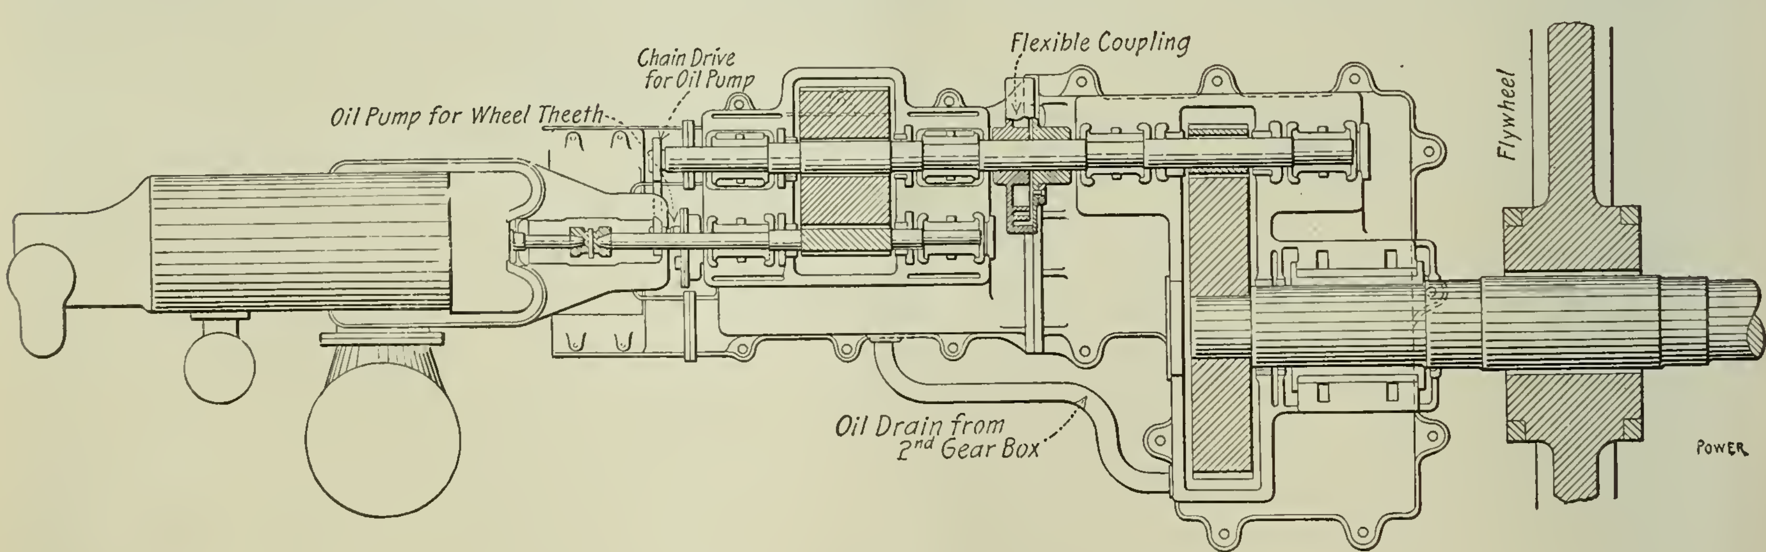

Fig. 3 General Arrangement of the Gears

The Summer School of Engineering under direction of the College of Engineering of the University of Wisconsin, opens June 26, continuing for six weeks. Regular and advanced courses are offered in direct and alternating currents, hydraulics, machine design, descriptive geometry, applied mechanics, shopwork, steam and gas engineering and surveying. Elementary courses adapted to the requirement of those not having preparation for the advanced work are offered in mechanical drawing, machine design and shopwork, in addition to which opportunity is offered for laboratory work in the electrical, steam and gas laboratories for those who have had power-plant experience or correspondence instruction. The teaching staff is taken from the regular instructional force, and all laboratory equipment of the engineering college is available for students.

Napier's Formula with Superheat

Some experimental observations upon the flow of superheated steam through an orifice. By applying these values to Napier's formula constants for superheated steam were obtained.

A short time ago, Mr. Harter presented a paper, at a meeting of the American Society of Mechanical Engineers, setting forth some incidental observations upon the value of Napier's coefficient with superheated steam. The values recorded were for superheats between 45 and 195 degrees Fahrenheit, but unfortunately the series was confined to a range of pressures between 138 and 148 pounds gage. Extreme care was taken in making all observations and the probable error was within 0.2 of one per cent.

The same orifice was used in all the tests and was formed in a ½-inch plate with edges rounded to a ¼-inch radius, the contracted diameter being 1.2 inches. In figuring the results no correction was made for expansion due to the temperature of the diaphragm, owing to the smallness of the error arising from this source.

The results are plotted in Fig. 1, in which curve No. 1 gives the Napier coefficient corresponding to each set of readings obtained in the tests. Calibration tests of the orifice for saturated steam showed a coefficient of about 72.3, the difference between this and the ordinarily accepted figure of 70 being, no doubt, due to the form of orifice. The formula for determining Napier's coefficient as plotted in curve No. 1 is

$$C = \frac{pa}{W}$$

where,

C = Napier's coefficient;

p = Test pressure, absolute;

W = Weight of steam flowing per second;

a = Area of the orifice in square inches.

Curve No. 2 shows the cubic feet of steam discharged per second for different amounts of superheat, the results being reduced to the basis of the average pressure existing during the tests in order to make the volume discharged depend upon temperature only.

Curve No. 3 shows the weight of steam discharged per second at the average pressure.

In commenting upon Mr. Harter's results, Professor Heck submitted some interesting comparisons of experimental re-

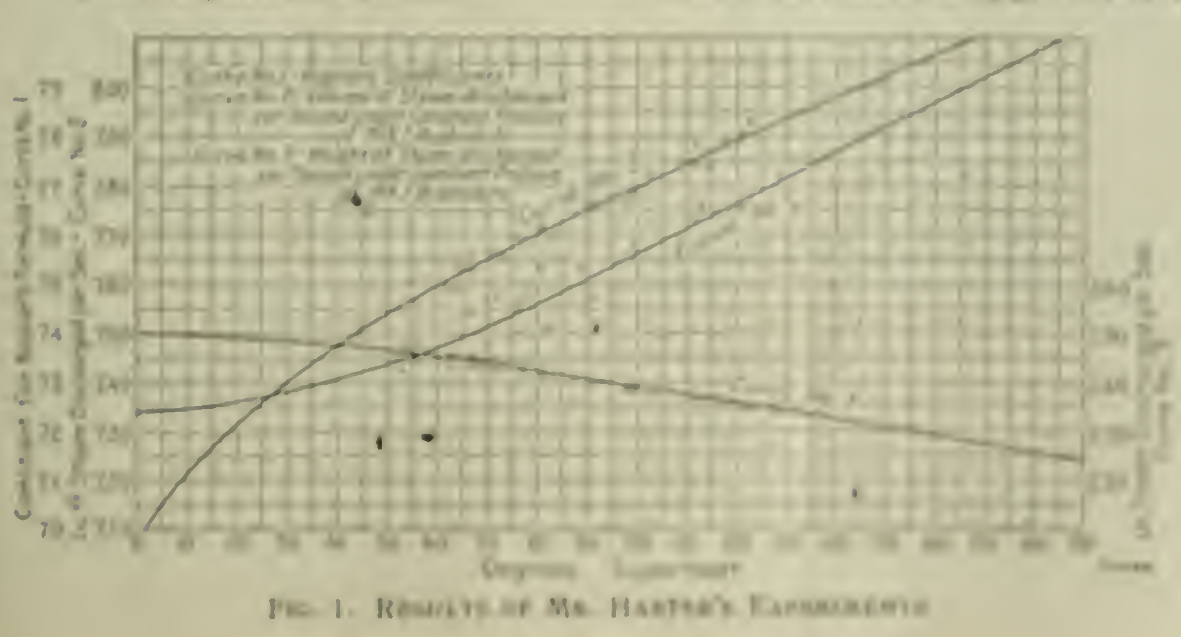

FIG. 1. RESULTS OF MR. HARTER'S EXPERIMENTS

sults with the theoretical values of Napier's divisor deduced from the truly adiabatic steam jet.

In Fig. 2, curve No. 1 represents Mr. Harter's curve No. 1, while curve No. 2 shows the ideal value of the Napier constant. The calculation for the five points along this curve is outlined in the accompanying table. The general data are: initial pressure p_1 equals 160 pounds absolute; pressure in throat of jet p_0 equals 92 pounds absolute, or 0.575 p_1, for which pressure the saturation temperature is 321.9 degrees Fahrenheit:

The steam quantities in this calculation were taken from an as yet unpublished table of the properties of steam, which differs from the Marks and Davis tables by amounts lying within the region of experimental indeterminateness.

The two curves in Fig. 2 show agreement in form, and indicate a coefficient of discharge of 0.97 to 0.98; this coefficient being the ratio of the ideal to the observed value of *N*.

In this connection it is shown how the coefficient of discharge works out for an important set of experiments made by Rateau, in 1900. Fig. 3 shows the nozzles and orifice used. In Fig. 4, curves *A, B* and *C* correspond with nozzles *A, B* and *C,* respectively. The curve *N* is the average of these three, while *D* applies to the sharp-edged orifice. The pressure ratio is the ratio of the final to the initial pressures, that is, $p_2 \div p_1$. The ideal flow is based on the assumption that when p_2 falls below 0.575 p_1, it ceases to exert any influence upon the rate of flow. These experiments show that it has a small influence; the discharge is equal to the ideal rate when p_2 is the same as the throat pressure p_0, but increases very slowly as p_2 falls. The coefficient of discharge thus becomes greater than unity, being about 1.02 when p_2 equals 0.1 p_1, which is about the governing condition in the tests reported by Mr. Harter. Curve *D* shows a marked contraction of the jet, which decreases, however, as p_2 becomes less.

Flow of Heat through Furnace Wall

As a result of recent investigations at the testing plant of the United States Geological Survey it has been found that a solid wall is a better heat insulator than a wall of the same total thickness containing an air space.

A set of exhaustive investigations have recently been completed at the fuel-testing plant of the United States Geological Survey at Pittsburg, Penn., by Messrs. Ray and Kreisinger upon the flow of heat through furnace walls. A specially constructed furnace was used, all temperature measurements were taken by means of thermocouples and every precaution was observed to insure accurate results.

The temperature difference was taken as a basis for measuring the relative heat transfer, the nearly true assumption being made that there is no cooling effect due to leakage currents of air through the brickwork or into, out of or along the air space. With this true, the quantity of heat passing through an inner part of the wall is exactly equal to the heat passing through another part farther out. For example, the quantity of heat which is conducted through the inner firebrick wall is exactly equal to the heat which passes across the air space, and is exactly equal to the heat which is conducted through the outer common brick wall, and also equal to the heat radiated from the outside surface. If this were not so, equilibrium would be impossible; that is, if more heat passed through the inner wall than through the outer wall and over the air space, then the heat would accumulate next to the air space and would be accompanied by a continually increasing temperature. Or, if more heat passed through the outer wall than through the inner one and through the air space, the heat in the outer wall would diminish and its temperature would drop—an event contrary to conditions of equilibrium.

The quantity of heat flowing by conduction from one plane to another through any portion of the furnace wall depends upon the difference of temperature between these two planes and upon the resistance to the heat flow. With the same temperature difference, if the resistance is high, a small quantity of heat flows through; if the resistance is low, a large quantity flows through. Or, if the quantity of heat is to remain constant, the temperature difference must be large if the resistance to the heat flow is high, and small if the resistance is low. For example, if the temperature difference between the faces of the firebrick wall is high, it may be said that the resistance to the heat flow through the firebrick wall is high; or, if the temperature difference between the two surfaces on each side of the air space is low, it may be inferred that the resistance to the heat passage across the air space is low. Thus it is possible to rely upon the temperature difference as being a true indicator of high or low resistance to heat flow between any two planes which are parallel to the surface of the wall.

The investigations particularly concerned the air-space type of wall construction as compared with the solid brick wall or walls in which the air space is filled with some solid material of low heat conductivity. The results showed conclusively the rather surprising fact that in furnace construction a solid wall is a better heat insulator than a wall of the same total thickness containing an air space. This is especially true if the air space is close to the furnace side of the wall. In view of this, where it is desirable to build the walls in two parts, so as to prevent cracks from being formed by the expansion of the brickwork, it is preferable to fill the space with some solid (not firm but loose) insulating material. Any such materials as ash, crushed brick or sand offer higher resistance to the flow of heat than an air space; furthermore, a loose material by its plasticity reduces the air leakage. It was found that one inch of asbestos was more effective as a heat insulator under the existing conditions than a 2-inch air space.

There is a general belief that since air is a poor conductor of heat, air spaces built into the walls of a furnace will prevent or reduce heat dissipation through the walls. Although there may be instances in which this is true, yet, as a rule, the effect of the air space is just the opposite. While the heat travels very slowly through the air by conduction, it passes over the air space very readily by radiation.

The quantity of heat passing through a portion of a solid wall by conduction depends upon the difference between the temperatures of the two planes limiting the portion of the wall, whereas the quantity of heat that passes across the air space in a wall depends upon the difference of the fourth powers of the absolute temperatures of the surfaces inclosing the air space. It follows that, in case the heat passes by conduction through the solid portion of the wall, the loss remains approximately the same so long as the temperature difference of the two limiting planes remains constant, no matter what may be the actual temperatures of the two planes. On the other hand, the heat passing across the air space by radiation increases rapidly with the temperatures of the inclosing surfaces, although the difference between these temperatures may remain constant. The important point is that the air space, which is advantageous in the walls of a refrigerator because the temperatures are low, is objectionable in a furnace wall because the temperatures are high.

A Perpetual Hydraulic Motor

By F. W. Salmon

How a young engineer was induced to spend his time working on a perpetual-motion machine which he knew was contrary to all natural laws and which he felt sure could not be made to work. The deception that he discovered and exposed and the lessons that he learned.

About the middle of a warm holiday afternoon in May, 18—, in the western corridor of an upper floor of a downtown office building in a city of the Middle West, an elderly man dressed in a gray suit was carefully searching for a certain door. This was made evident by the close examination he gave each door in turn. Although he was apparently fifty-five or sixty years old and had silver-gray hair, his walk was firm and decided; his face was clean shaven and he bore himself with a semi-military air.

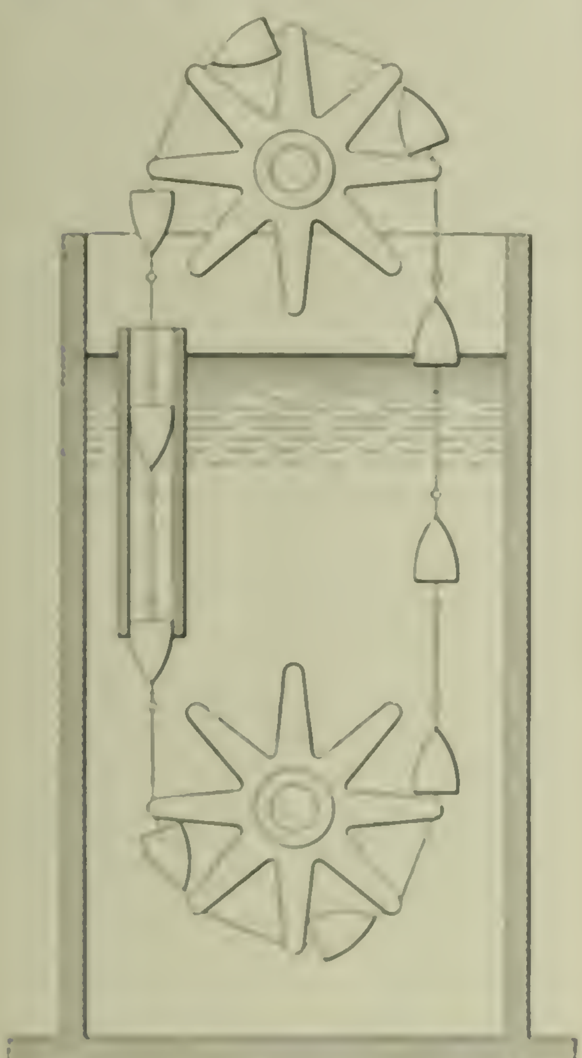

Fig. 1. Smith's Original Design

At room 418, after examining the sign on the glass, he tried the knob, but it would not turn. The door was opened by a man of perhaps twenty-five years. A few preliminaries and the men were acquainted; Charles F. Smith wished to consult Henry C. Bandcox about the former's invention—an invention that had been his dream day and night for perhaps thirty years. The dream was not a dream to him but, rather, a duty, his duty, to his race, his nation, yes, to the world.

Bandcox's erect carriage, his open and frank manner and the way in which he looked others straight in the eye, all carried confidence; surely he was honest and honorable, and surely he had a right to practise his profession as a consulting engineer, even though he was so young, for he had been trained in the best schools, the school of theory, the school of practice and the school of adversity.

Smith's most intimate friend, Hammond, had told him to find this man Bandcox and secure his service in perfecting the invention; Bandcox had but

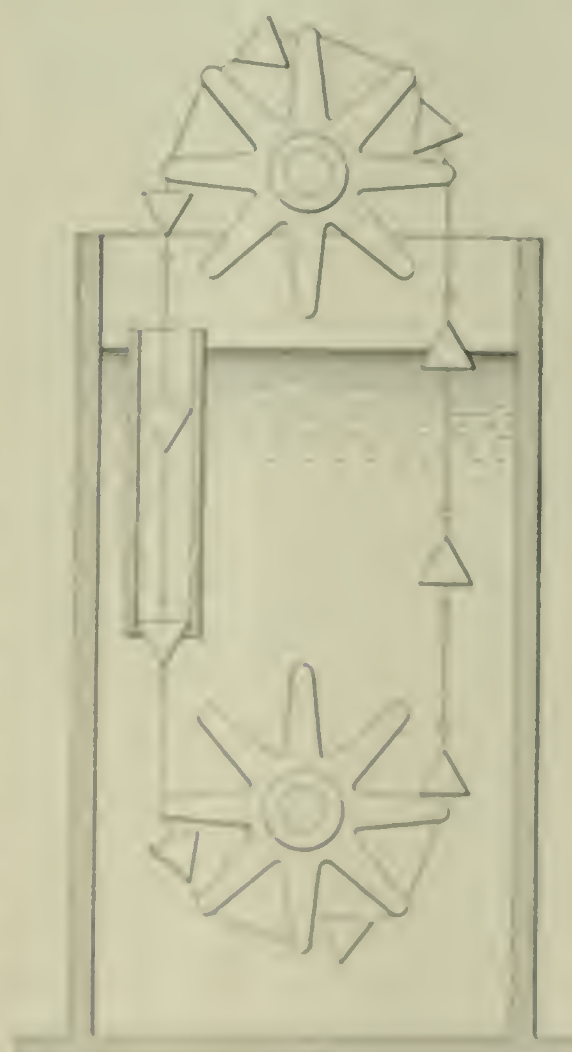

Fig. 2. Smith's First Improvement

a small practice and Hammond knew that he would give almost unlimited study and care to anything he undertook.

An hour later Smith folded up and put back in his pocket a sheet of paper on which there was a sketch, as shown in Fig. 1, while the words, "You are mistaken, Mr. Bandcox, I have seen it move, I know that there is power in it," were leaving his lips, and upon his face was a more set and determined look than before. Henry, in wishing him good-by at the door, courteously repeated his firm belief that no useful or profitable purpose could be attained by spending money on or time experimenting with such a device.

The old man had for half a lifetime treasured the idea that in the near future any man would be able to get power al-

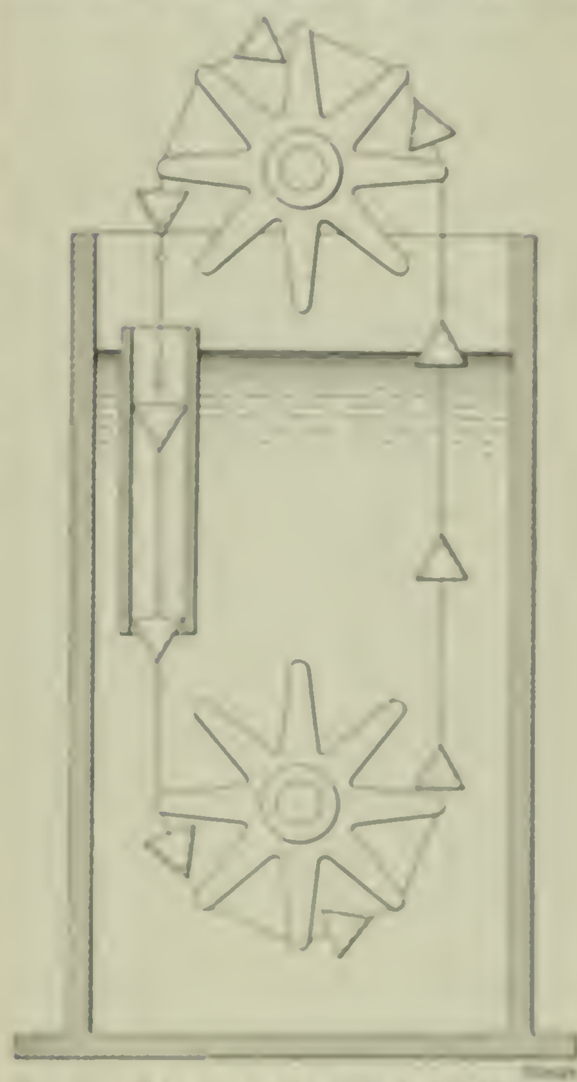

Fig. 3. Machine with Floats Open at the Bottom

most without cost with his device, as soon as some consulting engineer would show how to get the floats down again under the bottom wheel and mechanics would do "decent" work on his models, thus not allowing excessive friction to prevent the machine from making the initial move when tested.

The floats were made with the shape shown in Fig. 1, upon the theory that they would pass through the water with less resistance at the enormous speed that in the inventor's opinion they would attain in large machines when operated in deep water.

Perhaps a week later Smith again called on Bandcox, this time accompanied by his friend Hammond. Smith asserted that if a practical machine were designed and a satisfactory working model made to show to capitalists, unlimited capital would immediately be placed at their disposal. Hammond vouched for the excellent reputation of Smith and assured Bandcox that Smith would undoubtedly pay his bills for services promptly. Moreover, Hammond emphatically declared that he had seen a model run, though it was roughly made and very small. Bandcox, however, could not reconcile this with his theoretical knowledge.

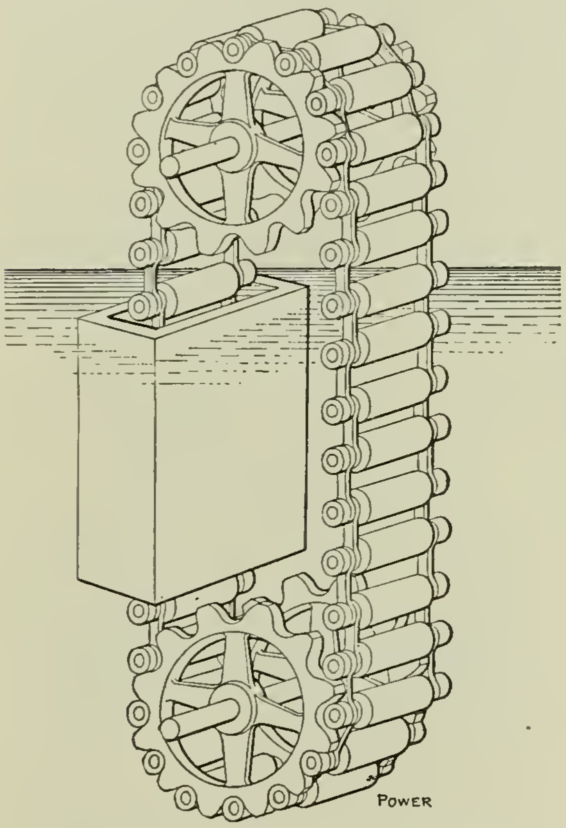

Fig. 4. Floats Built as Rollers to Eliminate Friction

During the discussion sketches as per Figs. 2 and 3 were made. In Fig. 2 the inventor arranged for a water-tight tube in which the floats were to pass downward. This was to nullify the objection raised by Bandcox that in the earlier design the efforts on the various parts of the chain were equally balanced.

In the design in Fig. 3 Smith thought he had solved every difficulty. The floats were open at the base of the cone so that they would fill with water in descending. Bandcox explained that there was nothing to cause them to rise on the ascending side.

Smith called later with pieces of the apparatus that it was claimed had "run"; still, Bandcox claimed that the machine was not feasible and advised against spending money in models or patents. But, Smith insisted that drawings be made upon which an application for a patent could be based. Finally, this was done; the drawings showed a design very similar to that in Fig. 4. Smith explained that in this design the last objection offered by Bandcox had been met, for should any of the floats in descending touch the side of the tube they would roll and thus not offer the resistance which was found so objectionable in the design in Fig. 2.

After this, Smith often called at Bandcox's little office, sometimes bringing interested friends with him, and many methods were talked over as to "the best way to overcome the cussedness of the thing," but Bandcox always protested against the machine as not being feasible. Still, Smith had several models made and these altered from time to time but to no purpose. So, gradually, his visits to Bandcox became less frequent and finally ceased entirely.

On one cold day of the following spring, Bandcox sat in a little workshop at a board on trestles in one of the back rooms of the factory of—well, let's say the Olivett Manufacturing Company, in the small town of, say, Olivett. He was a good engineer and a good student, but he was neither a good "business getter" nor a good "cash collector" so he had given up his office with the last of his little capital and "taken a job" on a small salary with an expert "business getter" who reaped large profits from Bandcox's labor and skill.

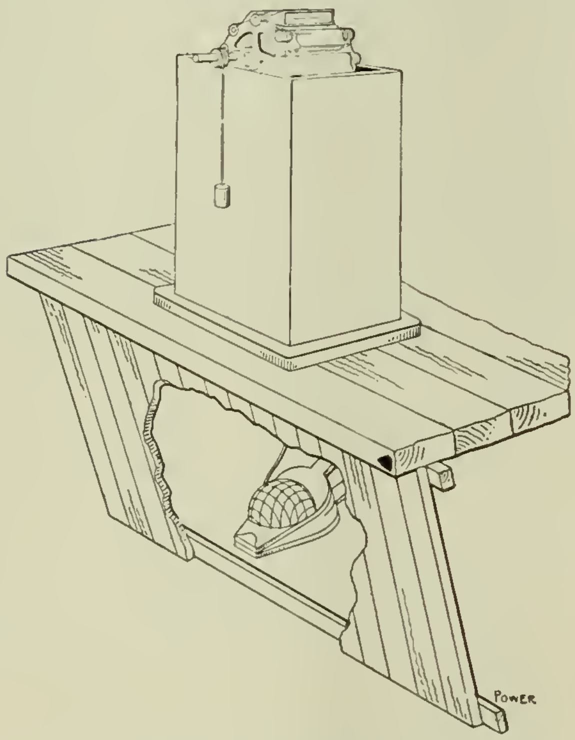

Fig. 5. How the Machine Was Made to Work

A letter in an envelop bearing several "Forwards" was thrown in to him; he shoved it in his pocket but later his curiosity awakened, apparently, and he opened and read it.

What, was it possible! Smith's machine a success—runs nicely and gives greater power than even the inventor claimed. A model had been made by Thompson, the modelmaker on Water street, and it was now in his shop where it runs daily and is seen by hundreds. The letter ran on, Smith wanted Bandcox to come at once and make the drawings and specifications, both for the patent and for a larger machine. The evident rectitude and honor of Bandcox had so impressed Smith and Hammond that they searched for him at this important time.

A few letters were exchanged and Bandcox paid out his hard earned wages for a ticket to go back to his home town. When he arrived he went directly to the model shop and found Smith waiting for him, more erect than ever, cordial and kind. Now what did Bandcox have to say? There was the machine, just like one of the sketches made in Bandcox's office which he had always thrown down as "not practical, no good, out of the question." This model ran and it gave power, yes, *power*. See it raise this large weight when the clutch is thrown in. Yes, Bandcox gives in, acknowledges that it works, that it gives power but he still insists that in some way or in some detail not readily discernible it differs from the sketches that were shown to him some months before.

Smith and Thompson talked and acted as though they thought Bandcox more or less insane. "Would he not believe what he saw with his own eyes?" Just pour in a few drops of fresh water and the machine would start, run and give power; anyone could pour in the water that Thompson would courteously hand him when desired.

The young engineer was quite busy for the next two weeks, examining the machine and its surroundings, measuring the volume of water it took, the weight it would raise and doing many other things. At last, he had his report ready to show Smith, Hammond and Thompson what he had found. How simple! For months a man in Thompson's employ had been drawing good wages for himself and for Thompson working on the model. The model worked because a small pipe conveyed air into the water tank just under the ascending buckets, as shown

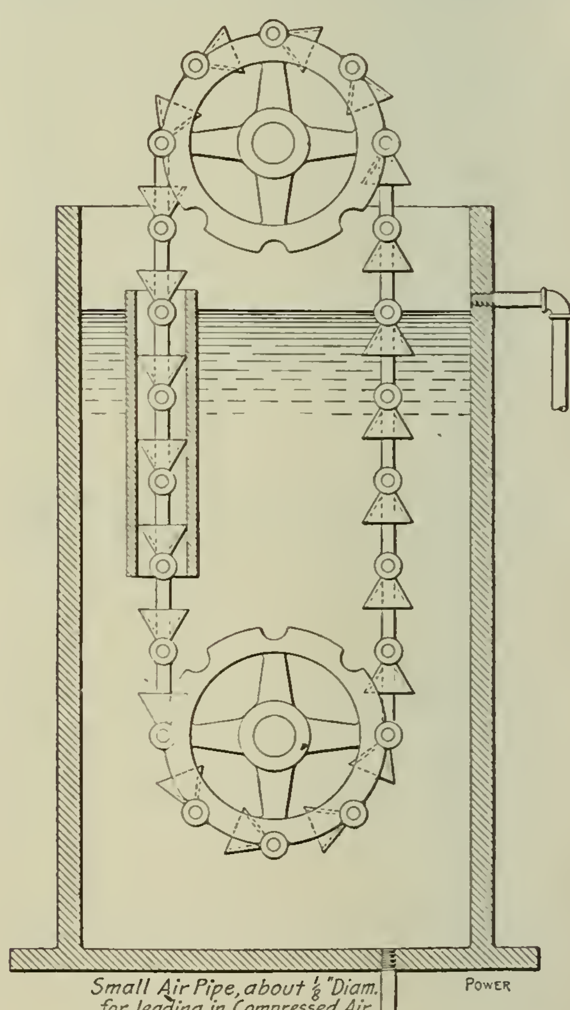

Fig. 6. Section of Machine, Showing Air Supply

in Fig. 5. The duty of the man whom Thompson employed was to work the foot bellows and keep out of sight. The air entering the bottom of the tank came in contact with the floats on the up side, as shown in Fig. 6, and caused the machine to work.

The exposure of Thompson's deceit caused Smith such great disappointment that he gave up in despair his cherished dream of securing power without cost.

Bandcox went back to his position in Olivett, poorer in pocket but richer in experience and wisdom.

It was but a short time ago that I sat on one side of the fireplace in Henry Bandcox's home on a cold night and Henry sat on the other. We were finishing our cigars after his family had retired and we talked of the incidents recounted above. He went on to say that it was a bitter experience and had cost him a high price one way and another but he learned many things by it. For instance, a young engineer, wishing to run a consulting office, must be a "business getter" as well as an engineer. He should not pay out much of his own cash for his clients but, on the contrary, should have them put up the cash for expenses as needed and balance often. Again, if a client comes along with something that is worthless, have nothing to do with it—just have nothing to do with it, drop it and keep away from it as though it were dynamite, for the only bills that are paid cheerfully (if any are) are those that represent a part of some profitable venture or transaction. Although some men seem willing to profit by the losses of their clients, honorable men would not wish to.

Economical Generation of Steam

By William Kavanagh

> *Attention is called to the losses occurring through poor firing and lack of attention to the boiler-room equipment. Suggestions for minimizing these losses.*

Economy in a steam-power plant primarily begins in the boiler room, and depends largely upon two factors: good firing and proper care of the equipment. It will not suffice to spasmodically clean boilers, repair furnaces and occasionally put the grate bars in good order.

How then are the highest economical results to be obtained in the boiler room? This question is partly answered by having the boiler equipment in duplicate or, at least, in having a sufficient number of clean boilers to replace an equal number that have been running for some time. The period during which a boiler can be operated economically depends in a great measure upon the quality of the feed water and also upon the attention the boiler receives while under steam. If boilers are handled in the following manner, they may be operated economically or, at least, with as good economy as conditions will permit:

First, the feed water should be filtered and softened (if hard) and its temperature raised as high as possible before it enters the boilers. Second, the bottom blowoff should be opened at a time when the least ebullition is going on in the water. This will occur at about the time steam is to be raised in the morning, assuming the boilers are shut down for the night with banked fires. Just before spreading the fires the bottom blowoff should be opened and some water allowed to escape to the sewer or tank provided for that purpose. If the boilers have been properly set and fitted with an independent feed pipe, the greatest amount of deposit will be found at or near the blowoff; therefore, it is poor policy to feed and blow through the same pipe, especially if the boilers cannot be shut down regularly for cleaning. The blowoff should be located at a point in the boiler where the least amount of agitation is present in the water and it should be independent of the feed pipe. Furthermore, the feed and the blowoff should not be located at the same end of the boiler.

Another factor which has an important bearing upon economy is clean boiler tubes; these should be blown free of dust at regular intervals, as dust is a good nonconductor of heat and its presence on the surfaces of the tubes always denotes a loss of fuel. If the boilers be of the horizontal tubular type the tubes should be scraped as well as blown and, if they be of the water-tube type, the tubes should be blown both horizontally and vertically; the mere thrusting of a steam pipe between such tubes and allowing the steam to blow for a few moments is little better than nothing at all. In general, it will be found that the water-tube boiler is difficult to keep clean, and the blower used for blowing the dust from the tube surface should be bent to nearly a right angle so as to enable a jet of steam to be directed against the sides of the tubes as well as along their upper and lower surfaces.

The feed water can be raised to a sufficiently high temperature by employing what is known as the "series system." With this system the water approaches the boilers by stages, passing from one heater to another, the coldest water entering the coldest heater and the hottest water the hottest heater, being subjected there to the temperature of the hottest exhaust steam. The first heater is called the "primary" heater and if three heaters are used the middle one is called the "secondary" heater and the third the "main" heater.

This system is practicable only where the steam is taken from such sources as the receivers of a triple-expansion engine. Where an economizer is used the water issuing from the main heater passes through the economizer and thence to boilers.

Another fault often met with in practice is that of leaving the feed line exposed. This is also true with respect to steam lines, engine and pump cylinders and steam chests. All surfaces containing steam should be covered when possible to prevent radiation. Furnace linings should be tight, and hollow walls should not be allowed in the boiler setting, and all cracks and leaks in the walls of the setting should be stopped.

The firing should be regular and in no case should the whole of the incandescent fuel bed be covered with fresh coal. Usually, the best method of firing is to cover one side of the fuel bed first and when this has reached its maximum incandescence the other side is covered, thus establishing an alternate method of firing. There is a wide difference of opinion as to how coal should be burned. Some firemen prefer the "sprinkling" method, that is, spreading the coal over the fire in a thin layer, repeating this regularly and often. The objection to this method is that the amount of cold air admitted to the furnace is largely increased. The opposite to this method is to fire heavy each time, thus excluding the cold air. This practice is also objectionable because a distillation of the volatile gases of the coal will occur and find their way to the uptake without being burned.

However, the most effective method of firing often depends upon local conditions and for that reason only experienced firemen should be employed. There is no doubt that a large percentage of the losses occurring in a steam-power plant originates in the boiler room, and is incurred by poor firing, dirty boilers, poor boiler settings, dilapidated furnace lining and grate bars, loss of coal by allowing it to mix with ashes and also by having a bed of good coal lying on the boiler-room floor to be ground into dust by continual walking upon it. Again, it is not uncommon to find a badly packed boiler-feed pump that must be run at high speed in order to maintain the water level in the boilers. Leaky pipes and joints, valves, etc., all have a tendency to increase the total loss.

Locomotive Tubes, Their Treatment*

By F. N. Speller †

In which the author touches on the main points requiring attention, such as corrosion, leaking, strength of material, weldability and uniformity of material.

The tube industry owes much to the railroads for its development; in fact, the invention of lap welding may be traced to the necessity which arose on the building of George Stevenson's first locomotive for a tube which would be safer and stronger than the butt-welded tube, the only one made at that time. Since Stevenson's day the manufacture of locomotive tubes has increased in quantity and quality as the demands of railroad service became more exacting and the whole tubular industry was no doubt favorably affected thereby. Seamless steel tubes were introduced about 1886 and established a new standard of strength and ductility and endurance under many conditions of service. Later on, a satisfactory grade of soft steel was produced which could be lap welded like charcoal iron and this also has been much improved, so that there are now practically three classes of tubes for locomotive service: charcoal iron (lap welded), steel (lap welded) and seamless steel. Charcoal iron formerly was made from a special grade of pig iron made in a small blast furnace using charcoal fuel. The product of this furnace was charged into the refinery, where about one-half of the impurities were oxidized and fluxed away, the metal being subsequently treated in lots of 300 pounds or so in a slightly modified type of the old catalan forge with charcoal as fuel. The use of so much charcoal has necessarily been stopped and in many other respects the manufacture of charcoal iron for tubes has of late years been considerably modified. Of those changes we are not in a position to speak, for, as it was evidently impossible for obvious reasons to continue the manufacture of charcoal iron strictly along the old lines, we abandoned the making of charcoal-iron tubes about two years ago in favor of lap-welded and seamless steel, which had by that time been proved a fit substitute and in some respects decidedly superior to the older material.

When steel is spoken of in this paper the method of manufacture is referred to more than the finished product, as the steel used in the manufacture of tubes, as a matter of fact, is a purer form of iron than that made by the charcoal process, and like the older metal cannot be tempered.

A special grade of bessemer steel was at first used in the manufacture of lap-welded tubes, on account of its superior welding quality, but later on had to be abandoned as under some conditions it was found to develop brittleness in the beads after the tubes had been in service some time. The substitution of basic open-hearth steel low in carbon and with less than 0.05 per cent. phosphorus and sulphur has been found after more than two years' trial to entirely do away with any tendency of this kind, and as now made there is little difficulty in securing a strong weld with this steel. Seamless and lap-welded steel tubes are now made from practically the same grade of soft basic open-hearth steel.

It is a good thing for manufacturers and consumers to get together and learn each others' troubles. Perhaps out of the discussion to which we are leading up, something of value to both sides will result. Let us then take up what seem to be the main points requiring attention in the locomotive tube in order that it may give the best service under modern conditions.

Resistance to Corrosion

The manufacturer should furnish a tube in the best possible condition to withstand corrosion and pitting; that is, the metal should be as uniform in composition and density as it is possible to make it. Much can be done to lessen the tendency to pitting by proper attention to the making of steel and the way it is worked. We have been experimenting on this problem now for several years and have gone to considerable trouble in the matter of testing and inspection of material and in the process used for manipulating the steel so as to produce a tube which will resist corrosion as well as iron can be made to do so, and, judging from the reports of comparative service tests which have been received, steel so made is, in this respect, at least the equal of the best charcoal iron.

After all, however, the solution of this problem is largely in the hands of the user. Iron or steel will corrode in spite of anything that can be done if certain material is in solution in the water, particularly dissolved oxygen or carbonic acid. By the removal of these harmful agencies corrosion may be reduced to practically nothing. It is generally understood nowadays that water conditions have everything to do with corrosion, and the simplest solution of the problem is to treat the water with the object of making it as harmless as possible. The development of the modern tube to withstand corrosion and the treatment of water have together practically eliminated this trouble, so that it is rarely the case that tubes fail nowadays through pitting.

Leaking in the Flue Sheet

The construction and handling of the engine has so much to do with the trouble experienced from leaky flues that it is difficult to determine how much, if any, of the responsibility for this should be placed on the tube material. If railroad engineers will tell us what qualities are required in the tube to make it hold tight in the flue sheet, we will be glad to follow their suggestions as closely as possible. At the present time the steel tube is made as stiff as possible consistent with the best welding quality and ability to stand up successfully under expansion and beading in the tube sheet.

Strength and Ductility of Material

The tube should be of such quality as to stand repeated tightening in the flue sheet without cracking or showing undue evidence of fatigue, nor should these weaknesses develop during the life of the flue in service. The material found best adapted to give these properties is a special grade of soft open-hearth steel carrying not over 0.05 per cent. phosphorus or sulphur.

Weldability

The quality of the metal and method of handling are equally important in safe ending. Soft steel has been found somewhat harder to weld than charcoal iron, but it has been greatly improved in this respect. The necessity for a good welding quality steel is of first consideration in making locomotive tubes so that they may be easily safe ended, and this point has received a great deal of study, especially in the manufacture of lap-welded tubes where it is, of course, one of the first essentials to manufacture. Charcoal iron carries considerably more impurities than soft open-hearth steel, and these impurities form a self-fluxing mixture which facilitates welding. Railroad specifications have been so tightly drawn on composition in some cases as to work against the production of a good quality of steel for locomotive-boiler tubes by calling for unnecessarily low phosphorus and sulphur. There is now very good reason to think that a mistake has been made in this direction and that the general welding quality of the steel would be much improved, and the steel at the same time would lose nothing in other respects, if the maximum

*A paper read before the Pittsburg Railway Club, April 28, 1911.

†Metallurgical engineer for National Tube Company.

phosphorus and sulphur limits were both raised to 0.05 per cent. With producer gas, now generally used of necessity, it is a very difficult matter to keep the average sulphur in the heat below 0.035 per cent. and in order to remove this sulphur in the open-hearth furnace the steel has to be held and worked in such a way as to frequently leave it dry and difficult to weld.

Before the steel can be welded in practice a fluid cinder must be formed on the surfaces which are to be united. If the metal is heated too far above the point at which this cinder should flow, it will be burned and destroyed. We endeavor to have the range of temperature between the cinder-forming and burning points in the steel as wide as possible, so as to assist in lap welding and give the largest margin of safety in safe ending. Considering the variety of the requirements it seems that the composition of the metal should be left largely to the discretion of the manufacturer so far as is consistent with a certain specified standard of physical quality in the finished tube. We frequently go to the trouble of rephosphorizing for the purpose of improving the fluxing and welding quality of the steel.

The method of safe ending has as much to do with obtaining satisfactory results as the material, but no attempt will be made to lay down specific rules as to construction of the furnace and heating, for many of the practical shop men present who are welding flues every day are much more able to discuss this side of the problem. However, there are a few broad principles on the heat treatment of tube steel which should be taken into consideration. The preliminary heating of the body tube preparatory to flaring out the end should be carried to a bright orange color, judging by good shop light, 1750 degrees Fahrenheit. In the case of steel on steel, if the body tube is allowed to cool black after heating to this temperature and inserting the safe end the grain structure will be refined and the metal put in much better condition for the welding operation which follows. Moreover, if the preheated body tube is returned to the furnace without cooling, the metal may be crystallized or burned before the safe end has been heated hot enough to weld. Should there be any considerable difference in thickness between the safe end and body tube, it is evident that there is again a risk of overheating the one before the other is sufficiently heated to weld. If the body tube is returned to the furnace while red hot and the safe end is at the same time a gage or two heavier, there is, of course, all the more chance of crystallizing or burning the body tube at or near the weld. Taking unnecessary risks of this kind often explains subsequent failures which should not be charged up to the flue maker.

Tube Subjected to Crushing-down and Flattening Tests

It is not unusual for a flue welder who has never handled steel to have trouble for a few days. Remembering the above points and using his experience to the best advantage as to the condition of the furnace, the character of the flame, temperature, etc., the average man will soon be able to do equally reliable work with steel as with charcoal iron, as the experience of welders all over the country will show.

Uniformity of Material

This is a quality which the tubes should have in a high degree, both as to physical and chemical properties. There is no difficulty as to the average steel tube nowadays standing the master mechanics' tests made on one sample out of each hundred tubes. We have, however, recently designed a machine to make the flange, crushing down and flattening test on each end of every tube. This gives assurance both as to the character of the metal in each individual tube and also, in the case of lap-welded tubes, as to the welding quality being satisfactory. Steel tubes are now made in one grade of material suitable for either body tube or safe ending.

There is no difficulty in making steel tubes to stand the Master Mechanics' test on one sample out of each hundred tubes, the company has, however, recently designed a machine to make the flange, crushing down and flattening tests on each end of every tube, as shown in the illustration. This gives assurance both as to the character of the metal in each individual tube, and also in the case of lap-welded tubes, as to the welding quality of the material. Steel tubes are now made in one grade of material, suitable for either body tube or safe ending. Analyses of ends of tubes which have been used on railroads in the Pittsburg district showed that while the sulphur of the body tube is about 0.03 per cent. when new, the tube after being in service a year or so shows 0.06 per cent. of sulphur, and sometimes more, indicating that the steel gradually absorbs sulphur from the gases, which suggests that perhaps we are a little too particular as to the initial percentage of sulphur. The Master Mechanics' requirements are sulphur and phosphorus 0.05 per cent. In the analyses made during production the sulphur will average 0.03 to 0.035 per cent., and the maximum will exceed this. It is difficult to get the percentage of sulphur down to less than this without drying out the steel so as to impair its welding qualities.

Discussion

Mr. Redding said that in their practice they brought the tubes up to a welding heat in one operation, stuck the safe end in and continued the heating without any cooling of the body tube, as Mr. Speller recommended. They had, however, very few failures under this process with the cold-drawn seamless tubes. He thought that the absorption of sulphur from the fire was an additional reason why the initial sulphur should be kept down. With a high initial percentage of sulphur, the undesirable limit will be sooner reached.

Mr. Speller claimed that men who have had a great deal of experience in tube welding will not get into trouble from the overheating of the body tube, even if it is not allowed to cool before the safe end is heated with it. He said that the analyses indicate that the sulphur on the surface of tube heads reaches a maximum independent of the original sulphur contents. The cases of burning that he had seen were where the tube is burned back on the body tube, rather than right at the weld, in consequence of the body tube being hotter to start with, reaching too high a temperature before the safe end attained the welding heat.

Angus Sinclair said that he remembered locomotives with 6-foot tubes, and had seen them grow to 22 feet, and could not remember any time when there was not trouble from leaky tubes. He thought that the greater part of the trouble came from gross negligence in handling the engines, although there is no doubt that inferior material has been used for tube purposes to some extent. In Scotland they had nothing but brass tubes, but they had the same trouble. The man on the dumping pit is the fellow who causes most of the leaky tubes. He told how he got along very nicely with an engine which had a bad reputation, by being careful with the feeding and firing, always bringing the engine in with plenty of water, closing the dampers as soon as the fire was out and keeping the cold air from running through. When a blower is put on after the fire is out, it is "beyond nature" that the engine should keep from leaking.

Mr. Redding said that in the later-day service the fireboxes are so big, and the demands for steam so great, that they had to fire with the fireboxes wide open. The ash pans do not have dampers any more, and after the engine starts for the roundhouse there is no reason why the cold air cannot get to the tubes. Tubes are necessarily cooled down very quickly after the fires are out.

A gentleman present stated that cases are frequently cited where steel has been subjected to a few hours' test with acid and reduced perhaps 40 or 50 per cent., wrought iron a little less, and the so-called ingot iron showed no depreciation whatever. If this were a fair test, it would indicate that we should return to the old wrought iron, but the speaker doubted the fairness of the test. He said that they were building quite a number of power houses, and for the smokestacks had used different kinds of metal with a view of ascertaining which would best resist corrosion. They had something like sixty power houses and were now using open-hearth steel, his people considering it the most economical, for the reason that when they specified wrought iron, they paid for wrought iron and got steel anyway. They did, however, use charcoal iron for safe ends for tubes, because they felt that they got a little better weld between the charcoal wrought iron and the steel tubes than they did with steel safe ends.

Mr. Speller replied that a committee of the American Society for Testing Materials had gone into this subject very thoroughly, and their verdict, in which they say that the acid test is unreliable and misleading, will be found in the *Proceedings* of that society for 1908 or 1909. The reason is that there is no comparison between the action of acid solutions and natural corrosion. The very pure iron that the speaker referred to as having stood the acid test is open-hearth steel refined to the very last point, so that it may contain as high as 99½ per cent. iron. So far the indications are that ordinary soft steel, if properly made, will stand up just as well, but it will be some time before we have enough tests to actually prove that point. They felt that steel especially made for welding is as good as anything procurable at present. They had watched this point for several years. The usual method of testing was to compare a set of tubes of one material with another in the same engine. They would then duplicate them and reverse the position in the engine. Sometimes railroad men preferred to take several engines and put several sets of tubes in. They had made tests on at least twenty railroads, with the result that they had found very little difference between modern steel and charcoal iron.

Mr. Lovekin said that about ten years ago he had fitted six steamers that were built for the American-Hawaiian Steamship Company, with the Shelby cold-rolled steel tubes, and they have been running with both coal and oil fuel ever since, with no tube troubles. Since that time they have built about twenty steamships, all of them fitted with the Shelby tubes. The small amount of trouble experienced in marine practice as compared with locomotive practice might be due to the fact that the marine men do not cool and heat up their boilers as the railroad people do. In a ship a fire is kept up continuously, sometimes for sixty days. With an oil-fired furnace no cold air enters; the temperature is much more uniform and the conditions more favorable. On the other hand, they had had trouble in their power houses and blamed it on the steel tubes (feed pipes?) which had rusted out in six years. They now have wrought-iron tubes and do not know whether they will last six years or not. He thought that the trouble was from air in the feed line. He asked Mr. Speller to explain what was meant by a Spellerized tube.

Mr. Speller replied that five or six years ago they started to study the question of corrosion in all its phases, and found that the amount of forging and working which steel received was a factor that had much to do with the durability of the material, so they got up a process, which has become known by the name referred to. It has a decidedly beneficial effect, but it is not the only thing by any means. Care must be taken in the making of the steel itself. They found that the lap-welded steel tubes so made will stand up at least as well as the best charcoal iron.

Doctor Unger said that the two points which had impressed him in listening to the paper and the discussion were—how easy it is for the user to destroy material that was initially good, and how easy it is for the purchaser to insist on specifications that do not have any value. Anybody who is interested in the question of corrosion can find a full discussion of experiments in the *Proceedings* of the Iron and Steel Institute for 1908. This fact, not previously known to metallurgists, was found: If iron or steel is heated to about what we call a blue heat, or approximately a temperature at which lead would melt, it would be corroded much more quickly than if quenched from a higher to a lower temperature. It is easy to see how one in welding tubes may get a condition such as that described.

We know that our water supply is becoming much more impure. On account of the coal developments the water has become much polluted, and it frequently happens that we have in the Monongahela river as much as seventy parts of sulphuric acid to a million of water. This means that the plant to treat this water requires a great deal of salts, and by an analysis of the water used in the boiler we frequently find that we are trying to make steam from what one might call a solution of brine.

The air in Pittsburg one hundred years ago was much more pure than at the present time. Vegetation is disappearing. We are filling the air with poisonous gases, with the consequence that roofs made of iron and steel will not last as long as formerly. You all know that the tinplate made years ago was very much better than today. The same is said of galvanized materials. He also understood that steamfitters must not use anything but wrought-iron pipes, especially if they go through ash piles, because they will be corroded very much quicker. "There is nothing lasts like old-fashioned wrought iron." They had taken locomotives and put some steel tubes and wrought-iron tubes in them, and after about three years the wrought-iron tubes were removed and found to be badly corroded and pitted and would not hold steam any longer, while the steel tubes put in in the same way and at the same time were in good condition. In order to satisfy himself on this question he had been carrying on experiments for three or four years by immersing wrought-iron and steel tubes for a period of a year, and then removing and cleaning them to learn the results. They afterward placed both wrought-iron and steel tubes in an ash pile for fifteen months, and had them removed and cleaned. They now have tubes buried in loam, and expect to allow them to remain there for two years to see what the effect will be. They had a number of sheets of various material, bessemer steel, two grades, open-hearth steel and three grades of wrought iron. They cut small pieces of these sheets and gave them what is known as the acid test. In one case a good grade of wrought iron dissolved 30 per cent. slower in acid than did the steel, but he found that the iron that had dissolved so slowly in acid did not resist atmospheric influences by one-half as well as the steel sheet. The only real test of corrosion today is an exposure test under service conditions.

Mr. Conrad said that corrosion is due, not only to impurities in the water, but to expansion and poor circulation and low temperature in the boiler. It has been his experience on modern locomotives, with tubes 20 feet and over in length, that the tube corroded mostly from the front tube sheet back about 4 feet. His conclusion was that this was due to the fact that the circulation was poorer at the front end of the boiler than further back, and the temperature lower. Dissolved oxygen and gases will attack iron at a low much more quickly than at a higher temperature. On one case, where an engine had run 101,000 miles with both iron and steel tubes, there were forty-six iron against fourteen steel tubes that were pitted badly enough to be consigned to the scrap pile. On three other engines, which had made a mileage of 62,000 miles, when laid up for general repairs the iron and steel tubes with which they were fitted had stood up equally well. Some years ago they had had trouble with corrosion in condensers and had tried a number of different kinds of tubes. They finally settled upon a brass tube, which resisted corrosion very well, but the bottom of the condenser would have holes eaten into it. They came to the conclusion that it was due to poor circulation, and overcame it by entering the steam at the bottom. He found that in certain cases tubes had been spaced too closely, impairing the circulation and producing trouble. This is especially true of an alkali water, which has a tendency to pull away from the hot sheets. He had seen this demonstrated by a model boiler with 1/4-inch tubes, filled with an alkali water, and heated by alcohol. When the water began to circulate and the fire became intense, the water frequently left the sheet, but only momentarily. This, of course, had a tendency to loosen the tube in the sheet.

A speaker said that they had been using steel tubes for about twelve years in districts that had very bad water. They used steel safe ends, with the seamless tubes. In heating for welding in the safe ends they do not depend upon swedging the tube, but ream it, thus giving a bright surface. They also cut off the safe ends with dies, which gives two bright surfaces of new metal to come together for welding. Their tubes are tested by hydraulic pressure up to about 300 pounds, and seldom develop a leak. It does not matter what kind of a tube you buy, if it is not given proper care. In applying their tubes at first they used a roller, but are using it very little now. At the roundhouse the rolls have been thrown away entirely.

It was stated that the superintendent of motive power on one of the railroad systems had reduced their boiler troubles to a minimum by carrying 10 per cent. below the pressure of steam allowed; that is, on boilers which were allowed 200 pounds, they carried only 180, and the question was raised as to why it would not be well to extend this practice to the railroads which were having boiler difficulties.

Mr. Redding replied that they need every ounce of power that they can get. He had tried both iron and steel tubes and found that the steel safe ends and the steel tubes would stand more punishment. On engines which do not receive very severe treatment they frequently have tubes that last too long, for some of the State laws require that they be removed every three years.

Mr. Lovekin asked what was the use of the copper ferrule between the tube and tube sheet. He said that he had visited the works of the Babcock & Wilcox Company abroad, and their manager said that they had very little trouble with tubes, as they reamed all of the holes and ground every tube, allowing no more than 0.005 clearance between the tubes and the aperture.

Mr. Conrad explained that the reason for the use of the copper ferrule is that that material is much softer and has a greater coefficient of expansion than iron. It helps to make a joint and cushions the tube, maintaining the tube tighter. He has known of a case where orders have been given on a railroad to extend the copper the same length that they would the tube, with the consequence that the tube was entirely away from the sheet, but the expansion of the copper under the bead was disastrous.

That the purchase of coal on specifications needs to be followed up with analyses of the deliveries has been amusingly demonstrated by the recent experience of a Massachusetts city. The school board of this city has for some time been buying coal for the school houses on specification, but only recently did it take any steps to see whether it was actually getting the quality it was paying for. Lately it has made the first analysis of the coal delivered to it, and discovered that the coal was below the stipulated quality. As a result of this analysis, costing $10, the coal dealer has paid to the city a rebate of $873.01.

Sampling Coal

Following are the specifications for sampling coal as prepared by Arthur D. Little, Incorporated, chemists and engineers, of Boston. By this process the final sample is fairly representative of the entire shipment:

The original sample should preferably be collected in a large receptacle with the cover attached, by taking small shovelfuls from many parts of the car, barge or vessel as it is being unloaded, or from as nearly all parts of a pile as possible, care being taken in all cases to secure practically the same amounts from the top, middle and bottom of the coal. The original sample thus taken should amount to 500 pounds or more, preferably 1000 to 2000 pounds. A separate sample should be taken from each thousand tons or less delivered.

The gross sample thus collected should contain the same proportion of lump and fine coal as exists in the whole shipment. It should be protected from the weather in order to avoid gain or loss in moisture and should be immediately quartered down to a smaller sample, according to the following method:

The large lumps of coal and impurities should be broken down on a clean, hard, dry floor with a suitable maul or sledge, and after being thoroughly mixed, should be formed in a conical pile. The pile is then quartered, the two opposite quarters are rejected and the remaining two broken down to a smaller size, mixed and reformed in a conical pile and quartered as before. This process should be continued until the lumps are 1/4 inch in size or smaller and a one- or two-quart final sample remains. All of this final sample should be placed immediately in one or more glass or metal jars and sealed air tight. The following table gives the largest sizes allowable in the samples of various weights and the coal should preferably be broken into still smaller sizes before quartering:

Weight of Sample	Largest Piece Allowable
[illegible] pounds or over	[illegible]
[illegible] pounds	[illegible]
[illegible] pounds	[illegible]
[illegible] pounds	[illegible]
[illegible] pounds	[illegible]
[illegible] pounds	[illegible]

The sample should be worked down as rapidly as possible to avoid loss of moisture through exposure to the air. The outside of the jar should be plainly marked and a corresponding designation placed inside. The following data should accompany the sample:

Electrical Department

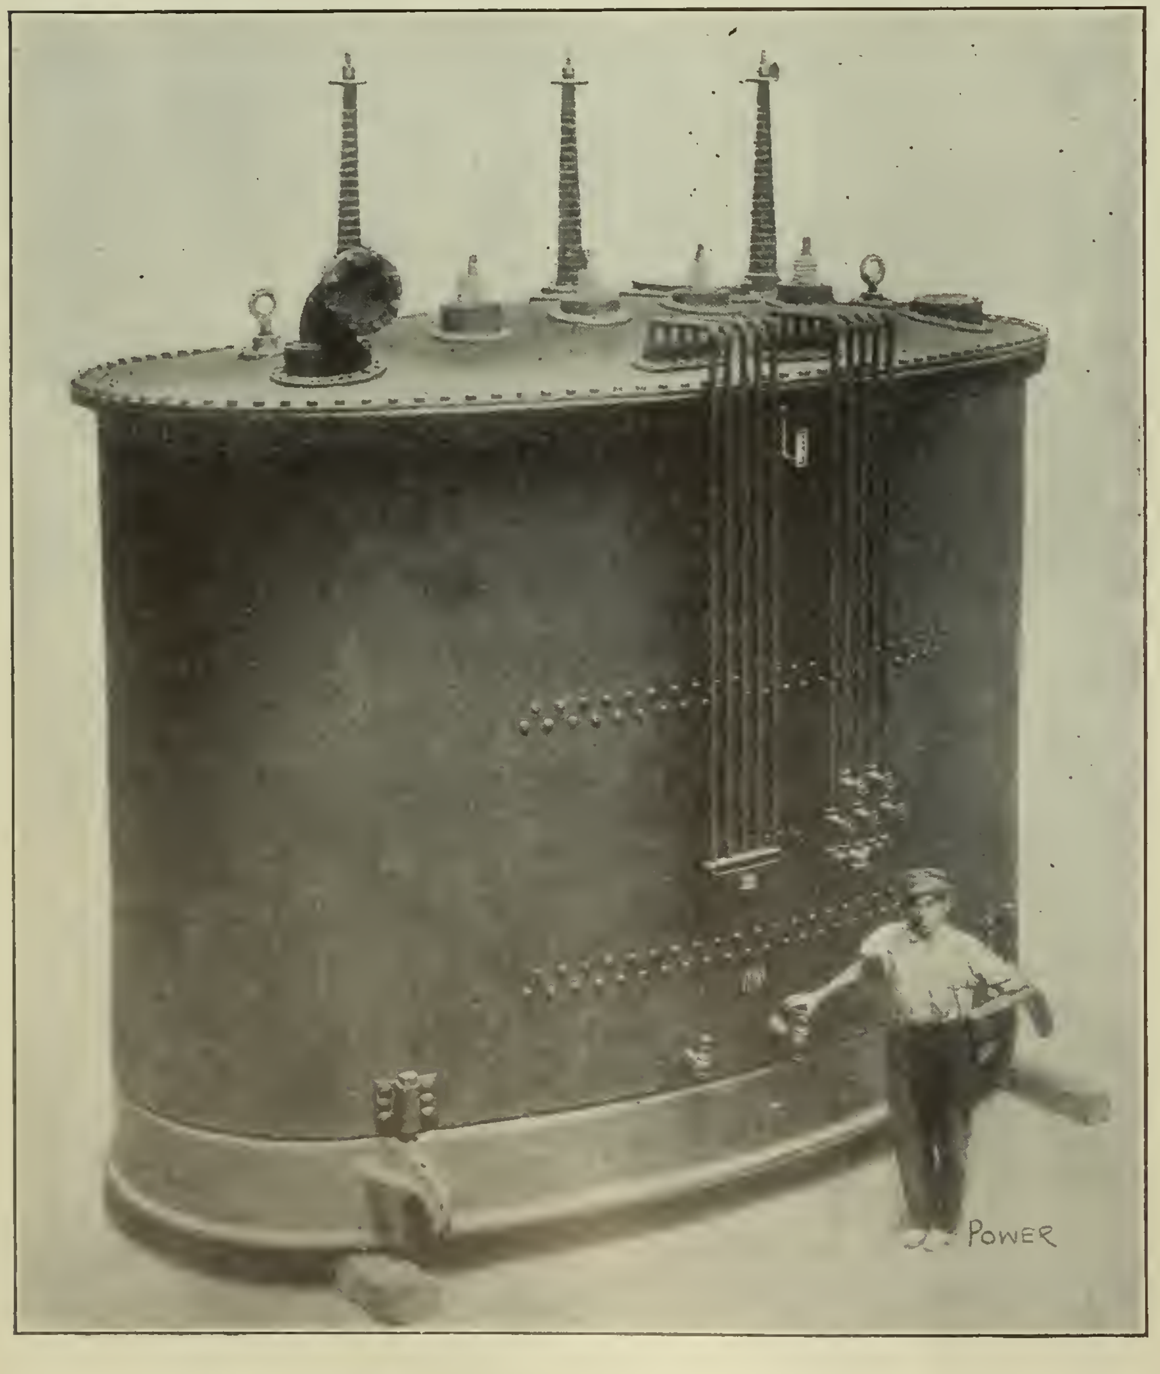
Especially conducted to be of interest and service to the men in charge of the electrical equipment

A Large Transformer

The Pennsylvania Water and Power Company generates power from the Susquehanna river at McCall's Ferry, where it will have an ultimate capacity estimated at 100,000 kilowatts. At present the power generated is transmitted 40 miles to Baltimore, and lines to other large cities, of which there are several within economical transmission distance, are contemplated.

The Baltimore substation at present contains four Westinghouse three-phase transformers which are interesting because they are the largest ever built. They are of the water-cooled shell type and are used to step down the 25-cycle line currents from 70,000 to 13,200 volts for primary distribution. Each transformer is rated at 10,000 kilovolt-amperes. The appearance of one of these transformers is shown in the accompanying picture, but this does not give an adequate impression of their size. The tank is elliptical, having an overall length of 15 feet 11 inches and an overall width of 8 feet 8 inches. The hight to the tops of the terminals is over 16 feet and the joint between the tank and the cover is 11½ feet from the floor. The weight of each transformer, complete with oil, is about 145,000 pounds—nearly 75 tons.

It is difficult to get a mental grasp of the magnitude of such a piece of apparatus. If the output of one of these transformers were delivered to 16-candlepower tungsten lamps, it would supply 500,000 of them; these lamps laid end to end would form a "string" 31½ miles long. If suspended at intervals of 10½ feet, they would illuminate a pathway a thousand miles long. Using arc lamps instead of incandescents, one transformer would supply 25,000 lamps and these would illuminate a boulevard 100 feet wide, reaching from New York City to Toledo, O., or from Chicago to Memphis, Tenn.



A 10,000 Kilovolt-ampere Transformer

Grooving Commutators

By C. L. Greer

It has for some time been a practice in street-railway shops to groove or undercut the commutators of car motors but the practice does not seem to have spread extensively to power-station apparatus. From my own experience I believe that this practice would be helpful in many cases of commutator trouble with generators and rotary converters. Where there is a tendency to high mica, the undercutting of the commutator (cutting the mica below the surface of the copper bars) will greatly reduce and sometimes completely eliminate sparking at the brushes. I know of a 300-kilowatt motor-generator set which gave continuous trouble from sparking, making frequent turning of the commutator necessary. After grooving the commutator the machine ran sparklessly and the commutator took on the chocolate-colored polish which follows perfect commutation.

I once had the care of a 250-kilowatt three-phase rotary converter which gave continuous trouble from sparking at the brushes. The commutator developed burned blackened spots at irregular intervals around its circumference. In some places six or eight bars were affected and in others only two or three were burned. The accompanying sketch illustrates the results of the trouble. The bar burned away from the mica, with bad sparking at the brush as the bar passed from under it. This kept the commutator very rough, making frequent use of the sand-paper block necessary. Finally it was decided to groove the mica out at the bad places, after which there was a decided improvement.

Where no special means is provided for grooving, the work may be done with a hack-saw blade. A new blade should be broken, which leaves a sharp tooth on the broken end of one piece; with this the mica may be cut down easily. A straight-

Effects of High Mica

edge may be laid along the mica and the blade drawn along between the bars. One or two strokes will produce a groove which the blade will follow easily. Only a slight depression is necessary; I have found a sixty-fourth of an inch to be sufficient. If, as in the case of my rotary converter, the trouble occurs in spots, the bad bars may be marked on the end before turning the commutator and only the mica at the bad spots cut down. Though my experience with this remedy has been limited, I believe that it is worth trying where sparking and burning of the bars occur.

Alternators for Waterwheel Drive

Alternators direct-coupled to waterwheels operating under such heads as are common in modern hydroelectric power plants run at relatively high speeds and operate under conditions which make rugged construction necessary. Hence one finds machines built especially for this class of service. In general features the waterwheel-driven alternator does not differ from its prototype driven by a large reciprocating steam engine; the chief differences are in mechanical construction.

Fig. 1 illustrates a polyphase alternator built by the General Electric Company for use in hydraulic stations. The picture shows clearly that the shaft and bearings are exceptionally massive; that the shaft and base are made extra long, to permit sliding the stationary armature along the base far enough to uncover

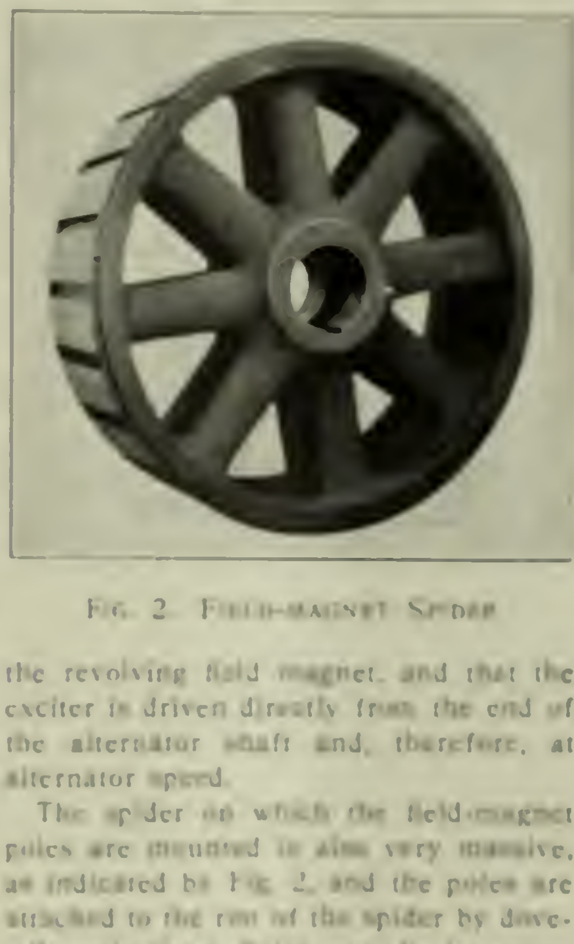


Fig. 2. Field-magnet Spider

the revolving field magnet, and that the exciter is driven directly from the end of the alternator shaft and, therefore, at alternator speed.

The spider on which the field-magnet poles are mounted is also very massive, as indicated by Fig. 2, and the poles are attached to the rim of the spider by dovetail projections fitting snugly in corresponding slots across the face of the spider. The poles are prevented from shifting in their slots by end rings bolted to the edges of the spider; these are shown in position in Fig. 2. The poles are laminated and the laminations are bolted together between heavy cheeks, as shown in Fig. 3. The free ends of the poles are stamped with extensions, or poletips, as usual, and the cheeks cover the polar extensions and are provided with flanges which support the ends of the coils.

The armature core is built up of circular segments with the joints staggered in successive layers, as usual in large

Fig. 3. Field-magnet Pole

sizes, and these are dovetailed in ribs across the inner face of the housing in exactly the same way that the magnet poles are dovetailed to the spider rim. Fig. 4 shows this construction and also shows a simple bolted-on type of magnet pole that is used in alternators which run at sufficiently low speeds not to require the dovetail fastening. The armature housing is ventilated by openings through the main ring and by spaces behind and at the sides of the armature core, as illustrated in Fig. 3. The core

Fig. 4. Section of Armature

and joints are ventilated by the usual spaces or radial ducts at intervals in the core body; two of these spaces are provided in the core here illustrated.

When the armature winding is a basket coil, the protecting coils are secured to

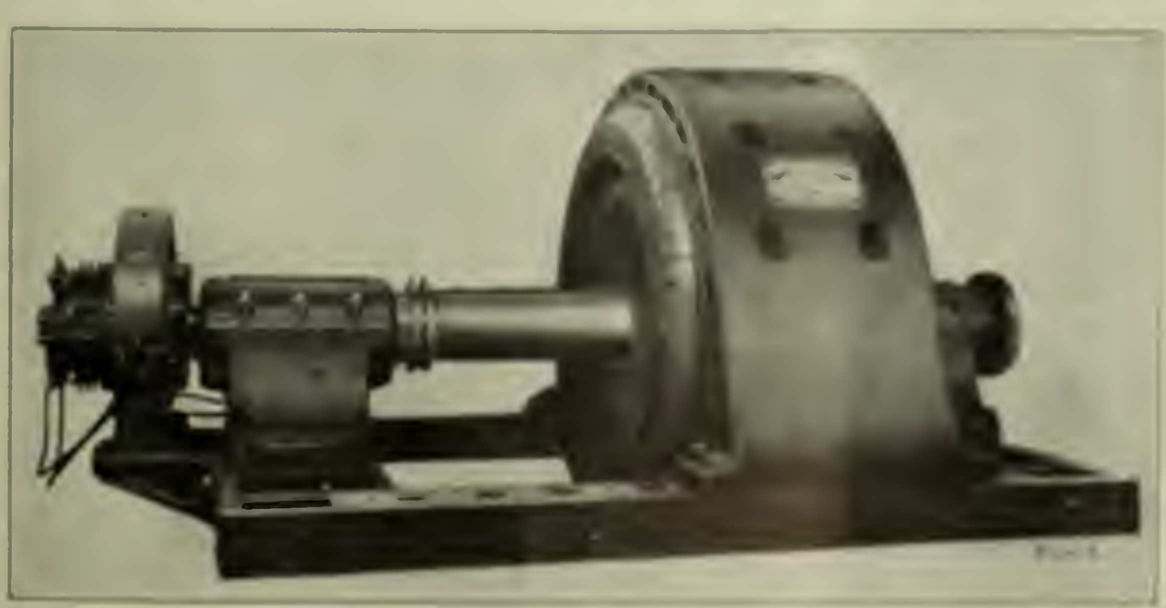

Fig. 1. Alternator for Direct Drive by Waterwheel

insulated metal rings in order to prevent accidental displacement or distortion due to magnetic disturbances produced by violent load fluctuations. Both the field-magnet and armature coils are form-wound and heavily insulated, of course, before being put in place.

The bearings are self-oiling and in the larger sizes provision is made for water-

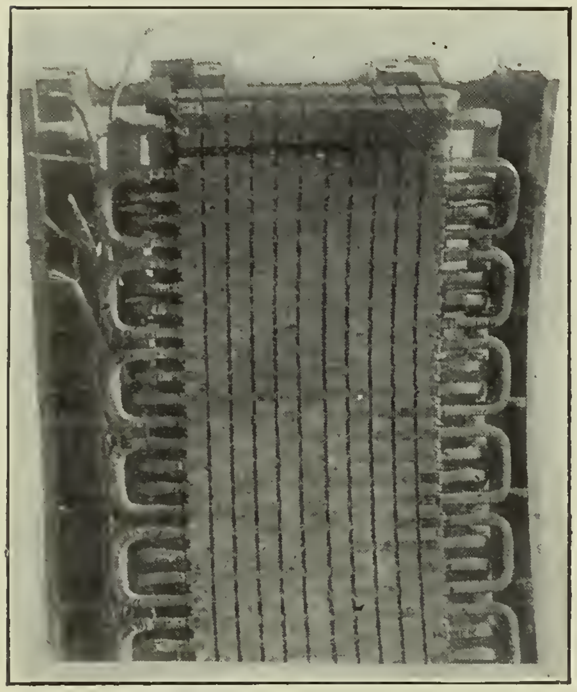

Fig. 5. Part of Armature Face

cooling by means of tubes extending horizontally through the oil wells; the cooling water is circulated through these tubes and takes out the heat from the oil.

CORRESPONDENCE

Trouble with Series Incandescent Lamps

We had a little experience with a lamp on a series circuit which, although not exactly in the usual operating engineer's line, may prove of interest to plant operators in smaller places who have more or less to do with the outside distributing system.

Our street circuit contains 67 series incandescent lamps of 32 candlepower each, supplied with a constant current of 6.6 amperes controlled by a reactive regulator. We added one new lamp to the circuit and on the first night it burned out. It was replaced the next day and the burned-out lamp was found to have a hole burned in the glass, but not much importance was ascribed to this fact. The next night the operation was repeated and the damaged lamp was found in the same condition as the first one. This appeared strange, as in a series system all the lamps get the same current and it was not reasonable to suppose that a lamp at any particular point could receive any more current than the others.

Our next move was to take one of the old lamps from another point in the system, and try it at this point; it worked perfectly. We next put in a new lamp and it burned out in less than five minutes; it looked like a defective lamp, but we decided to investigate elsewhere before trying any more lamps. An examination at the station showed that the circuit was getting a little more than 7 amperes. The regulator was adjusted to pass exactly 6.6 amperes and another new lamp was put in; after that no more trouble was experienced. That was more than six months ago and we have added a number of new lamps since but have had no more trouble with burnouts.

By way of explanation, there had been no new lamps added to the system for some time previous to the trouble and it was known that the regulator could not have been out of adjustment for any great length of time.

Can anyone explain why the new lamps would not stand the excessive current and the old ones would?

G. S. Sprague.

Geneva, Neb.

Mr. Wilbraham's Interpole Motor Trouble

I found Mr. Wilbraham's article of March 28 concerning brush setting on interpole motors very interesting, but cannot in all respects agree with his conclusions. He states that he had compound-wound interpole machines arranged for variable speed by means of a combined armature and field controller and that after cutting out all armature resistance the speed was 800 revolutions per minute, which by field weakening could be increased to 2800 revolutions per minute, but some of the motors at about 2600 revolutions per minute would stop and reverse.

While the armature reaction and flux distortion are more or less as he outlines them, the fact that the motor stops and reverses is not due to a shifting of the neutral point and with it the zone of commutation but to the fact that the compound winding is differential rather than cumulative. As the magnetism due to the current in the series winding is maximum and that due to the shunt field current constantly decreases as the field is weakened, the final result is reversal of the polarity of the field-magnet poles and consequent reversal of the direction of rotation. Now if the series field winding were so connected that it assisted the shunt field winding instead of opposing it, the action described could not take place. Changing the direction of the current in the series winding is, therefore, to my mind the correct remedy rather than shifting the brushes.

It is primarily an error to buy a compound-wound interpole motor, for several reasons. Trouble may be caused by it, as already shown, and the compounding adds uselessly to the cost. The series winding on the interpoles of a shunt-wound motor will serve the same purpose as a main series winding; therefore, a main series winding in addition to this represents a duplication of equipment subserving no desirable end.

H. T. Dean.

Cambridge, Mass.

Mr. Dean's idea as to the prevention of the reversal of the motors by changing the series field windings from differential to cumulative is correct; that was tried at the time but the commutation was so much worse that it was abandoned. Moreover, preventing the motors from reversing was not the only thing to be considered; the guarantees as to speeds at different points had to be met and with the series field winding connected cumulatively the magnetic densities were so high that a greater range of shunt field adjustment was necessary to effect the range of actual field strength that was necessary. For this reason, as well as because of the impaired commutation, the remedy used was the only one that was practical under the operating conditions.

Mr. Dean's supposition that the interpole winding serves the same purpose as the series winding of a compound-wound machine is entirely wrong. The interpole winding adds no torque or counter electromotive force whatever to the armature; a shunt-wound interpole motor will have the same sort of speed characteristic as the ordinary shunt-wound motor, except that the speed regulation will not be so good because of the additional resistance of the interpole winding in series with the armature. It is to correct this poor regulation that a differential field winding is used. The only use of the interpoles is to give good commutation under conditions which would cause sparking in an ordinary motor and this is done by inducing in the coils that are short-circuited by the brushes an e.m.f. which reverses the current in those coils and thereby prepares them for insertion in series with the coils beyond them. The interpoles exert no influence upon the coils that are not short-circuited and these are the coils that do the work.

R. W. Wilbraham.

Philadelphia, Penn.

[The delay in printing the foregoing letters was due to our inability to reach Mr. Wilbraham, who was absent from his office.—Editor.]

Bill Grimes tried t' get funny tother day an' put wun over on yer Uncle Si; he didn't get anythin' on me so ez it cud be notised very much. He called me up an' sed he'd lost th' vacuum on his condenser, an' ast me ef I'd loan 'im wun. I told 'im ter use th' wun he carried in his hed.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

A Reversing Marine Diesel Engine*

By Th. Saubeblich

The prejudice against Diesel motors which still exists in shipbuilding circles has to a great extent broken down, and recently it has become clear that various shipyards are in position to build Diesel engines free from faults and reliable in working, even with their present equipment.

Hitherto the Diesel engine has been made almost exclusively single-acting. As a rule, the four-stroke cycle has been used, but recently the two-stroke cycle has come into prominence. The efforts to utilize the Diesel engine for large stations and finally for the propulsion of large vessels have given an impetus to the employment of double-acting engines both on the four-stroke and two-stroke cycles. In fact, leading ship owners, having recognized the great value of internal-combustion engines, are already approaching shipbuilders with orders involving their use.

The constructor is now confronted with the task of giving to the Diesel engine the reliability in working and capacity for maneuvering which distinguish the marine steam engine, and further, in consequence of the absence of steam supply, to find gear simple enough in handling and maintenance to suit the rough requirements of a ship's auxiliaries.

The advantages of the Diesel engine for marine purposes as compared with the steam engine differ according to the type of ship and the size of the equipment, but in general the following are among the most notable: The gain in useful space by the reduction [elimination?] of boiler equipment and small size of the fuel holders; increased capacity due to the small weight of the engines and the fuel; utmost utilization of the otherwise limited useful space taken for fuel bunkers; gain in time, and economy of wages due to quicker and easier bunkering, and also to decrease in coal trimming; quicker starting of the engine; reduced and easier management; wages and space economy by reduction of the number of the stokers; reduced cost of fuel; better engine rooms, resulting in the increased mechanical capacity of the personnel, especially in hot climates; the possibility of carrying more fuel, and therefore enlarged field of action.

But the introduction of Diesel marine engines also involves the solution of recent economic and constructional problems, of which the chief are the lack of suitable fuel in many harbors and the lack of steam for actuating the auxiliary engines on deck and in the engine room, as well as for heating.

The engine here described is the first marine Diesel engine built according to special design and put into service by a shipyard on the North Sea—J. Frerichs & Co., in Osterholz-Scharmbeck and Einswarden. It is a reversing four-cylinder engine of 200 horsepower, installed in the service boat "Frerichs," which is a single-screw vessel. She has been in commission about a year, being used principally, but also serving occasionally for transportation between Einswarden shipyard and the opposite bank of the Weser. The fuel employed is the so-called gas-oil, 1000 kilograms (2200 pounds) of which are stored in two tanks under the cabin. Double this quantity can, however, be carried. This quantity of fuel is sufficient for a voyage of 240 sea miles at 9½ knots.

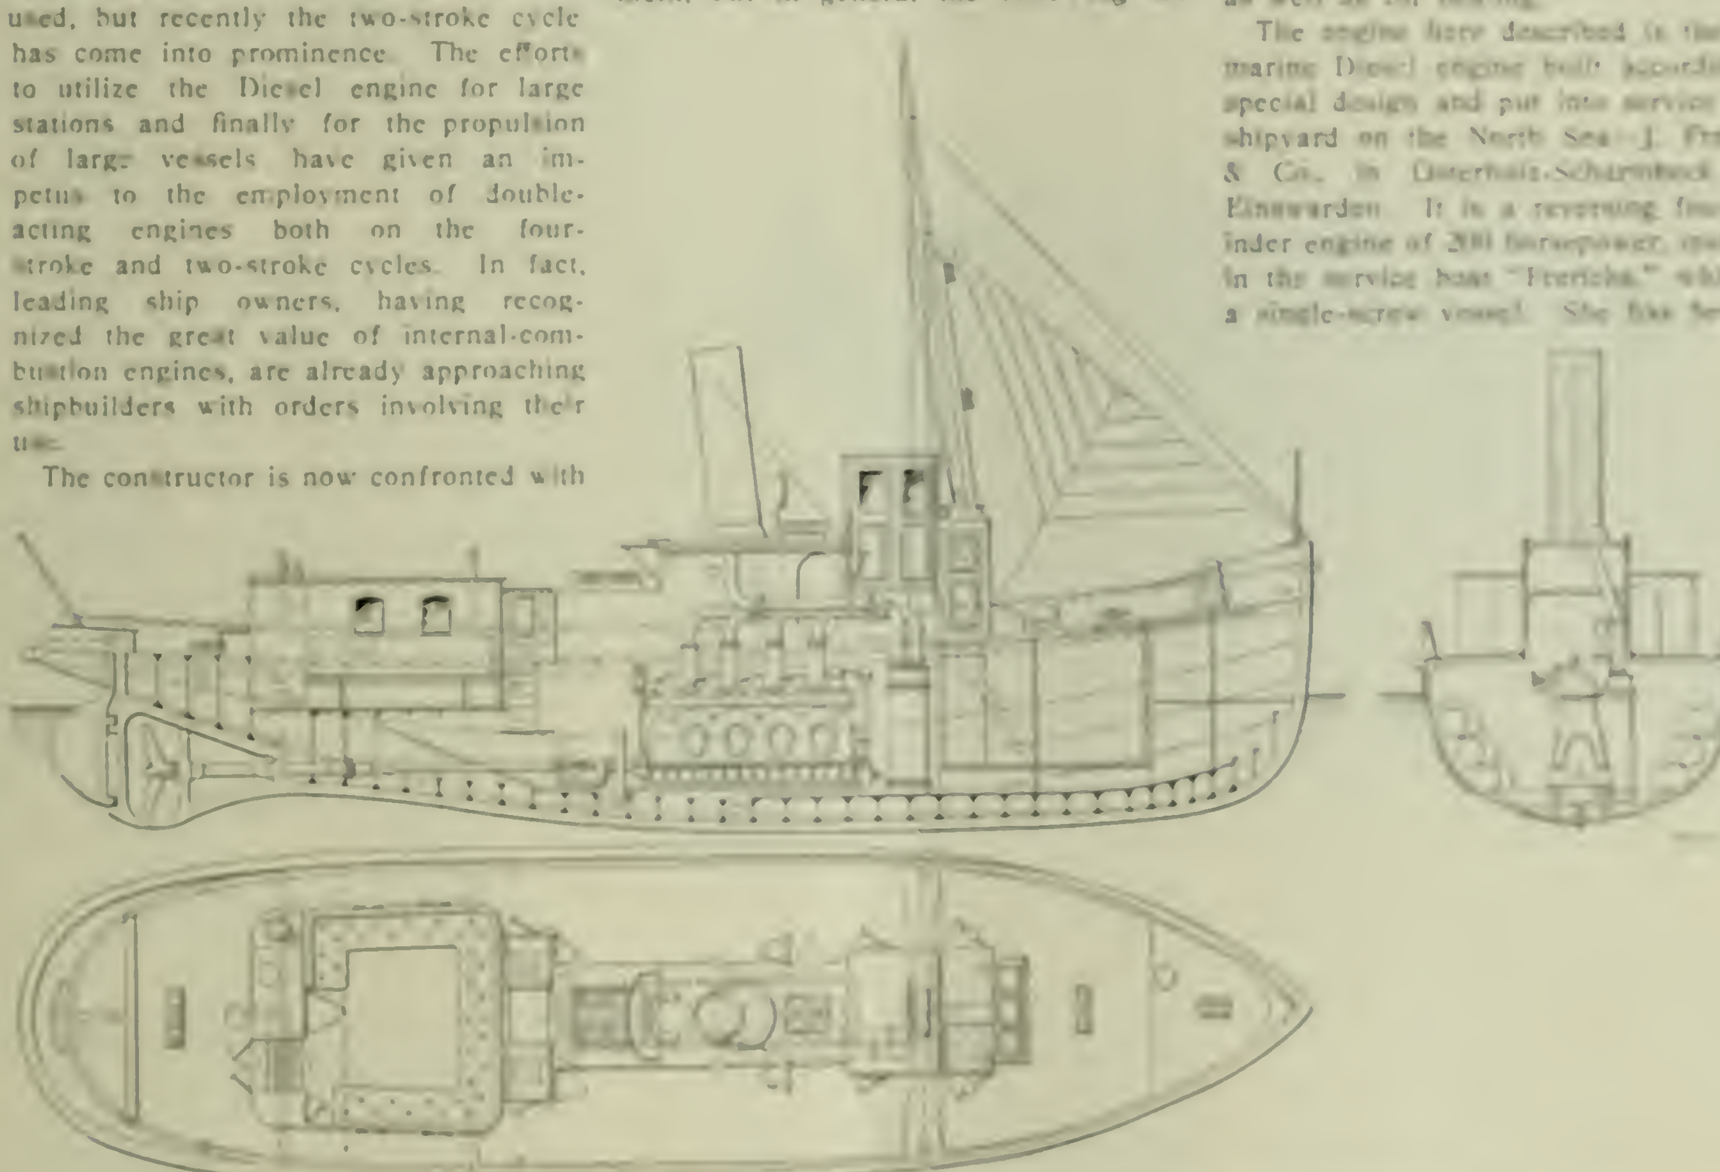

Fig. 1. Showing Arrangement of Diesel Engine Equipment of the "Frerichs"

*Abstract of a paper recently read before the Schiffbautechnische Gesellschaft (Technical Shipbuilders' Association), Germany.

The external appearance of the vessel is similar to that of a steam tug, because of the funnel provided for carrying away the exhaust gases.

Fig. 1 shows the arrangement of the power plant in the vessel and Fig. 2 gives an excellent idea of the appearance of the engine. It operates on the four-stroke cycle and the maximum speed is 360 revolutions per minute; at this speed it develops 200 brake horsepower—50 horsepower per cylinder—and drives the vessel at a speed of about 10 knots.

The cylinder head is the largest and heaviest casting in the engine, and on it are collected all the principal valves—the suction valve, the exhaust valve, the starting valve and the fuel valve. All these parts have to be got into a restricted area little bigger than the piston diameter, and yet to avoid unequal thicknesses of metal reasonable spaces must be left between the separate parts. This arrangement is also necessary to insure equal cooling and to avoid stresses being set up by unequal heating. Furthermore, an exceedingly sound casting is absolutely essential, particularly at the joints and valve faces and at those surfaces subjected to the high internal pressure in the cylinder or connected with the high-pressure air supply.

Fig. 3 indicates how all these requirements were met. As may be seen from the engraving, the suction and exhaust bends are separated from the two tubes or passages which take the starting and fuel valves. The exhaust bend is entirely surrounded by water and is of such a shape as to give an easy flow to the gases. The exhaust and admission valves seat direct on the cover, for in no other way was it possible to bring them so close together.

It may be objected to this arrangement that dismantling is more difficult than when separate valve cages are employed, as it involves the removal of the whole cylinder head, but in engines of this size no trouble in this direction has been experienced. The only real objection is that that part of the valve spindle exposed to the hot gases may wear more rapidly than the remainder, which is water cooled, but to reduce this objection the lower part of the spindle is protected by a cone from the direct impact of the hot gases. In the case of larger valves the employment of a liner is, of course, recommended. In order to make the cooling as effective as possible, the walls are made only ½ inch thick.

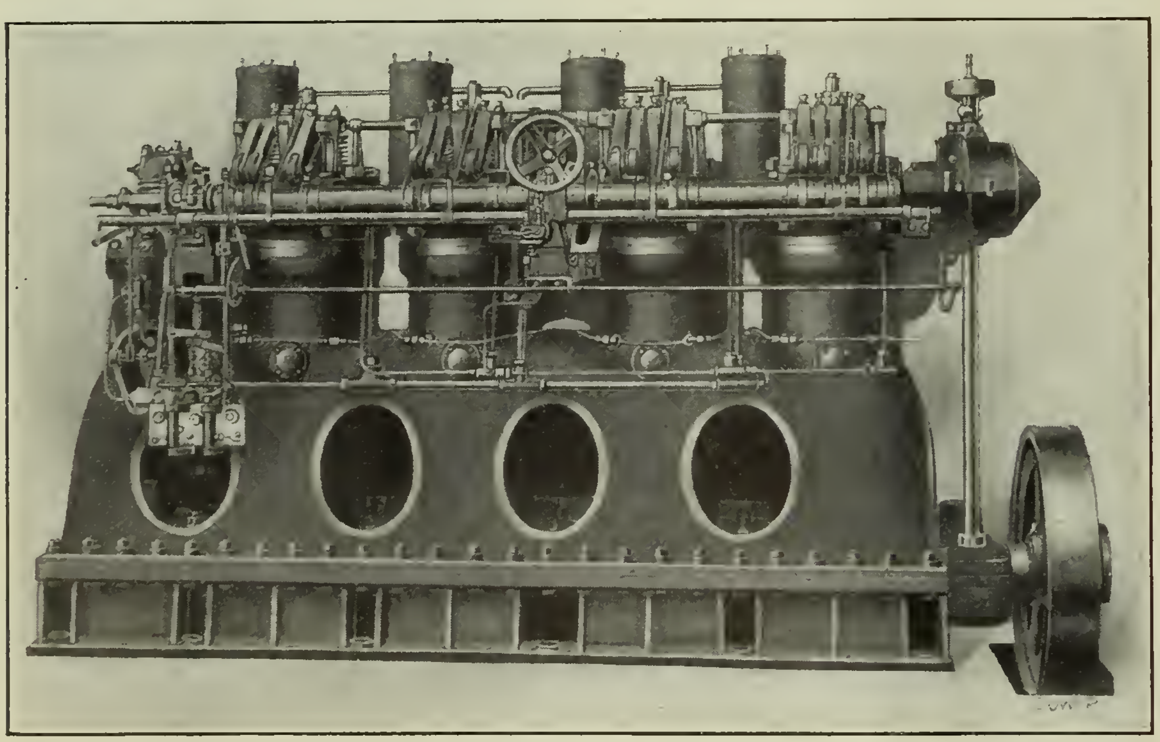

Fig. 2. A 200-horsepower Reversing Marine Diesel Engine

The reversing gear of the engine is based on the principle of shifting the cam shaft, on which two separate sets of cams are fashioned, endwise, the valve levers being raised just before this movement takes place and lowered again when it is complete. These movements are effected in the following way by the use of a single handwheel: The shaft *a*, Fig. 4, passes over all the cylinder heads, being carried by the columns *b*, of which there are two mounted on each head. To this shaft are keyed the fingers *c*, one over each exhaust and inlet valve, and the lever *d*, linked by *e* to the curved lever *f*, which, in turn, is linked to the piston rod of the reversing cylinder; the latter has pipe connections *g* and *h* extending to the valve box beneath the handwheel. Here either valve can be released by movement of the ⊥ lever *l*, which is effected by one end or the other of the notched quadrant *n* coming into contact with it; this quadrant is keyed to the handwheel shaft. The valve being opened, further movement of the plate releases the lever and the valve again closes. Owing to the form of the quadrant *n* and the notches in the quadrant *p*, this movement can only be effected in the central position *II*.

In Fig. 5 is shown a sector *T* which is provided with the cam face which moves the lever *B*, and thus moves the reversing cam shaft *N* endwise. The sector is coupled, by the link shown, to the shaft *w*.

The action of the reversing gear will now be easily understood. The hand wheel is moved to the middle position and is then revolved till the stop *r* on the notched quadrant comes against the quadrant *p* and stops further movement. During this action the valve *i* would be opened for a short time, allowing compressed air to get under the piston *k*, forcing it up. This causes movement of the linkage and presses the valves down into the cylinder. When they have reached their lowest position the action of the cam *T* moves the cam shaft endwise. By that time the piston *k* has returned to its starting position, lowering the valve rockers on to the second set of cams. The glycerin dashpot acts as a brake to prevent reversal taking place too violently.

Provision for lifting the rocker arms of the starting and fuel valves off their cams is effected, as indicated in Fig. 6, by mounting the respective rockers on eccentrics keyed to the shaft *w*. By turning the sleeve, the fuel-valve lever moves away from its cam while the starting-valve lever approaches its own cam; in this position both levers are clear of their cams and the shaft can be moved end-

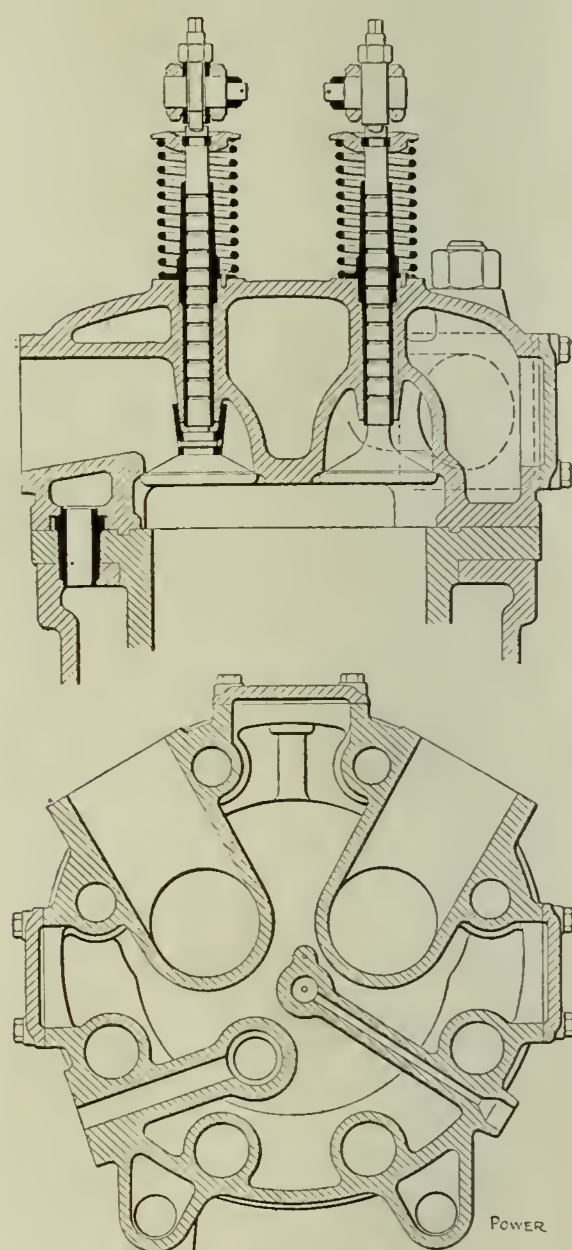

Fig. 3. Cylinder-head Sections

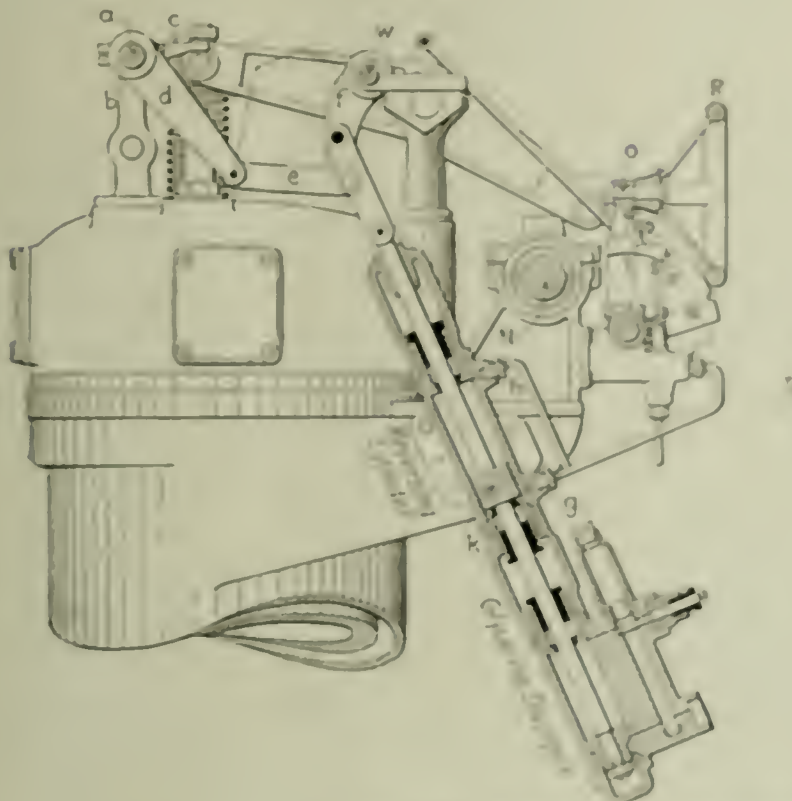
wise. By further movement to the starting position, the fuel-valve lever leaves its cam while the starting-valve lever comes into actual contact with its own.



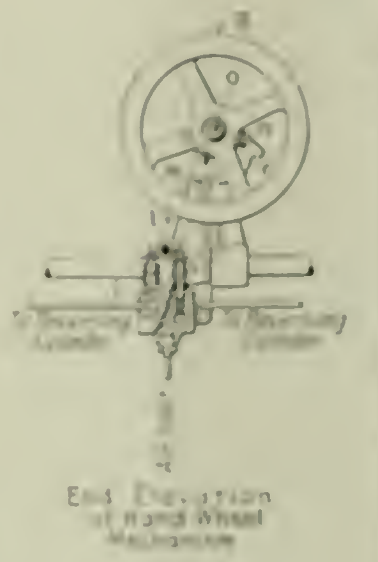


Fig. 4. Reversing Mechanism

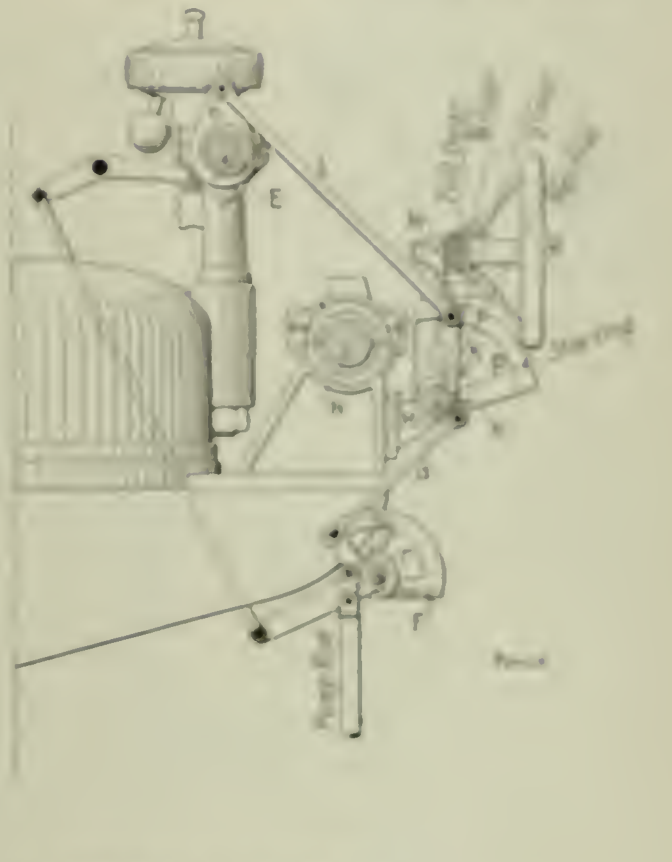

Fig. 7. Reverse-gear Details

Rotation is given to the eccentric sleeve by means of the mechanism shown in Fig. 7, from which it will be seen that it is coupled by the rod *L* to the shaft *M*, to which is also keyed the hand-wheel bracket *H*. This bracket, with the hand wheel, can be moved to three principal positions on the notched quadrant *p*: the first for running, the second neutral and the third or lowest for starting. Further notches for half and slow speeds are also provided. This control is effected through the link *d*, which acts upon the fuel-pump regulator rod. As the centrifugal governor also acts upon this rod, an elastic coupling in the form

Fig. 5. Cam-shaft Shifting Mechanism

of a flat spring *F* is provided. The governor was originally provided for the test stand, but in view of the fact that the engine might run light it has been retained.

The engine is started by means of compressed air and the compressor is a two-stage machine driven from the main shaft by a crank which is so set that when the engine cranks are on the dead center the compressor crank is not. Consequently, the compressor can be used as an air motor to start the engine even though the latter may stop on the center, which, however, is unlikely. Fig. 8 is a sectional elevation of the compressor. The low-pressure stage is double-acting and with-

Fig. 6. Air- and Oil-valve Mechanism

out suction valves, air being admitted by the piston overrunning a central port. On this low-pressure cylinder are placed the starting valves *A* and *B*, operated by the cams and links shown. This stage being double-acting, it is easy to arrange that it shall start in any position from which it is not possible for the power cylinders to start.

The lubrication of the gudgeon pins, which is always troublesome, is effected in this engine by the device shown by Fig. 9. The tube *A* on the piston at each outward stroke is driven into oil contained in the cup shown, some oil enters the tube and, being retained by the little ball valve, is driven up by the next stroke of the tube.

It is not generally possible to obtain such good diagrams from high-speed as from low-speed engines, owing to the very short space of time in which combustion has to take place, but almost ideal diagrams, as shown in Fig. 10, are obtained from this one. The average pressure shown by this diagram is about eight atmospheres. The fuel consumption measured on the test bench is between 215 and 220 grams (7½ ounces) per brake horsepower-hour.

The boat which is driven by the engine just described fully meets all the expecta-

Fig. 8. Air Compressor

tions formed of her as to maneuvering. The insurance companies have made exhaustive tests in this respect with a view to fixing the premiums payable and have satisfied themselves that the maneuvering capacity is equivalent to that of a steamship; they have therefore made the premium the same as that customary for steamships. The maximum speed of the

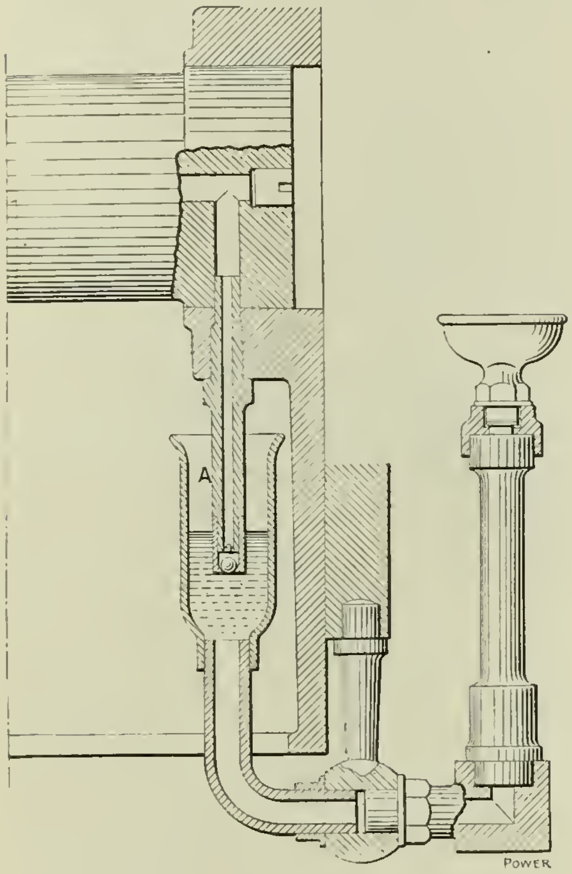

FIG. 9. GUDGEON-PIN OILER

FIG. 10. AN AVERAGE DIAGRAM

boat can be reduced, by regulating the engine, from about 10 miles to about 3.8 miles per hour, the revolutions of the engine being lowered from 360 per minute to about 150 per minute.

Reversing is carried out with surprising celerity and smoothness. Tests carried out in comparison with similar ships with steam engines have given the results stated in the accompanying table.

Comparison of Actual Gas Power and Central Station Figures

BY SAMUEL W. RUSHMORE

The central-station people have been urging us to use their service for our plant* having motors of a total rated capacity of 350 horsepower, at the following wholesale rates:

CENTRAL STATION RATE FOR 20,000 KILOWATT HOURS PER MONTH

Primary charge per month..........	$225.00
First 3,000 kw.-hours @ 3c..........	90.00
7,000 kw.-hours @ 2c..............	140.00
10,000 kw.-hours (or over) @ 1c. kw.-hr	100.00
Total per month at present load....	$555.00

As we are using producer gas for our japanning ovens, soldering-iron and annealing furnaces and blacksmith forge, if we adopted the central-station service we would be obliged to purchase about $125 worth of city gas per month, making the total cost of station service for our present load of 20,000 kilowatt-hours per month 3.9 cents per kilowatt-hour.

We therefore made a test run of one week, keeping the fuel bed in the producer at constant level and carefully weighing all coal used day and night. The switchboard watt-hour meter had been calibrated and found to be accurate a short time before; also, the water meter in the connection to the vaporizer. The producer is of our own construction, of the common suction type with a shaking grate; the fuel bed is 5 feet in diameter and carried 5 feet deep above the grate. The test was made with two single-cylinder horizontal Körting engines: one of 21¼-inch bore by 34½-inch stroke, rated 140 horsepower at 160 revolutions per minute, and the other of 19¼-inch bore by 31½-inch stroke, rated at 100 horsepower at 155 revolutions per minute. Business being rather slack, the total load was only about 180 horsepower but of a very steady character.

In addition to the engines there is a Sturtevant gas exhauster drawing the gas from the producer for the furnaces; this quantity is estimated at about 125,000 cubic feet during the week. The plant was operated nine hours a day for the first five days and four hours on Saturday. The total energy delivered from the switchboard was 5094 kilowatt-hours, with following operating costs:

Total pea coal consumed during the test, including all standby losses, 15,218 lb. @ $3.15 per ton..................	$21.51
7½ gallons cylinder oil @ 40c..........	3.00
5 gallons engine oil @ 25c............	1.25
2 gallons kerosene @ 10c.............	0.20
8 lb. waste @ 10c..................	0.80
Wages, engineer and producer man....	33.00
Total............................	$59.76

*Manufacturing acetylene-gas search lamps.

According to these figures the average cost of labor and supplies was 1.17 cents per kilowatt-hour. If, however, we credit the plant with $30, which would otherwise be paid for city gas, the cost comes down to about 0.6 cent per kilowatt-hour. Of course, these figures do not include any fixed charges or repairs, but with liberal allowance for these items the cost directly chargeable to power would not be much over 1¼ cents per kilowatt-hour. Should we adopt the central-station power, we would not throw out the engine plant, so the comparison was made on actual operating cost.

In this particular plant the cost of repairs is practically negligible. The 100-horsepower engine has been in operation for about four years, often day and night, with no actual repairs. The large engine has been running for over a year with only the usual adjustments, costing about $10 per engine (average for two years) every sixty days. In two years the producer has required no repairs. We dump the fire only twice a year and point up the brickwork with carborundum cement. The producer had been in continuous service without dumping for three months prior to the test.

During the test the water meter showed that the vaporizer had taken 91 cubic feet of water, or about 0.38 pound of water per pound of coal. The water was all evaporated and passed through the fire. The gas was of good quality throughout and there was no trouble from clinkers. Noting the low water consumption and having been told that the proper ratio was 0.7, we tried to increase the water feed, but this seemed to impair the quality of the gas and the best results were obtained with the proportion stated.

In our plant the exhaust gas is passed through a special boiler from which we obtain about 150 pounds of steam per hour. Although this was not considered in the test it forms a valuable addition to our steam-heating plant and during the summer months when the heating boiler is shut down we use a large part of this steam for distilled water in our chemical work and for drinking in shop. The jacket water from the engine is passed through pipes buried in the cement floor of one of the buildings, making a further saving in coal for heating; all things considered, therefore, we believe we are producing our power at a cost, including all charges, of not much over 1 cent per kilowatt-hour.

To the quoted cost of central-station power must be added interest and depreciation on a $3000 investment for a motor-generator—about $25 per month—and at least $15 per month for attendance.

We have two producers, each rated at 200 horsepower, but up to 225-horsepower output we secure very satisfactory results with but one in service.

Some Test

Herewith are the results of a recent boiler test with which I do not agree.

In the first place, the test was started with what he designated as a "flying start," which consists of running the boiler to its utmost capacity for an hour, getting the walls white hot, then winging the fire back and forth on the grate several times and immediately starting to weigh water.

The first thing he did after starting was to rake all the coke and unburned coal from the ashpit that had been dropping through the grate bars during the preliminary run and put it on the fire, although it was not weighed and no record taken or allowance made. This performance was repeated three times during the nine hours' run.

The log of the test shows 121 weighings of water, 37 readings of feed-water temperature, 109 readings of steam-gage pressures and 17 readings of stack temperatures and drafts.

The accompanying table gives, first, the results of the test as a whole, and, second, the results for the first and the last half of the test as shown by the detailed log and by memoranda not forming a part of the official record.

The first reading of the steam pressure at the start was 132 pounds. The pressure kept going up until a maximum of 148 pounds was reached within the first 20 minutes and continued high for some time. The highest pressure recorded for the last hour of the run was 124 pounds, from which it gradually decreased until the finish of the test, when it was 93 pounds.

At the start there was a good, clear 8-inch fire and at the finish there was not enough fire to barely cover the grate; as was evidenced by the fact that it was dead out and the walls black in ten minutes after the draft was shut off and the test stopped. No new coal was used in the last thirty minutes, although the steam pressure was steadily falling; in fact, 32 pounds of coal was weighed back as not used.

I have been present at or have conducted many boiler tests, but I never yet have been able, by fair means, to increase the evaporation in the last half of a test and make it 9 per cent. better than in the first half when the fire was new and clean and the walls red hot from the preliminary run.

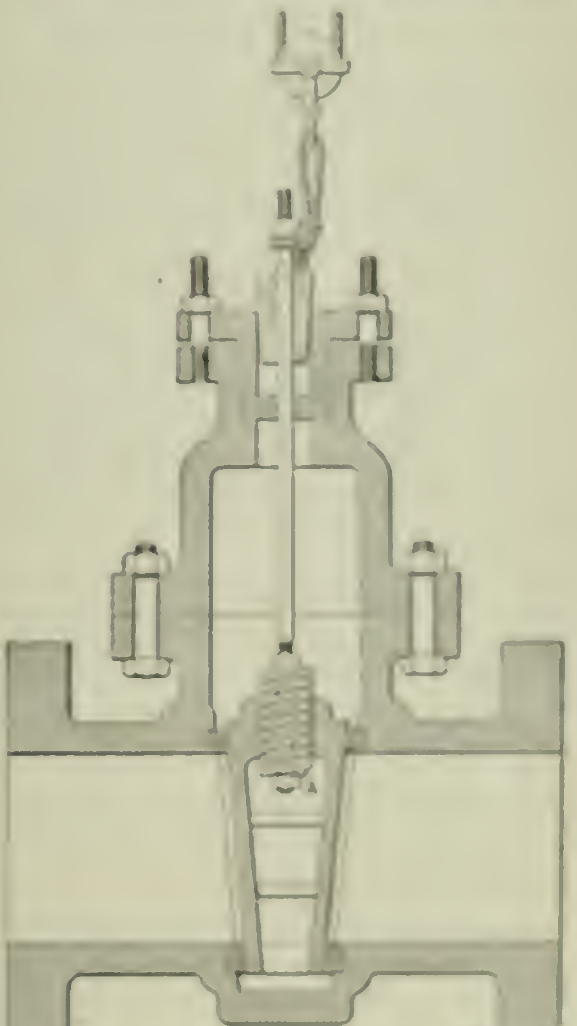
Operating a Broken Valve

A pumping engine was shut down in order to renew some rubber valves and make other minor repairs. When the work on this unit was completed the discharge valve was opened and the pump was slowly started while the suction valve was being opened. The valve at first turned hard and then, all at once, turned easier than usual. It was thought at the time that the threads on the stem had worn down. So the gear wheels, packing box, gland and valve stem were removed and just below the collar it was found that the stem had twisted off, the result of an old fracture.

To get a new valve stem and cut threads on it would take some time. It was necessary, however, that the pump should be started as soon as possible for the water supply in reserve was decreasing while this unit was down. It was decided to open the valve with a tackle, a part



SHOWING HOW THE VALVE WAS REPAIRED AND OPERATED

of the threaded stem was cut off and a hole drilled through from end to end for a threaded rod so that a nut could be screwed on each side of the stem to hold it tight in the valve disk, as shown in sketch at A.

Threads were put on the other end of the rod for a nut. Then the end with the threaded stem was screwed into the valve disk and the packing box put into place. A wooden plug with a hole in the center through which the rod could pass was made to fit the packing box.

The plug was hammered in place and a nut was screwed on the end of the rod and a rope fastened to it. From a beam above, a tackle was fastened and connected to the rope on the rod. The engine was then started as usual and the valve was gradually opened by means of the tackle.

Some air leaked in around the rod where it passed through the plug. As this type of pump is given air on its suction, to make it run smoothly it is not necessary to stop the leakage. When convenient the pump was shut down and a new stem was put in place.

Tank Gage

Water is pumped from a well into a tank several hundred yards distant from the engine room. This tank is fitted with a float indicator, but owing to the fact that it was not in view of the engine room an inconvenience was experienced.

To remedy this fault a pipe line was run from the tank to the boiler room, on the end of which was connected a low-reading pressure gage. The gage was placed on the wall of the engine room beside the steam gage. Aside from having a very neat appearance, it is accurate and saves the attendant many useless steps.

Boilers Foam

In my plant there are five 78-inch by 18-foot return-tubular boilers. These boilers are supplied with water from three sources: First, from what is known as table water from the mine; second, drain tile water from the farm, and third, deep-well water. The deep-well water is practically the same as the table water from the mine.

Trouble is encountered with the engines taking over water from the middle to the latter part of the week on account of the boilers foaming.

Nos. 1, 2 and 3 are domeless boilers and each has a 6-inch pipe connection about the center of the boiler on top for supplying steam to the main header. The water line is carried about 18 inches from the top of the shell.

No. 4 boiler has a 30-inch dome. Inside the dome, in the upper sheet, there are four 4-inch openings which allow steam to pass into the dome and through a 6-inch pipe to the main header.

No. 5 boiler has a 36-inch dome also and an opening of 8x14 inches in the upper shell inside the dome to allow the steam to pass into the dome and from there through a 6-inch pipe into the main header.

The foaming trouble only occurs when the hoist engines are in operation and, sometimes, after they have been in motion a few minutes. Most of the trouble apparently comes from the domeless boilers.

These boilers are washed out once a week and the water is carried as low as safety will allow.

Can any engineer suggest a remedy for this foaming and state whether the domeless boilers are responsible for the trouble?

JAMES M. STEWART.

Elgin, Ill.

Did Not Hook On

The diagram herewith is from the low-pressure cylinder of a Corliss cross-compound engine, one end of which did not hook on.

Why does the diagram from that end include any area? Why does not the expansion line follow back upon the same line as the compression?

Furthermore, the expansion line for the last half of its length runs practically parallel with the atmospheric. What holds it up?

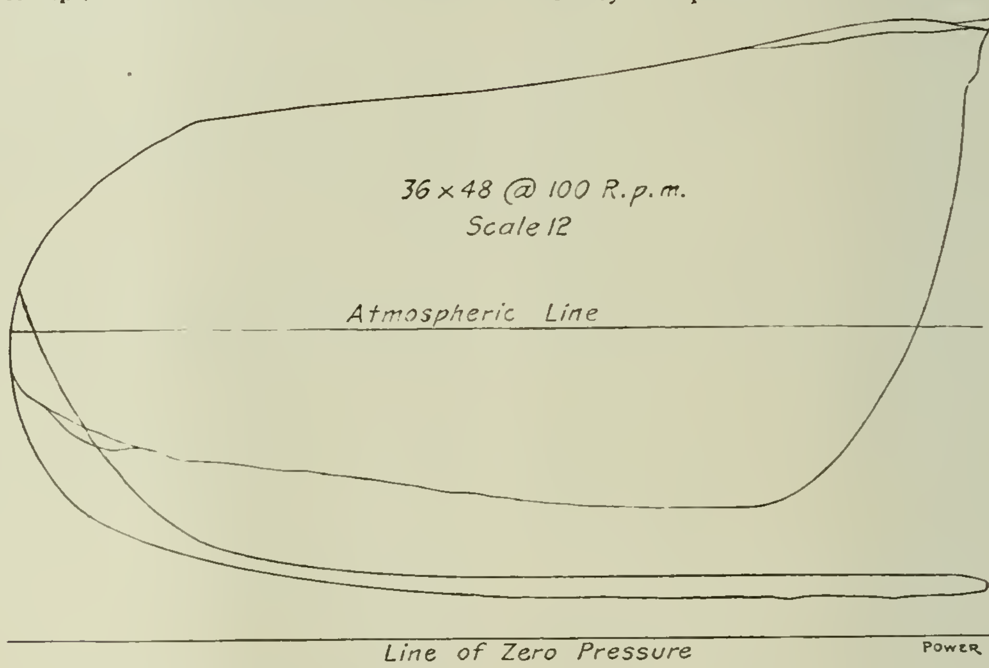

DIAGRAM FROM LOW-PRESSURE CYLINDER OF CORLISS ENGINE

The diagram was taken with a 12 spring.

Shall be interested to see the comments of POWER readers upon it.

New York City.

Co-operation

The personal factors in a power plant are, the proprietor or the board of directors, the chief engineer, the assistant engineers and the rank and file. Each of these has his own business to attend to and any encroachment causes friction and ultimate trouble.

The owner, or the board of directors in the person of the managing director, is the "boss." He superintends the marketing of the power and has plenty to do in interviewing and arranging terms with customers and keeping an eye on the net financial efficiency of the concern.

It is to the advantage of the chief engineer to get up schemes for increasing the efficiency and cutting the costs of the plant operation. To him should be left the purchase of fuel, lubricants and other supplies and stores, the examination of subordinates and the ordering of the internal management and working of the engine-room and boiler-house staff.

The assistant engineers should look upon their chief as a friend who is there to be consulted and not, as is too often the case, as a man who is holding down a better job and is, therefore, to be envied and, if possible, ousted. All repairs and adjustments should be made by, or under the immediate supervision of the assistant engineers and their reports should be passed on to the chief.

The rank and file, or the oilers, water tenders and firemen, should be under the immediate control of the shift engineer with whom they are working, but complaints of all kinds, whether from the ranks or from the assistants, should have the personal attention of the chief.

Everyone in the plant should have free access to the "boss" at all reasonable times. One of the surest ways to insure friendly coöperation and smooth working is by the "boss" considering the personal comforts of the staff by the provision of good accommodations in the way of coat cupboards, lavatories and the like.

Manchester, Eng.

Blowoff Valve Left Open

The boiler equipment of a plant where an accident recently happened, consisted of two return-tubular boilers set in one battery with the blowoff pipes connected to a single pipe at the rear.

One boiler had been cut out for cleaning, and, after it was washed out, the engineer went inside to examine the internal conditions. His assistant was left in charge of the plant. When the usual time arrived for blowing down the boiler under steam, he opened the blowoff cock.

The cock on the dead boiler was still open and as the steam filled the idle boiler the engineer inside was scalded to death instantly. This was the result of carelessness on the part of two men and both should have known better than to have gone about their work with the blowoff valve open.

EDWARD T. BINNS.

Philadelphia, Penn.

Solvents in Boiler Water

In most methods of feeding solvents into steam boilers the amount of the solvent fed bears no fixed relation to the amount of the feed water used and, although the solvent may be fed in direct proportion to the feed water, the amount of the scale-forming matter in the water often varies. Therefore, some means of determining the strength of the solvent in the water in the boiler is desirable.

Too much solvent in the water is a waste and may also cause foaming; too little solvent leaves scale-forming matter that is not acted upon.

A simple test for compounds containing soda, soda-ash, or tri-sodium phosphate is phenolpthalein. If the phenolpthalein, which can be purchased at most any drug store, is dissolved in alcohol and five or six drops of the solution added to one-half pint of the water to be tested the water will assume a red or pink color, the shade depending on the amount of soda in the water. A large amount of the soda will produce a deep red color; a small amount will produce a lighter pink color.

If the sample of the water to be tested is drawn from the water column, care should be taken to blow out all condensation before taking the sample. The water should be allowed to cool before testing and the same proportions of solution and water should be adhered to for uniform results.

If the engineer will apply this test to the water in his boiler each day just before introducing the compound used and vary the amount of the compound according to the strength of that already in the boiler he will effect a saving in compound and secure better results.

Skimmer Caused Boiler to Scale

There are two boilers in the plant where I am employed, one of 40 horsepower and one of 100 horsepower capacity.

Before a producer-gas plant was installed, the large boiler was used to run the works and the small boiler was used for heating purposes. Both boilers were fired extremely hard. The 100-horsepower boiler had a boiler cleaner attached to the back of the boiler on the inside for the purpose of removing all the scum from the water. The small boiler had no cleaner.

We cleaned the boilers once a month and used the same water in both and under the same treatment. To the surprise of all, the large boiler was always badly scaled and nothing that was done would prevent it. The small boiler never had as much as a double handful of scale, and that was in the form of a soft, white sludge that was easily washed out. The same boiler compound was used in both boilers.

After weeks of hard work, I decided to take off the cleaner, and while some may think it a queer thing to do, it turned the trick. There has been no more trouble with scale and the tubes are as clean as the day they were put in. It appears that there was something in the water that the cleaner took out that prevented the boiler scaling when it got a chance to work.

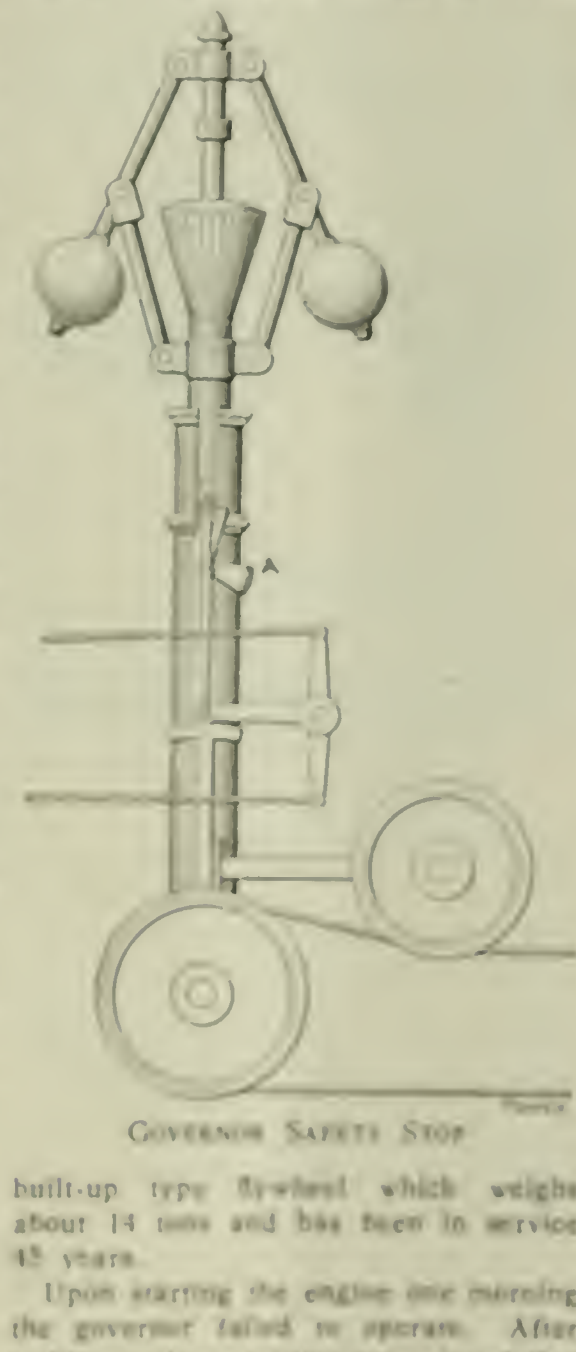
Governor Safety Stop

The accompanying sketch shows a safety device for a governor which I have had on a 16x42-inch Corliss engine that has been in constant service for 31 years. This engine carries a 16-foot built-up type flywheel which weighs about 14 tons and has been in service 15 years.



GOVERNOR SAFETY STOP

Upon starting the engine one morning the governor failed to operate. After making a close examination I found that the key holding the pinion on the upright shaft had worked out. Had this key come out while the engine was running, the engine would have been wrecked. The governor is of the old style, with a safety device which acts only when the governor belt breaks, as shown in the sketch.

I afterward discarded the belt arrangement and fixed a safety latch on the governor column, as shown at *A*. This latch rests under the guide boss, which is connected to the bell crank, when the engine is not in motion. Upon starting the engine this latch drops out of the path of the guide movement as soon as the governor rises from it. This allows the governor full control, if either the belt should break or anything else should affect the gearing. The latch is held in place by the hand while the engine is being stopped.

Burning Fuel Oil

The plant I am in charge of is burning crude oil as a fuel. The plant consists of a 55-horsepower automatic engine and a 16-foot by 54-inch tubular boiler. Before I started to burn oil I ran the plant on two tons of slack coal per day at $1.85 per ton.

Six barrels, 42 gallons each, of crude oil is now burned per day. The burners are of the jet type and air is drawn into the burner by the suction of the jet where it mixes with the oil in the burner.

The oil tank is located about 100 feet from the building and has a fall of 3½ feet to the burners. I would like the advice of other engineers as to whether I could run on less oil, and whether it would pay to install a pump and a gravity burner; would a heater be necessary, also?

W. A. HARLOW

Paola, Kan.

Automatic Lubricators

After an experience with automatic lubricators, since their introduction, I am convinced that their proper location is upon the cylinder or steam chest of the engine, for when so placed the temperature of the oil remains practically constant.

If the lubricator is located upon the engine frame, the temperature of the oil changes with that of the air in the room, and the amount of oil fed also varies. The ball valves used in the pump cannot seat quickly, because the low temperature of the oil causes it to become thick and the ball has a tendency to float in the oil; therefore, part of the oil drawn in at each stroke of the pump is forced back into the reservoir before the valves close. This causes the engineer as much trouble in obtaining a proper feed as the older style of lubricator.

The best results are obtainable when the plunger feeds two or three drops at each stroke and the speed of the pump is regulated to give the desired number of drops per minute.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Engine Running Under

In the March 7 issue in reply to an inquiry it was stated that the frictional load on an engine is reduced by running an engine under instead of over. This decrease, it is claimed, is made by the diagonal thrust of the connecting rod pushing the crosshead against the upper guide with a pressure which is reduced by the weight of the crosshead.

I cannot see how the frictional load is reduced, as the connecting rod in order to lift the crosshead must put a pressure equal to the weight of the crosshead on the wristpin and crankpin, thereby reducing the friction in the guides but increasing it on the wristpin and crankpin.

RUSSELL B. BUCHANAN.

Leadville, Colo.

The Stuffing Box

The interesting "talks" on the stuffing box which appear serially in the advertising space of the current issues of POWER are worthy of consideration. The statements seem revolutionary, but I am heartily in accord with them.

One of these statements, that the square-bottomed stuffing box and gland are more efficient than the beveled sort, I have always believed. Any engineer may test this by fitting babbitt rings to the bevels. Then notice the difference in gland tension required to cause ordinary

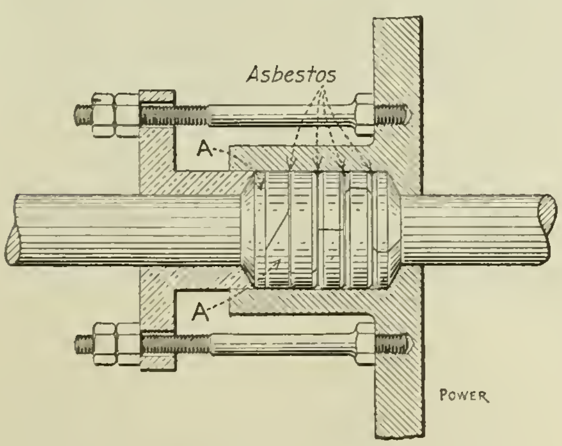

FIG. 1. A CASE OF PACKING RINGS

packing to become steam tight, as compared with that necessary to make the same packing steam tight, when the babbitt rings are omitted. As every turn of the gland nuts means increased friction on the rod, the experimenter will at once question the advantages of a beveled-bottom box. The life of the packing is considerably prolonged, as less of its elasticity is wasted when it is first applied.

Another valuable truth expressed by the writer of the "talks" is that, the temperature of the stuffing box being lowest nearest the gland, the inner rings of packing deteriorate faster than the outer rings. The inner rings, I believe, soon become nothing more than space fillers in the box, so that something more wearable and ultimately less expensive

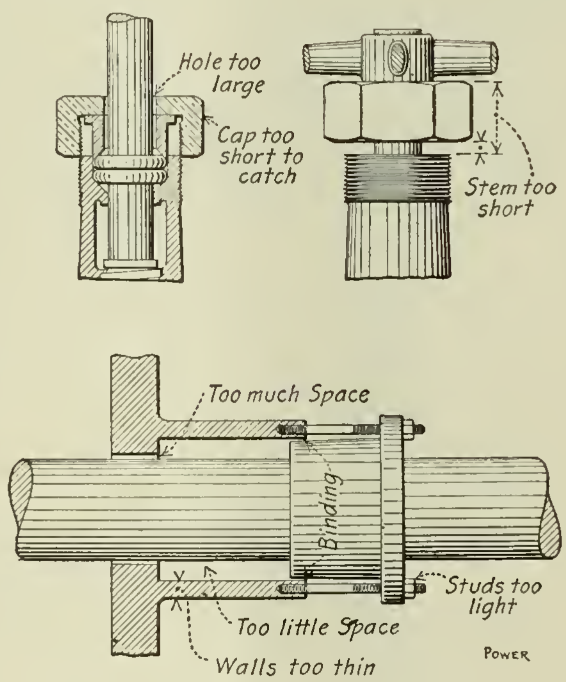

FIG. 2. COMMON FAULTS IN DESIGN

could be advantageously substituted. To test this, I once placed four well fitted babbitt rings of good grade in a certain stuffing box, which required six rings of ordinary packing to fill. Between each, a layer of asbestos was interposed, as shown in the sectional sketch in Fig. 1. Now this box when packed entirely with soft packing required renewal of its contents every six months, resulting in the use of twelve rings yearly. After the change was made the two soft rings *A* were found to give satisfactory service for four months, which now results in the use of only six rings yearly. Thus, at the expense of a little more labor, a material saving of packing was effected. And I believe there exists less total friction on the rod; though, probably, as all the friction is constrained within a narrower limit, there may be present a tendency to wear shoulders more quickly. As yet, however, the rod looks good, and shows no deleterious effect from the change, though the precaution of allowing more lubricating oil and distributing it better was taken.

I heartily wish that the writer of the

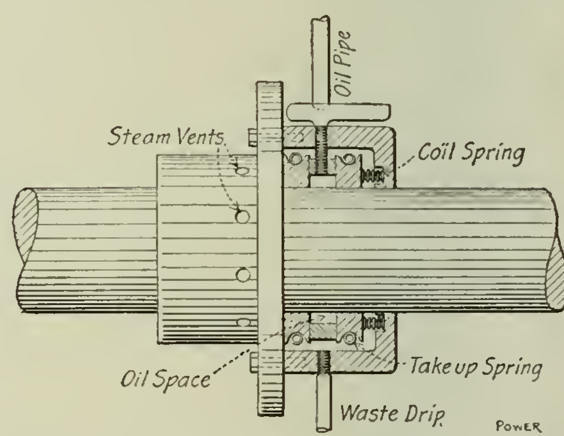

FIG. 3. PREVENTING SHOULDERS ON ROD

advertisement would discuss some of the evils of construction which at times sorely beset the engineer. In Fig. 2, I have endeavored to illustrate graphically the most common faults, with the expectation that they will be noticed by some designers. The stuffing box should not be cast integrally with the cylinder, but rather it should be bolted on in such a manner as to allow slight up and down adjustment, which would permit the packing to enter freely and fit snugly around a rod that is a trifle low of center. Even where adjustments can be made in the bull ring of the piston and the shoes of the crosshead, it is not always convenient to take off the cylinder head. If the rod is out of center with the stuffing box, how beneficial to the packing it would be, not only to be able to level the rod, but also to drop down the stuffing box to accommodate the new center, while waiting for an opportunity to center the piston.

I once ran across this improvement. An engineer had had his rod trued up and was fearful lest the packing would again form shoulders upon it. To prevent this, he bolted to the gland a small extension casing which inclosed two spring-tied metal rings; see Fig. 3. Between these he fitted a space ring which he ground oil tight with the two split rings, and into this space he led the oil pipe, which supplied a thin mixture of flour of graphite and cylinder oil. If he made a good job at surfacing the rings, it will be perceived that the rod is evenly lubricated.

M. CASSIDY.

South Framingham, Mass.

Dangerous Boilers

When reading Mr. Utz's letter in the March 28 issue, entitled "Operating a Dangerous Boiler," I was reminded of an old boiler at this place, operated by a railroad company. The boiler and engine are an old "traction" engine with the wheels removed. The back end of the boiler rests on two tee-irons and the front end is supported by railroad ties. A hole dug in the ground under the back end serves as an ashpit. The sheet around the rivets is wasted away to a dangerous extent and the plates are rusted and pitted badly. The boiler leaks badly around the mud ring and around the bolts that hold the bearing lug to the boiler. This lug supports the flywheel end of the crank shaft. The boiler is fitted with an old lever safety valve which is not in operating condition.

This outfit is used to drive a centrifugal pump which pumps water from a creek into a large reservoir. It is only run when the supply of water in the reservoir gets low. Anyone that can shovel coal is allowed to run it. One evening a few months ago, I happened along by the boiler house and saw the engineer (?) standing on the creek bridge about four rods from the boiler. I asked him what he was doing out there. He said that he was waiting for the steam to go down. When asked how much steam he had, he said that about two minutes ago when he left "her" there was 140 pounds.

Walter B. Brown.

Deshler, Ohio.

Water Hammer

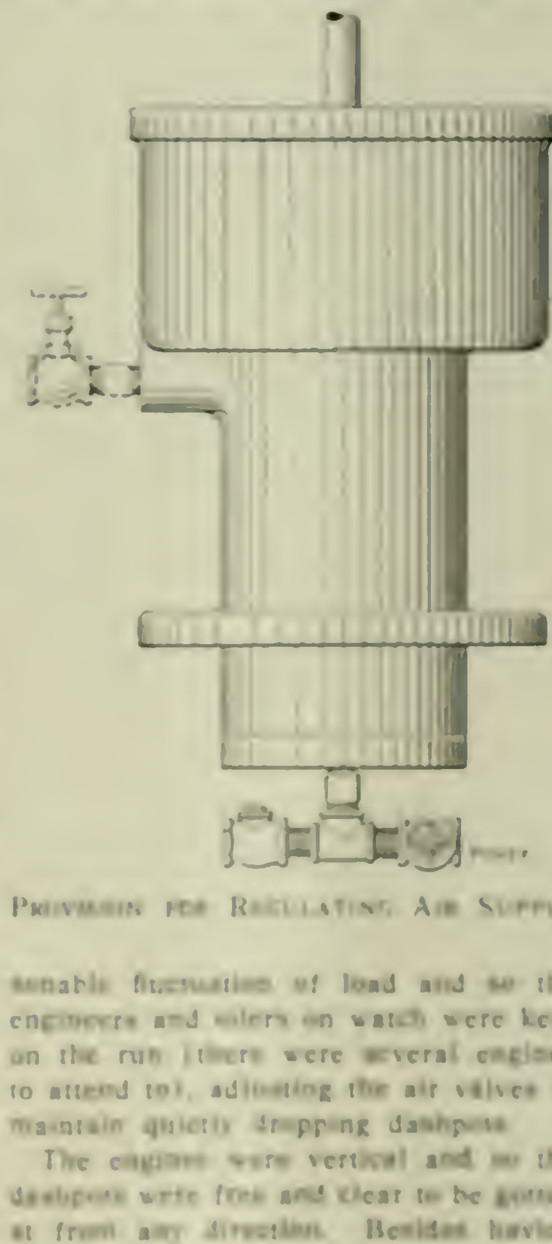
In reply to Mr. Payler's letter of March 7, in which he asks, "Is water hammer due to the presence of water lying along the bottom of the lowest part of a line of piping, or is it due to a conflict between the cold air and the inrushing hot steam which causes the violent hammering?" I think that water hammer is due to the above two causes; directly to the first cause, while the second cause helps it along, or indirectly due to it. When steam is admitted into a pipe containing air at a lower temperature than the steam, part of the steam is condensed. Water hammer can result if the amount of steam condensed is large enough to form a slug and if this slug travels at a rapid rate through the pipe. When steam is admitted into a line of piping containing cold air and water lying along the bottom of its lowest part, some of the potential energy of the steam is immediately changed into kinetic energy. This inrushing steam sets in motion the water that was there before and the condensed steam. It is the sudden stopping of this water by an elbow, a closed valve, etc., that causes the violent hammering. Again, the kinetic energy that the water had is now changed to potential energy, and if the pipe is not strong enough a rupture will occur.

Thomas H. Brickman.

New Orleans, La.

Dashpot Troubles

Dashpot troubles described by R. A. Cultra, in the April 18 issue, bring to mind something in that line which happened in a power station in which I was engaged some time ago. The low-pressure cylinders were equipped with the Corliss valve gear, with dashpots for the steam-admission valves. The pots had the regulation air-cushion valves attached, but in spite of these the pots would slam under heavy-load conditions. If attempts were made to adjust the air valves to stop the slamming, the pots would not act quickly enough with light or even normal loads. The adjustment could not be made so as to cover a reasonable fluctuation of load and so the engineers and oilers on watch were kept on the run (there were several engines to attend to), adjusting the air valves to maintain quickly dropping dashpots.



Provision for Regulating Air Supply

The engines were vertical and so the dashpots were free and clear to be gotten at from any direction. Besides having the regular air valve referred to, the center of the bottom was drilled and tapped for an ordinary brass pet cock, to drain the pot in case of leakage of oil past the leather packing and also to admit air to the chamber when drawing out the pot for overhauling. These pet cocks were of little or no use as means of regulating the drop of the pots. It was a case of the pots either dropping too hard and slamming or not dropping fast or far enough.

Someone in the station suggested that the pet cock at the bottom be taken out and a check valve, opening outward, be put in. This was tried on one of the pots with partial success. With the check valve, the slamming was not quite as bad as before, but with very heavy loads the slam was enough to be troublesome. The next move was to have a globe regulating valve connected up with the check valve, as shown in the accompanying sketch. The quantity of air admitted could be controlled to a nicety and the best thing about it was, that it could be regulated to suit quite a range in load changes. On the upstroke of the dashpot a certain amount of air was admitted through the globe valve into the vacuum chamber; when the releasing gear permitted the pot to drop, the contained air was forced out of both the check valve and globe valve, bringing the pot to its seat quietly. This depended on the hight the pot had been raised and the amount of air admitted through the globe valve.

It did not require very much skill to regulate the globe-valve opening and, when regulated, it very seldom required any more than ordinary attention. All the engines were equipped in a similar way and the men were not bothered in that way again. It is the best plan that I have ever seen for the purpose.

Charles J. Mason.

Scranton, Penn.

High Pressure Drips

I noted R. E. Knigge's comment in the April 11 issue, on my criticism of Mr. Meinzer's arrangement for returning condensation from high-pressure traps to the heating main. I must say that I am still skeptical. Theoretically, there may be an apparent gain, but practically, local conditions and the arrangement of the drip-return pipe have a great deal to do with the advisability of so utilizing the drip returns.

I have a number of high-pressure traps in the place where I am employed and I find that the drip-return pipes are quite cold a short distance from the trap. This would indicate that the heat liberated through a drop in the pressure will recondense very quickly if led away in the same pipe with the condensation. As a matter of fact, I am inclined to believe that evaporation and recondensation take place almost simultaneously.

I have had experience, as marine engineer, with compound or quadruple-expansion engines, but I have never run across such an arrangement as Mr. Knigge describes, although I readily see the advantage that may be gained by something like it but not exactly the way Mr. Knigge describes the arrangement, that is, to drain the high-pressure condensation into the low-pressure receiver. If the outlet of the high-pressure traps are connected to the low-pressure receiver by a vapor pipe which carries the vapor only to the receiver, instead of the whole condensation, the results undoubtedly would be beneficial, but if the whole condensation is led into the receiver, I am very skeptical of results.

The same thing in my opinion is true when returning high-pressure drips to the heating system. If the traps should be lined up along the heating main and piped at the outlet with a vapor pipe to the heating main and a condensed-water pipe to the heating return, I have not the slightest doubt of the benefit to be derived.

Condensed water when released from under, say, 100 pounds to atmospheric pressure or slightly above, as used for heating, will liberate enough heat to evaporate approximately one-tenth of the water. If this liberated steam is collected from all over a large plant in a common return with the condensation and carried any distance, I am of the opinion that it will recondense before getting into the heating main.

At any rate, I would not recommend to anyone to invest good money in an improvement, which seems to me very doubtful of beneficial results.

VICTOR BONN.

New York City.

Water Coils Burn Out

Many good men have encountered the difficulties described by R. A. Booth, in the April 4 number. Coils placed in a furnace require a continuous stream of water circulating through them to prevent pipes from bending or burning out. The scheme of running feed water through pipes placed in the combustion chamber has been attempted with unsatisfactory results.

An exhaust-steam feed-water heater is probably the most economical method of heating feed water; otherwise the exhaust is wasted. Exhaust from all steam pumps and other engines should be utilized for this service with proper heaters. Live-steam feed-water heaters always proved to be a success where they were properly installed and equipped. Peculiar as it appears, it has been proved that a decided economical advantage is gained with live-steam feed-water heating over hot-water heaters separately fired. Where I am employed, there were three boilers directly fired for heating-water purposes only; they were cut out and a large live-steam feed-water heater was installed. The heater received its steam supply from a battery of steam boilers already in use.

I hesitate to state the amount of fuel saved for fear my veracity may be questioned. I will state, however, that the saving in labor and fuel was considerable and that the water supply was even more satisfactory than in former times.

The pipe described by Mr. Booth burned out or bent because the water heated up to such a degree that an overpressure was raised, forcing the water out of the pipes into the boiler and leaving the pipes empty for a short period. While empty the pipes were overheated and ultimately burned out. If they lasted four months with Mr. Booth they did exceptionally well.

In several cases serious accidents have happened to boiler brickwork, due to ruptures of the feed pipes in the furnace space.

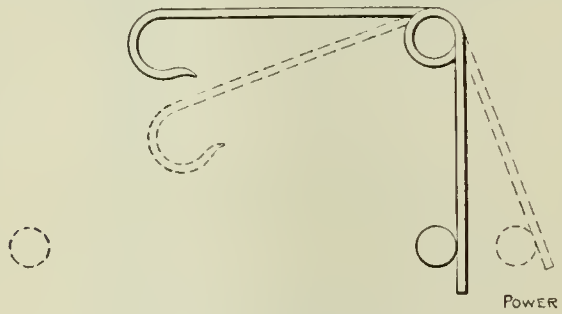
J. E. NOBLE.

Toronto, Can.

Indicator Cord Hooks

I noticed in the March 28 issue of POWER an article on indicator-cord hooks by Julian C. Smallwood. I am using a hook which is similar to the one Mr. Smallwood describes, only I believe my hook has his beaten for high speeds. After numerous attempts with several different kinds of hooks, I gave up the task of trying to indicate a high-speed engine, which was part of the power equipment of my plant.

While searching the advertising sections of POWER for a way out, I ran across a small cut of a Trill indicator with a cord hook attached. I sent for



INDICATOR-CORD HOOK

the hook at once and tried it out. I was both pleased and surprised at the results. The engine ran 220 revolutions per minute, and I indicated it without an error on the part of hooking on and unhooking. The illustration shows the hook and the method of attaching.

To hook on, hold the eye of the hook lightly between the thumb and forefinger and above the rod onto which you wish to hook. Advance the hand forward so that the hook will overlap the travel of the rod about 1½ inches. When ready to hook, drop the hand suddenly so that the rod may strike the lower part of the hook.

To unhook, close the hand around the cord and advance toward the hook until at its extreme travel it nearly touches the hand. When ready to unhook, suddenly advance the hand forward about 1½ inches, allowing the forefinger to strike the lower part of the hook.

JOHN C. PITTS.

Cherokee, Okla.

Cleanliness in the Power Plant

The editorial in a recent issue on the above subject was interesting and correct. There is perhaps no one who does not admire beautifully polished and well groomed machinery and clean, orderly power plants. It pays to keep them in that condition.

A corner filled with filth and trash invariably invites and receives more of the same. Rusty and oil-stained brightwork means more and continued rust and stain, and a greasy and ill kept floor will get into such a chronic state of deterioration that everyone who comes along will take pleasure in adding to the general mess.

Such conditions mean a slovenly crew who are too lacking in pride and ambition to keep up and properly care for the requirement in their charge, too indolent to be concerned or interested in anything but the clock.

Where the spirit of cleanliness and order is lacking in the chief, it is apt to be absent among the crew and the tendency is toward the plant "running down." In time this means a general overhauling more costly by far than if the care had been given in the regular daily order of things.

It is very easy to keep a plant to the top notch of cleanliness when once started in that direction. The spirit of neatness is infused into all hands and becomes a habit. An employee, though not directly interested, would look twice before dropping a piece of waste or trash upon a freshly scrubbed floor, and he would be a great deal less apt to roughly handle or mar the clean and shining valve gear than the rusty and oil-stained one.

Cleanliness about the power plant fosters thoroughness and carefulness in the employee, and often leads to the detection of flaws in machinery that might go unnoticed were polishing and wiping not attended to. It raises his self-respect and develops his esthetic qualities.

Cleanliness always pays from the standpoint of the engineer. Traveling salesmen spread the fame of a power plant, mill or factory of exceptional cleanliness, and the name of the engineer responsible for it becomes favorably known over a wide territory. Better positions have frequently been obtained in this way.

A young man holding his first position as chief in a small power plant was approached one night by a visitor who had been admiring the spick and span condition of the little station and was asked if he could keep a certain factory as clean as he did that station. He gave an affirmative answer and forgot the incident, but two years later he was sent for by his erstwhile visitor and made superintendent of the factory mentioned.

His cleanliness and good order were his silent though eloquent recommendations.

In another case a firm had been much embarrassed by the insurance inspector's reduction of ten pounds of steam from the boiler pressure. A new engineer cleaned the room and settings thoroughly, scraped the boilers inside and out and the insurance company voluntarily raised the pressure to its former limit.

For a similar reason a fire-insurance inspector will frequently recommend a reduction of rates on an otherwise bad risk because of the good order and cleanliness or "on account of management."

Yazoo City, Miss. F. C. HOLLY.

Piston Rings

I noticed in the April 11 issue of POWER, George H. Handley's favorable comment on a letter, contributed by me in the March 7 issue, on the lap-joint and diagonally cut piston rings. It seems that his plan for leakage prevention in rings of the lap-joint order is not exactly faultless, though an improvement when used in conjunction with this ring.

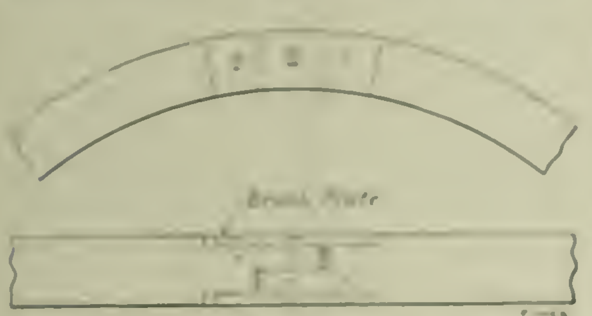


FIG. 1. MR. HANDLEY'S METHOD

There are two objections to the use of such a ring as Mr. Handley proposes: First, he says that care must be taken to use tap screws of proper proportion, with thin rings—an acknowledgment that the ring is unduly weakened at an already delicate point. This has been proved by numerous reports of instances where "tips" of rings of this order have broken and caused a badly cut cylinder, if not a general smash up, even though they were made as strong as possible.

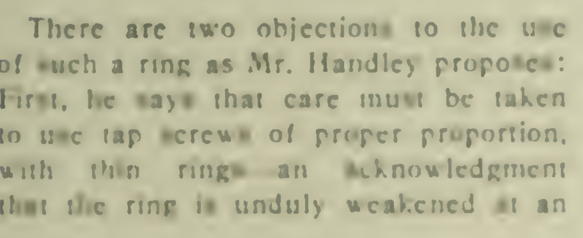

FIG. 2. BACKING UP PISTON RING

In the second place, this does not render the ring absolutely "leak proof," since leakage will occur past the brass plate when the ring becomes worn. This leakage, however, cannot be so great as in the ring without the plate, because the opening exposed is not so great and, too, the steam has a more constricted and "round about" passage to cross over, before reaching the other side.

I believe the method I proposed is less objectionable, because the ring cannot leak, if the cover plate is properly made. The ring would not be weakened much, even if a small hole were drilled and a curved-spring cover fastened underneath, as indicated in the cut. Whereas, in Mr. Handley's plan, the ring is much weakened by drilling across the ring and more still by the cut on each side.

LLOYD V. BEETS.

Nashville, Tenn.

Central Station vs. Isolated Plant

This is in confirmation of W. J. Creelman's article under the above heading in the April 18 issue. It should be remembered, however, that the conditions at each place must be fully considered before judgment can be passed. After an ordinance had been passed, forbidding the installation or retention of boiler rooms under sidewalks, the question among business men arose as to whether the purchase of light and power, as formerly done, would be cheaper than the running of a private plant. The city and central plant referred to are among the largest in the country.

To purchase the power would cost about $67,000 annually, which was quite an item. The engineer convinced the owners that it would be cheaper to install their own plant, and here are a few of the obstacles they overcame in doing so:

It was a case of swapping places with the kitchen as a starter. Then this change of location necessitated a new chimney, and to accomplish this meant the sacrifice of a living room on each floor, clear to the top of the hotel. The complete change cost $[illegible].

When they came to excavating about the boiler room, it was noticed that a great amount of seepage was present, and kept increasing as excavations progressed. Many of the older buildings in our city are on what are called "floating foundations," and at places where our building had settled, the plumbing drains beneath the cellar floor had broken at various places, causing the seepage. This required the complete overhauling of all the plumbing drains, which amounted to an additional $50,000. Since completing the plant they have been enabled to save from $[illegible] to $[illegible] annually over what it would have cost them had power been purchased at the above price.

C. S. COLLINS.

Notre Dame, Ind.

I have read so many arguments for and against the isolated plant that I would like to put in one word myself. I positively know that the isolated plant will pay if properly installed and given a fair chance. Too many plants are thrown together with cheap apparatus and little discrimination.

One of the first things which should be looked after is to see that good apparatus is provided and carefully installed. If the engineer on the job cannot do it, put the work in the hands of some good conscientious consulting engineer. Then by all means have a system of operation. Keep track of every detail. Run it as any successful business is run—as the central station is run. When asked for reports have them on tap. Then you need not fear the outside interests. Reports are as important as the operation of the plant. We have been running here for seven years and have not had a shutdown for any cause, except when cutting in new lines to add apparatus—this is done after midnight. We run day and night the year around and have produced electrical energy for 1.[illegible] cents per kilowatt-hour. While the central station is all right in its place and is needed, it cannot touch the isolated plant if handled right. The report shows what we are able to do. The output was considerably increased without adding to the running expenses.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Causes of Pitting of Boiler Tubes

The tubes in my boiler are pitting badly. The feed water comes from a coal mine most of the time, but I use rain water when I can get it. What causes the pitting?

M. F. H.

The pitting is caused by sulphuric acid in the water which comes from the mine. The acid may be neutralized by an alkali. Equal parts of unslaked lime and crude soda ash dissolved and fed to the boiler with the feed water will stop the pitting. But just how much to use can only be determined by experiment. Blue litmus paper will turn red in the water if acid is present and the red paper will turn blue if there is an excess of alkali. No change of color will take place if the water is right. If the water is passed through an open heater, most of the solids will be deposited there.

The soda will serve to prevent some of the scale-forming material from depositing as a scale and will keep it in a condition in which it may be blown out. An analysis of the water will determine whether soda or something else is better for this part of the process. Heating the water to 200 degrees or over will cause most of the scale-making impurities to precipitate.

Advantages of Butt-Strap Boiler Joints

Why is a butt- and double-strap boiler seam a better form of construction than a lap seam?

L. J. F.

The butt joint allows the shell to be built truly cylindrical while the lap joint prevents it. The pressure inside the shell tends to make it round and this tendency bends the lap-jointed sheet near the outer row of rivets at every change of pressure, however slight. As the pressure changes at every stroke of the engine, there are thousands of bending effects each hour. With the butt joint if the shell is round at the start changes of pressure do not bend the sheet.

Capacity of Expansion Tank

What capacity of expansion tank will be required for a hot-water system of 30,000 square feet of radiating surface, allowing 1.75 pints of water per square foot, assuming that the water expands 0.00043 of its volume for each degree of rise in temperature?

J. J. B.

It will require $1.75 \times 30{,}000 = 52{,}500$ pints of water. Assuming a temperature rise in the water from 60 degrees to 200 degrees, the increase in volume of the water will be $0.00043 \times 140 \times 52{,}500 = 3160$ pints, or 395 gallons, and the expansion tank should have this capacity. This is a little over 5 per cent. of the capacity of the system. Heating engineers usually allow 10 per cent. of the volume of the system for expansion with a temperature rise of 120 degrees.

Safety Valve Blow Back Adjustment

If a safety valve is set to blow at 100 pounds and stops at 90 pounds, how can it be adjusted to stop at 98 pounds?

C. D. N.

In most pop safety valves there is a supplementary ring surrounding the valve disk which forms a huddling chamber, increasing the effective area of the disk. This ring is threaded and may be turned, through the holes provided in the case, increasing or diminishing the huddling area. Increasing this causes more blow back, and diminishing it causes less.

Flat Bearing Surface

Can a perfectly flat surface, suitable for a bearing, be made on a planer? If not, how can it be made?

P F. S.

A perfectly flat surface cannot be made by planing. Such surfaces are obtained only by scraping. For some kinds of bearings planed surfaces are suitable but not if extreme accuracy is necessary.

Producer Output

How much horsepower should a No. 7 Wood producer deliver, using Texas lignite?

How many cubic feet of gas should be delivered per pound of lignite gasified?

With gas of 135 B.t.u. per cubic foot, how many horsepower should a 600-horsepower gas engine deliver at the belt?

H. W. N.

A producer does not deliver horsepower, but the horsepower that can be developed from producer gas depends on the quantity and quality of the gas and the efficiency of the engine. With lignite of 8000 B.t.u. per pound a No. 7 producer will deliver about 25,000 cubic feet of gas an hour containing about 125 B.t.u. per cubic foot; a good engine will develop about 300 brake horsepower on that quantity and quality of gas.

From 35 to 55, according to the character of the lignite and the way the producer is handled.

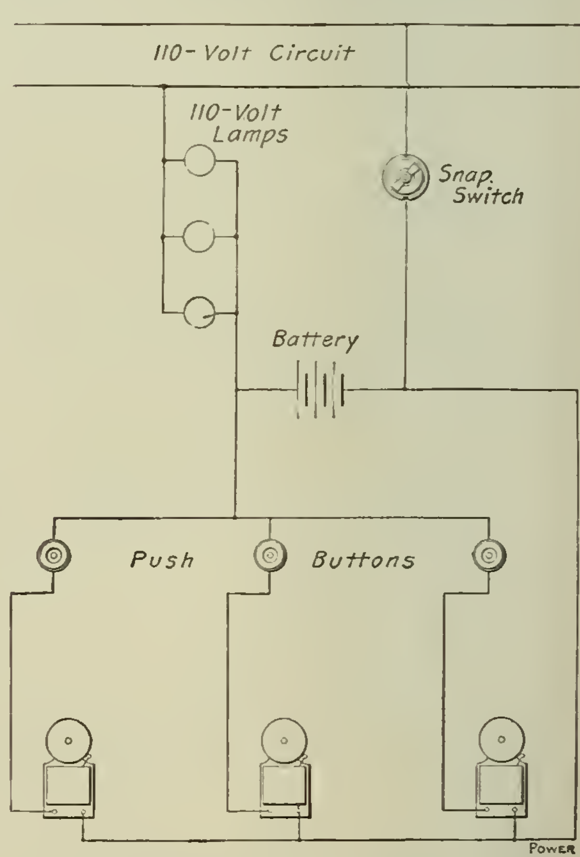
Its full rating: 600 horsepower.

Reducing Direct Current Voltage for Bells

How can I make a transformer to reduce the voltage of a 110-volt direct-current circuit to about 5 volts for ringing bells?

E. G. H.

You cannot. A transformer will not work on direct current. If you have a large number of bells, the best arrangement is a dynamotor to take motor current at 110 volts at one commutator and



Bell Supplied from 110-volt Circuit

deliver bell current at 5½ volts at the other. If you have only one or two bells, connect three or four 110-volt incandescent lamps in parallel with each other and in series with three storage-battery cells; then supply the bell circuit from the terminals of the battery, as indicated in the diagram.

A Square Deal and Efficiency

The manager was recounting the advantages that had accrued on the installation of a series of devices that enabled him to keep accurate record of operating conditions. The changes had brought the plant from chaos, on the one hand, to system, order and economy on the other; from guesswork and hit-and-miss methods, worry, loss and inefficiency to smooth running and profit making.

But after all this, he wound up with the information that, "For a short time we gave the firemen a small bonus for good performance, to find out what they could do. After they had demonstrated what they could do if they tried, we set their best mark as a standard and made them live up to it!" That is one way of doing business.

Every manager must determine at the beginning whether he will or will not give his men a square deal. On this depends in a great measure the permanent success of the undertaking. Dissatisfaction among the men may easily result in as much loss as a lack of proper cost keeping. Bonus systems, in one form or another, have been introduced in many places, with good results, but if a firm does not intend to keep up the bonus system when once installed, it had better not establish one at all, for the reaction when it is discontinued is bound to result in dissatisfaction.

It would be interesting and rather instructive, we imagine, to look over the payroll of this company about the time the bonus was discontinued, and note the new names coming up on the list.

Habitually getting new names on the boiler-room payroll is not a policy which can be followed to the best advantage. The new man, however willing, will require time to attain the efficiency demanded and this will mean loss of money to the company. One firm estimates that it costs one hundred and fifty dollars, in inefficiently burned coal, to break in a new fireman. At this rate it will not require many changes in a year to mount up to a respectable figure. One day and one night fireman changing every two months would mean, on this basis, a loss of eighteen hundred dollars a year.

The better way is to keep the men who have been trained to the standard of efficiency prevailing in the plant, giving them substantial evidence of appreciation, and this, in connection with an accurate system of coal records, will go farther toward insuring a high and continuous state of efficiency than any other plan that can be adopted.

Legislation and Engine Accidents

Many of the States have factory-inspection boards, whose duty it is to inspect factories and to call attention to conditions inimical to health and safety. The duties of these inspectors are often laid out with a precision which leaves them little, if any, discretion, and in most cases, beyond calling attention to actual violation of the law, they have no power to enforce their recommendations.

A matter which naturally receives general attention is the placing of guards about moving machinery, the prohibiting of projecting set screws upon revolving shafts, etc. One of the provisions directed at the reduction of injury from accidental entanglement with shafting, or from a machine gone wrong, is the requirement of a clutch upon each floor, by means of which the motive power may be cut off in case of accident. While this may occasionally serve its purpose, although the damage has usually been done before the clutch can be thrown, it has in it the possibility of aggravating trouble and precipitating a catastrophe which might otherwise be averted. If the engine commences to race and the machines to run wild, the natural impulse of somebody on every floor will be to throw the clutch, taking the load off from the engine and aiding it in its race to destruction. The fragments of a big flywheel ploughing their way through the several floors may be the result.

A much more logical and a safer arrangement is a number of reliable circuit closers or other arrangements conveniently distributed throughout the building, by the use of which the engine may be shut down in case of accident. The mechanism by which this is effected may be, and usually is, arranged to be operated automatically by a device attached to the engine itself and independent of the governor in case the speed increases beyond a fixed limit.

In some of the States automatic engine stops are required by law, but the law is not always sufficiently explicit to require an engine stop to the true sense. It might be established, for instance, that the usual safety cams on a Corliss engine constitute an "automatic engine stop," preventing as they do the hooking on of the valves and the admission of steam when the governor balls fall below a certain plane. But this is really a part of, an attachment to, the primary governor and subject to derangement with that governor. If the governor belt breaks and the balls drop, it will act; but if the belt slips, so that the governor runs slowly enough to permit a late cut-off, but not so slowly as to bring the safety cams into play, there may be an accident. It is a too common practice, moreover, to leave in place, while the engine is running, the pin which holds the safety cams out of action while starting up, although most modern engines are fitted with latches which automatically drop out of the way when the governor collar rises away from them.

A rider upon the governor belt, arranged in any of the usual ways to shut off the steam when the belt breaks and the rider falls, might be construed as satisfying the requirements of the law; but it is far from a positive safeguard.

The law should require specifically, and every provident engine owner should install whether the law requires it or not, a device entirely independent of the main governor, which will positively cut off the supply of steam when the speed becomes excessive. The danger in a mass of swiftly rotating metal is very real, and destructive explosions of flywheels not uncommon. There were twelve reported in January, and four each in February and March of the present year. Such an explosion may be far-reaching in its effects. The fragments of a wheel fly for hundreds of feet and are ugly and destructive missiles. People who live and pass near industrial establishments, as well as people who are obliged to pass their working hours within the range of flywheels, should have the assurance that something more than a two-inch belt and a fallible ball governor stands between them and eternity.

The Laborer Is Worthy of His Hire

The manager of a small hotel where an isolated plant has been in operation for some time says that if he had it to do over again he would install central-station current and go back to his old low-pressure heating system.

The plant in question is a model little installation which is saving the company twenty-five or thirty dollars a day net, and paying about twenty-five per cent. on the investment. It is not owing to financial considerations that this manager is so much dissatisfied. He claims that it is impossible to get competent help to operate his plant and that the petty labor troubles to which he is subjected are causing him more gray hairs than the money saved will warrant.

He is always worrying for fear the night engineer will get careless and explode the boiler, causing heavy damage suits as well as property loss. All manner of imaginary calamities haunt his mind and he claims to have a constant load of anxiety which he would be glad to pay twenty-five dollars a day to get rid of. This is one of the strong arguments of the central station. It seems to work out to perfection in this case.

As a matter of fact, he is trying to run his plant with the same wages and class of help that he formerly paid for janitor service with his old low-pressure heating system. It cannot be done. An electrical plant delivering twenty-four-hour service must have supervision of a higher order.

If this manager would take two dollars and a half a day out of his savings of twenty-five dollars a day and add it to the wages of his day and night engineers, dividing it in proportion to the money they are now receiving, he could get men who would operate his plant in a first-class manner and there would be no necessity for him to lie awake nights waiting for something to happen.

And, incidentally, he cannot get rid of that worry by putting in central-station current, for he will have to have boilers in operation all the time for hot-water service, and a "low-pressure" boiler can raise as much fuss as another when its pressure accidentally becomes "high."

Technical Graduates and the Public Service

A recrudescence of the disposition of examining boards to look rather to where a man got his knowledge than to what he actually knows appears in an advertisement by the Municipal Civil Service Commission in a New York daily announcing an examination for the position of mechanical engineer in the office of the Commissioner of Public Works.

Candidates must be graduates of a technical school and have had drafting room experience on details of mechanical appliances, together with at least three years' experience in assembling and erection of units connected with steam plants. They must show a familiarity with the details of complete mechanical equipments of public buildings—plumbing, elevators, heating, electric lighting, pumping and power systems.

We submit again that it should be no concern of a civil-service commission or other examining board whether a candidate got the knowledge requisite for the position at an institute of technology or at home on the kitchen table *so long as he has got it*. It is for them to know the kinds and degrees of knowledge which he should possess and to determine by examination whether or not he possesses them; and if he does possess them and can prove it, he ought to be as eligible to the position as another of equal attainments, whether he has gained a degree in the classic shades of a university or won competence in the school of experience.

Duplication in the Power Plant

To insure continuity in the operation of steam plant it is necessary to install considerably more apparatus than is actually necessary.

Naturally, the character of the load carried by the plant has much to do with the character and arrangement of its machines. A manufacturing plant generally contains just enough power units to operate the works. No idle engines are seen, the boilers are all under steam and there is just enough auxiliary apparatus to keep the plant in operation with everything working satisfactorily. If, due to an accident, such a plant is shut down, it affects comparatively but a few people.

But, if the plant were used for electric-lighting or street-railway service, a more exacting service would be required. In this case the public is to be served and a shutdown becomes a serious matter.

Many of these plants were formerly fitted with duplicate units throughout, duplicate feed-water and steam lines and apparently every precaution taken to guard against a possible shutdown. This practice, although expensive, has been the means of preventing a tie-up of the service, and accidents to the machinery have been tided over by the duplicate units without a break in the service.

Probably the weakest part of a modern power plant is its piping system. Exposed to varying degrees of temperature in the steam main, the action of acids and other deteriorating elements in the feed-water mains, together with water hammer and strains due to other causes, the pipe lines of a power plant should claim the particular consideration of the designing engineer.

Formerly it was considered good practice in the larger plants to install duplicate piping connections to the main units. Due to the large initial expense, increased radiating surface, double the number of joints and valves to keep in repair, the present-day engineer has reverted to the single pipe line, both for boiler feeding and for supplying steam to the engines.

To insure continuity of service, such a system requires good material, careful designing and placing of valves so that a break at any point in the header will not interfere with the operation of a single unit, for, if proper provisions are made, steam may be obtained on either side of the break. Although the single pipe line has its disadvantages, it is now considered preferable to the older method of duplicate piping.

Union Clam Shell Buckets

The Union clam-shell bucket is designed for handling hard and soft coal, sand, gravel, crushed stone and earth excavations.

The bucket is designed so that the closing drum does not sink into the substance being dug, but revolves in fixed bearings.

The advantages of this type of bucket are as follows: First, the weight of the drum adds to its momentum when falling, and exerts a downward force. Second, the drum cannot sink into the material being handled, thus insuring a full load, and third, the bucket does not spill its contents when in transit, due to the shields over the top of each section.

The design of the bucket shown in Figs. 1 and 2 is known as class A and is rigged with a fixed frame and flexible head. This is used mostly for handling coal and loose material. It has an unusually large reach, is light and takes up very little head room.

Class B has movable supporting arms and the bowls are manipulated by a link motion, and is designed for handling crushed stone, sand, coal and light excavation.

Class C is built on the same principle as class B but is heavier in construction. This style of bucket is used for heavy work. Teeth are furnished with this bucket when desired.

The drum is made of a steel casting of the self-oiling type and holds approximately one quart of oil. The bowls are made of flanged steel with flanged corners only. The arms are of iron and are built to withstand heavy strain. The shoes are made so that they may be easily removed and are of steel.

These clam-shell buckets are made by the Union Iron Works, Newark avenue, Hoboken, N. J.

Governor Valve Oil Relay

An oil-relay system, for large high-pressure turbines, has been developed for operating the primary and secondary admission valves of the largest size of Westinghouse high-pressure turbines.

The operation of this relay will be understood by referring to the accompanying illustration, in which sections through the operating cylinder *A* and valve *B* are shown. Attached to the operating cylinder is a safety release valve *C* that is under the control of the speed-limit device.

The governor operates the rock shaft *D*, and its motion is transmitted to the pilot valve *B* through the arm *E*, link *F* and the floating lever *G*. According to whether the governor weights move in or out with increase or decrease in load, the pilot valve will either be raised or forced downward from its neutral position, admitting the oil (under pressure from the chamber *H*) underneath or above the relay piston, as the case may be, at the same time opening the ports at the opposite end of the cylinder to exhaust through the passages *I*. The oil-pressure chamber is located between the exhaust passages so that leakage escaping from the relay pistons is prevented. A drain pipe is provided to entrap the small leakage past the relay-piston rod.

As soon as the operating piston has traveled a short distance, it returns the pilot valve to its closed position, by means of the floating lever *G*, immediately restoring equilibrium, and thus holding the admission valve in a fixed position. The floating lever *G* first turns about the point *K* as the position of the governor clutch which imparts the governor travel to the rock shaft *D*, changes, and thus swings

Fig. 1. Bucket Open

Fig. 2. Bucket Closed

about J as the relay piston A begins to move. As soon as the governor gives the pilot valve B one direction of travel, the following motion of the operating piston will immediately reverse it, closing both ports and locking the valves in a fixed position until further movement of the governor takes place.

The motion of the relay piston A is transmitted to the primary valve O and the secondary valve P through the levers M and N. The arrangement of the two levers for the two valves will be found the same, with the exception that the secondary-valve linkage is provided with an adjustable backlash at R so that the time of opening of the secondary valve may be changed by the operator. Ordinarily, this valve is regulated to open at the moment the primary valve P has reached its maximum port opening. To overcome the friction of rest provision is made for the fixed oscillation of the plunger, which causes a very slight up and down motion of the main operating piston, and the main poppet valve. This, however, is not sufficient to cause any observable fluctuation in the flow of steam to the relay system. A spring-loaded bypass valve is provided in the pipe line so that the oil in excess of that required by the relay escapes through this valve. This surplus oil together with the exhaust from the relay is led to a cooler and thence to the bearings as usual, whence it is again returned to the reservoir and back to the pump.

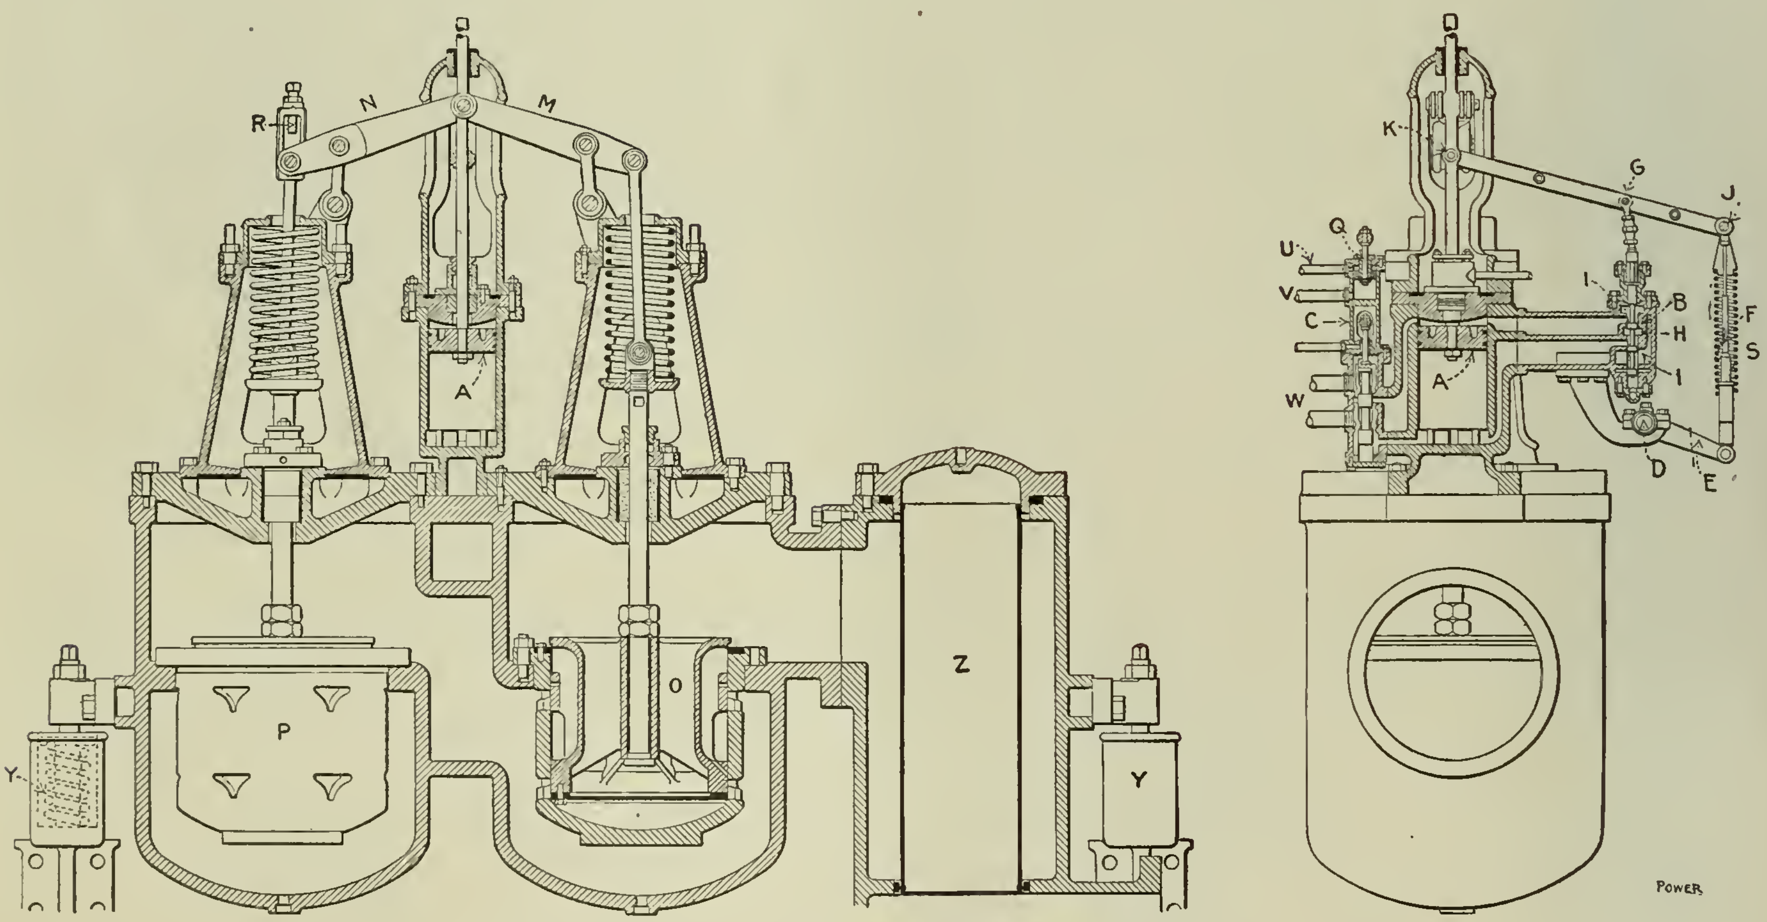
The poppet valve possesses some novel features.

The valve is essentially a combination of a poppet valve and piston valve, the poppet-valve feature being in effect only when the valve is closed, or nearly so. When the valve is partially closed, the opening past the valve seats is at all times very much greater than the passage through the ports. Hence wire drawing of the steam will take place at the latter point, where it can do no harm. The valve ports are all of a peculiar form, so as to admit constant increments of steam for constant increments of valve lift.

In addition to the automatic throttle, an auxiliary safety steam valve Q is provided, receiving live steam at U. With leakage of steam past the piston, it is by heavy coil springs, as shown at Y and Y.

Steam is supplied to the valves through the strainer Z and the secondary receives its supply through the primary valve. The governor link F is provided with a compression spring S. On shutting down the machine, relieving the oil pressure, the effort of the governor weights to come together would tend to raise the primary valve, which tendency would be resisted by the main spring on the primary valve. This would put a serious strain on the governor linkage, but the interposition of the comparatively light spring S in the linkage absorbs the governor travel without imposing any undue strain on the regulating mechanism.

Should the oil supply to the relay fail, the main spring would bring the valves to their seats, raising the relay piston to the highest position. The governor would then have a tendency to open the valves through the lever G. But as the spring S is unable to operate against the more powerful main-valve springs, it collapses and prevents the lifting of the main valve by the governor.



Sectional Views of the Governor-valve Oil Relay

to the turbine. The advantage of this method is that the governor becomes more sensitive, and the least move of the governor produces its consequent change of steam distribution.

The oil-relay apparatus will use more oil than the steam-relay system, but this oil is afterward used in the bearings. The oil required for this apparatus involves nothing additional in the turbine system beyond the oil-relay mechanism. The same pump is, as heretofore, pumping the oil at a somewhat greater pressure, and delivering a constant supply held in a raised position due to the unbalanced pressure. When the automatic trip operates, the steam from underneath this piston is exhausted through the outlet V. Through external linkage, an oil valve W is then operated which relieves the pressure above the relay piston and admits the pressure beneath, correspondingly forcing it to the top of the cylinder, thereby closing the valve.

In order to relieve the turbine casing of any strains due to the operation of the oil-relay system, the steam chest is mounted on the bedplate and supported

This oil relay is manufactured by the Westinghouse Machine Company, East Pittsburg, Penn.

Pete Blowoff kum inter my ingin room tother day an' sed thet th' exhoust uv my ingin sounded jist like th' pants uv a fat pug dorg thet hed bin tryin' ter ketch wun uv them Kansas jack rabbits. Meeting of the American Association of Refrigeration

The second annual meeting of the American Association of Refrigeration was held in the east assembly room of the La Salle hotel, Chicago, May 9 and 10, Theodore O. Vilter, president, presiding. In opening the meeting the president gave an account of the visit of the American delegates to the second international congress of refrigeration, at Vienna, and urged upon members of the American association the importance of making the coming international congress in this country in 1913 a success. After the report of the secretary and treasurer the meeting adjourned in a body to the blue room of the La Salle hotel, where a luncheon was served to all those in attendance, as guests of the association.

AMERICAN ASSOCIATION OF REFRIGERATION IN SESSION AT LA SALLE HOTEL, CHICAGO

The following session was occupied largely with the reports of standing committees and with the consideration of cold-storage subjects. Another subject which engaged considerable attention was that of the adverse legislation which is being introduced in many States. Special committee reports were made on this subject and means for obtaining proper consideration of cold-storage interests were discussed in detail.

One of the principal objects of the meeting was to decide on the place and time for holding the third international congress of refrigeration, which, as noted above, will be held in this country by special invitation of the United States Government. A spirited contest developed between New York and Chicago for the honor of entertaining the foreign delegates and American representatives of the coming congress. The discussion of this subject was carried over until the following day, when, after repeated ballots on motions and amendments to motions, it was finally decided to hold the international meeting in Chicago. The plan as tentatively outlined by the Chicago Association of Commerce, in connection with the executive committee of the American Association of Refrigeration, is to have the foreign delegates gather at New York, leaving that city September 14, 1913, for Washington, where, on September 15, the opening exercises will be held and participated in by the President of the United States. After the exercises at Washington have been completed the delegates will be taken on special trains to Chicago, where the business sessions of the congress will be held and where the delegates will have the opportunity of inspecting the application of refrigeration to the enormous packing industries of the city.

Following the Chicago meeting it is proposed to have the special trains return East by way of Niagara Falls, holding the closing exercises in New York City.

Officers of the American association for the following year were elected as follows: William J. Rushton, president, Birmingham, Ala.; vice-presidents, E. O. McCormick, San Francisco, Cal.; Thomas Shipley, York, Penn.; Jacob Ruppert, New York City; Homer McDaniel, Cleveland, O.; Joseph Allerdice, Indianapolis, Ind.; George L. Flanders, New York City; Frederick H. Taft, St. Louis, Mo. John S. Field, Chicago, was elected treasurer and J. F. Nickerson, editor *Ice and Refrigeration*, Chicago, was reëlected secretary.

An organization to take care of the arrangements for the coming international congress was perfected and two general officers were elected as follows: J. B. Forgan, First National Bank, Chicago, treasurer-general, and J. F. Nickerson, Chicago, secretary-general. Election of the other officers was left until later action by the executive committee.

N. E. L. A. Convention

The executive committee of the National Electric Light Association held on May 11, at the New York offices, a final meeting before the coming convention. The report of the secretary showed a flourishing state of affairs. Over 1800 new members were admitted, showing the gross gain since the last meeting about two months ago, and a net gain of over 1000.

Although the convention was three weeks off, it was stated that the registration had already reached about 1750, which would indicate an actual attendance of at least 3500 to 4000. Additional facilities for the meeting have been secured in the Engineering Societies building which will assist in distributing the throng over several floors. On the ground floor the ingenious idea has been adopted of supplementing the foyer by inclosing the entire large driveway around the building so that the members can also sit and lounge in the open air. The three largest meeting rooms will be devoted to the regular sessions and on the floor above another meeting room has been appropriated as headquarters for the New England section, the Eastern New York section, the Pennsylvania section, the Sons of Jove and any other affiliated or auxiliary body applying for such accommodation. The exhibition committee will also have its headquarters on this floor and the subcommittee on theaters, which will distribute the tickets for the three theaters which have been engaged for Thursday evening of the convention week, May 29 to June 2.

The Public Policy meeting is to be held on Wednesday evening, May 31, at the New theater, when Secretary Nagel will represent President Taft and deliver an address. The report will be presented by Past President Samuel Insull, of Chicago.

The baseball game will take place on Wednesday afternoon at the baseball grounds in Brooklyn, which are very accessible from headquarters; the competing teams will be those of the Brooklyn and Philadelphia companies.

The regular meetings have been arranged to occupy some sixteen sessions extending throughout Tuesday, Wednesday, Thursday and Friday.

A Memorandum Booklet

Charles C. Moore & Co., engineers, of San Francisco, Cal., are getting out a memorandum booklet for distribution among the engineering fraternity and managers of plants. The book, 3¼x7 inches, is bound in black leather, with a pocket on the inner side of either cover, and the pages are perforated into five squares, each of which is large enough to jot down a specific note or engagement. As soon as the matter has been attended to, the square may be torn out regardless of any of the others. This in itself is a great convenience as it saves the trouble of wading through a miscellaneous collection of notes of no current value to find what is wanted, and for the same reason the live material is more readily found. When the pages are all used, new inserts, as they are called, may be obtained by application to the nearest branch office of the company.

The A. O. S. E. to Meet at Philadelphia

The twenty-fifth annual convention of the American Order of Steam Engineers will convene at Philadelphia from June 5 to 10. Every available foot of floor space in the large auditorium of Odd Fellows' Temple has been assigned to the various firms in the engineering line for the display of their goods and appliances. The committee are putting forth their best efforts in devising ways and means to accommodate the many late applicants, who are now anxious to secure exhibit space, and it is feared that it will be impossible to locate all of them. The several sessions of the delegates will be held in an upper hall in the same building.

The dealers and engineers, and, in fact, everybody interested in the power-plant industry in Philadelphia and vicinity, have been invited to attend the convention, and there is an assurance that the exhibit hall will be well patronized at all times.

An excellent program of entertainment has been arranged, and taken altogether, the outlook favors a most successful meeting.

A Correction

In the May 9 issue, page 718, the word Keeler, instead of Kellogg, was inadvertently used in specifying the make of the 175-foot radial-brick chimney for the municipal pumping and power plant of Orange, N. J.

PERSONAL

Gordon C. Keith, managing editor of *Canadian Machinery, The Power House* and *Canadian Foundryman,* has resigned to join the editorial staff of *The Canadian Manufacturer.*

E. Heinrich, M. E., who, with Doctor Junge, has been writing a series of articles for POWER upon "The Steam Turbine," has given up his position upon the designing staff of the Fore River Ship Building Company to fulfil an assignment of two years in the research department of the technical high school at Stuttgart, Germany, under Doctor von Bach.

John F. Wallace, formerly chief engineer of the Panama canal, who retired after inaugurating the American work on the canal and afterward designed the new Chicago & Northwestern passenger terminal at Chicago, which has just been completed at a cost of $25,000,000, has assumed active charge as president of Westinghouse, Church, Kerr & Co., replacing H. H. Westinghouse upon the latter's recommendation to the board of directors.

SOCIETY NOTES

At the regular monthly meeting of the Internal Combustion Engineers, of Chicago, held on the evening of May 12, at Fraternity halls, 19 West Adams street, officers for the following year were elected as follows: Charles Kratsch, president; Wallace V. Pye, secretary, and I. J. Babcock, treasurer.

On Thursday evening, May 11, Branch No. 1, District No. 2 of the Institute of Operating Engineers, New York City, held its regular monthly meeting, at which F. L. Johnson presented his paper on the "Needs for Industrial Education." The paper drew forth considerable comment from the members and the discussion was both lively and interesting. About 50 members of the branch were present and the interest in the Institute seems to be growing constantly.

On Saturday evening, April 22, the seventh bimonthly meeting of the Colonel Goethals branch was held. A paper on the "Theory and Operation of Hydraulic Laws" was given by R. V. Madden and a short paper on "Water in Pipes" was delivered by W. R. Vernon.

On account of the interest manifested on the subject of "Fuel Testing," considered at the meeting of the American Society of Mechanical Engineers in Philadelphia on April 22, when a paper by J. C. Parker of that city on the "Work of the United States Fuel Testing Station" was presented, the meeting on June 3 in that city will be given up to further discussion of the same topic. The Engineers Club, of Philadelphia, will cooperate in the meeting.

The annual convention of the New Jersey State Association of the National Association of Stationary Engineers, will be held at Newark, N. J., June 2, 3 and 4. The several meetings of the delegates will take place in the New Auditorium, on Orange street, and in the main hall of the same building the mechanical exhibit will be shown. On Saturday evening, June 3, there will be a banquet at the Continental hotel, and several prominent speakers will address the diners.

NEW PUBLICATIONS

ELECTRIC POWER PLANT ENGINEERING. By J. Weingreen. Published by the McGraw-Hill Book Company, New York, 1910. Cloth; 431 pages, 6x9 inches; 291 illustrations; numerous tables. Price, $5.

This book was written to fill the want of a treatise upon present practice in the electrical equipment of power plants. The subject is divided into two groups: direct-current apparatus and alternating-current apparatus. In the first group are taken up dynamos, synchronous converters, mercury rectifiers, storage batteries, direct-current motors and switchboards. The second group deals especially with high-tension transmission, switching equipment and remote control. In each case the standard types of apparatus are illustrated and explained, various types of construction are shown, and complete wiring diagrams are submitted. A considerable portion of the text is devoted to illustrations of a number of large central stations and substations now in actual operation.

The book is in no sense a textbook and does not go into any theoretical considerations of electricity. On the other hand, it represents present power-plant practice and as such should prove of great service to consulting and constructing engineers.

POWER

NEW YORK, MAY 30, 1911

SOME years ago, so the story goes, a certain uptodate storekeeper hired two boys and set them to work undoing rolls of cloth in a rear room.

One of the boys was thrifty by nature and training; so was the other, but in a different way.

The first boy untied the cords that were around the rolls of goods he was working on, and carefully and painstakingly wound them up in a ball to save for future use. The wrapping paper was precisely folded and also tenderly lain aside.

That boy was saving the cost of the cord and wrapping paper for his employer.

When the second boy began undoing his bundles, he got out his pocket knife, slashed the cord with one deft stroke and while placing the unwrapped goods in a pile with one hand gave the wrapping paper a fling that sent it on the floor behind him.

That boy was saving the cost of the cord and wrapping paper also, and then some.

Careful, painstaking methods of doing work are all right in their place, but the first boy, although saving the cord and paper, cost his employer more than it was worth in so doing. His output of useful work was reduced just the amount that could have been accomplished while wasting his time saving strings and brown paper.

The other boy expended his energies in useful work and left the paper and cord for the janitor to look after.

Now what does all this amount to to the engineer?

The same principle will apply to his work.

There is no saving in spending time picking coal out of the ash pile while air leaks are allowed to exist in the boiler setting.

The first boy might do it, but the boy with the knife would get after the leaks and let the ash handler look after the ash pile.

It is a waste of time to spend energy in stopping up a pin hole leak in a steam pipe and allow the valves of the engine to be so set that the machine would run backward if given half a chance.

Fussing with the ash pile and the pin hole leak will make a show toward economy, but attending to the real point of saving is what counts.

Can you imagine a ditch digger carefully selecting the exact spot where he intended to deposit each shovelful of earth?

But there is just as much sense in such a procedure as for the fireman to carefully spread green fuel over the fire and then leave the furnace doors open.

One procedure is a waste of time, the other a waste of money; both amount to the same in the end.

There are several methods of producing economy in a steam plant, as elsewhere. It is better to do things that produce results than to save paper and string.

A Remodeled Street Railway Plant

By Warren O. Rogers

This power plant contains the largest horizontal seven-stage Curtis turbine that has been put into service and also four of the largest Edge Moor boilers in New England. The station has been remodeled and provision made for future expansion.

One of the difficulties which the designing engineer encounters is that of looking ahead and providing for future growth and demands upon the steam plant. Frequently a power plant will be designed with such a capacity that, seemingly, it will be sufficient to meet all demands made upon it for years to come, when in reality two or three years finds the plant overloaded and incapable of economically carrying the load.

That is what occurred at the plant of the Worcester Consolidated Street Railway Company, which has recently been remodeled to meet the greater demands placed upon it. It is now constructed in such a manner that from the present plans its capacity can be increased threefold.

Prime Movers

The new power plant, shown in Fig. 1, is situated on Providence street, Millbury, Mass., a few miles out of Worcester. It contains two 300-horsepower reciprocating engines, direct coupled to generators; these two units comprised the original power plant. There is also one 5500-kilowatt horizontal Curtis turbine and generator, which furnishes electrical energy at 13,200 volts. Space has been provided for four additional units of the same capacity, as demands may be made. At the present writing, this is the largest seven-stage horizontal steam turbine that has been installed in a power plant by the General Electric Company, although several of larger capacity are being constructed; it is illustrated in Fig. 2. With the exception of the seventh stage, the machine is built along similar lines to the five- and six-stage turbines.

The unit is self-contained. Oil is kept in circulation from an oil tank cast in the base of the turbine frame and is supplied to the bearings at a pressure approximating 15 pounds per square inch. The bearings are cooled by water circulating in copper coils which are embedded in the babbitt bearings. The turbine is connected to a Worthington surface condenser which has a cooling surface of 10,000 square feet. It is located in the basement under the turbine and connection is made by the usual copper expansion joint. Water is supplied by gravity from a canal by means of an iron flume and escapes to a stream below the power house through a concrete flume. This eliminates the expense and trouble of operating a circulating pump.

On the turbine-floor level are located the exciter and air-pump units. The exciter set consists of a Curtis turbine di-

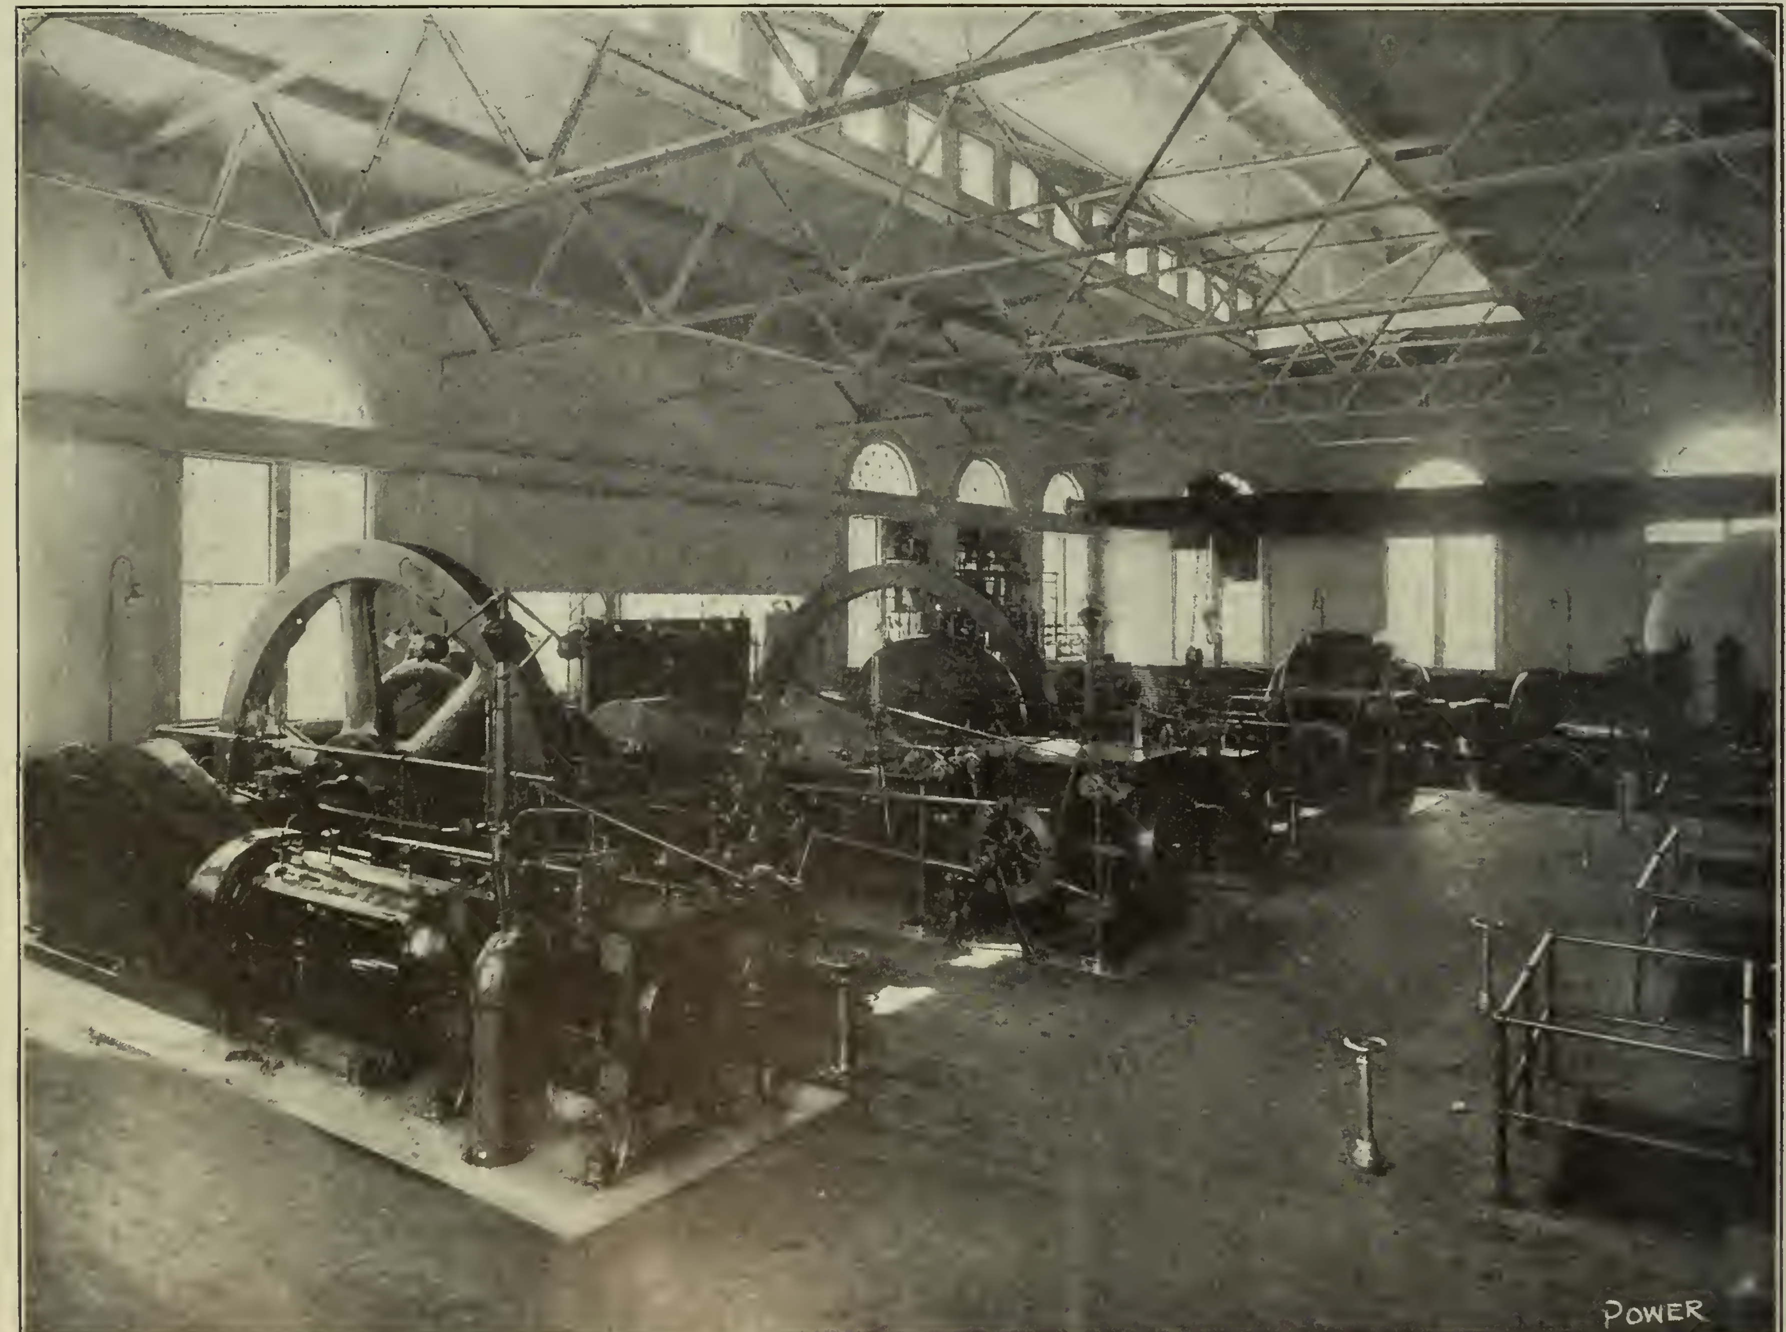

Fig. 1. Engine Room of the Worcester Consolidated Street Railway Company's Plant

rect coupled to a General Electric 125-volt direct-current generator. The turbine is of 75 kilowatts capacity and operates at a speed of 3300 revolutions per minute. The air-pump unit has 10 and 22 by 18-inch cylinders and main-

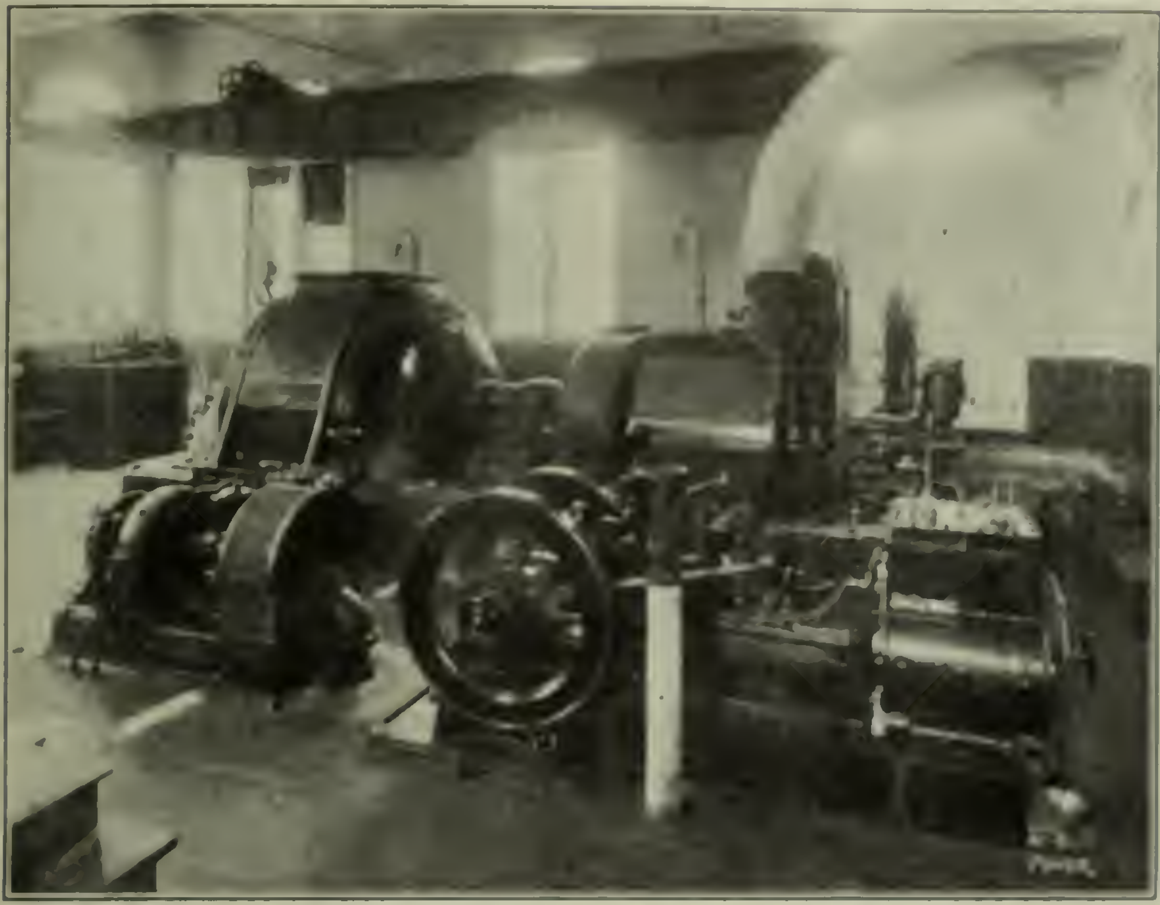

Fig. 2 View of Turbine Unit and Auxiliaries

tains a vacuum of 29 inches on the condenser.

The turbine generator is of the standard type, three-phase alternating current. The rotor is ventilated by means of fans secured to the revolving field. Air is taken from the outside of the building through a concrete duct built in the foundation and is carried to the machine at as low a temperature as possible. The high-tension switchboard is located on a raised platform at one end of the turbine; the main switch is electrically operated. On the switchboard is mounted the necessary indicating devices and recording instruments. Back of the switchboard are the choke coils and lightning arresters.

Boiler Room

The boiler room has been altered and enlarged. The old return-tubular type of boilers has been removed and four 850-horsepower Edge Moor boilers are now installed. Each is fitted with a Foster superheater, which superheats the steam 150 degrees. The steam pressure carried is 200 pounds per square inch. Each boiler is fitted with two Murphy stokers.

These boilers are housed in a building that is 100 feet long, 15 feet 6 inches wide, and 40 feet high, and has a monitor roof. Under the boiler-room floor there is an ash tunnel 115 feet long, which is constructed of reinforced cement. This tunnel terminates in an ashpit that is 25 feet deep and 10x10 feet inside dimensions. Fig. 3 shows the arrangement of the boilers.

Incidentally, it may be said that these Edge Moor boilers are the largest of the type ever installed in New England. They are of the four-pass type. These boilers are not equipped with economizers, but provision has been made for installing them on top of the concrete smoke flue which extends from the back of the boilers to the brick stack. This concrete flue, contrary to the general practice, is placed on the floor level, which gives ample opportunity for installing economizers later on. This flue is lined with firebrick and connects the boilers with a 225-foot Kellogg sectional radial-brick chimney having an internal diameter of 12 feet.

Double piping is supplied in the boiler room, and both the feed pipes and the steam lines are designed, not only with a view of extending the length of the boiler plant, but also of connecting to a second row of boilers at some future time. The feed water to the boilers is passed through a Wheeler heater of the closed type, and is pumped by means of two Wheeler heavy-duty boiler-feed pumps.

Fuel

Coal is delivered to the yard in carload lots, and is dumped in a pile under a high trestle that is 350 feet in length. An electric locomotive draws the cars 1500 feet over a siding from the main railroad track, and after the coal is dumped, it is hoisted by means of a two-ton bucket operated by a McMyler traveling locomotive, which dumps the coal into a hopper of a crusher that has a capacity of 125 tons. The arrangement is shown in Fig. 4.

From the lower hopper of the crusher the coal descends into a Larry coal car, which operates on a track extending over the top of the furnaces. The car discharges the coal wherever needed. The ashes from the grates drop into a concrete tunnel under the furnaces into a car which deposits the ashes into a revolving pit outside of the building. It is then taken by the bucket of the locomotive crane and deposited in cars on the trestle and is then drawn away.

Fig. 3. Arrangement of the Four Edge Moor Boilers

Transmission

The transmission lines are carried a distance of six miles to a substation that is located at Worcester, Mass. There consist of two three-phase lines of No. 0 stranded wire. These lines are capable of carrying a voltage of 33,000. The transmission lines enter a brick lightning-

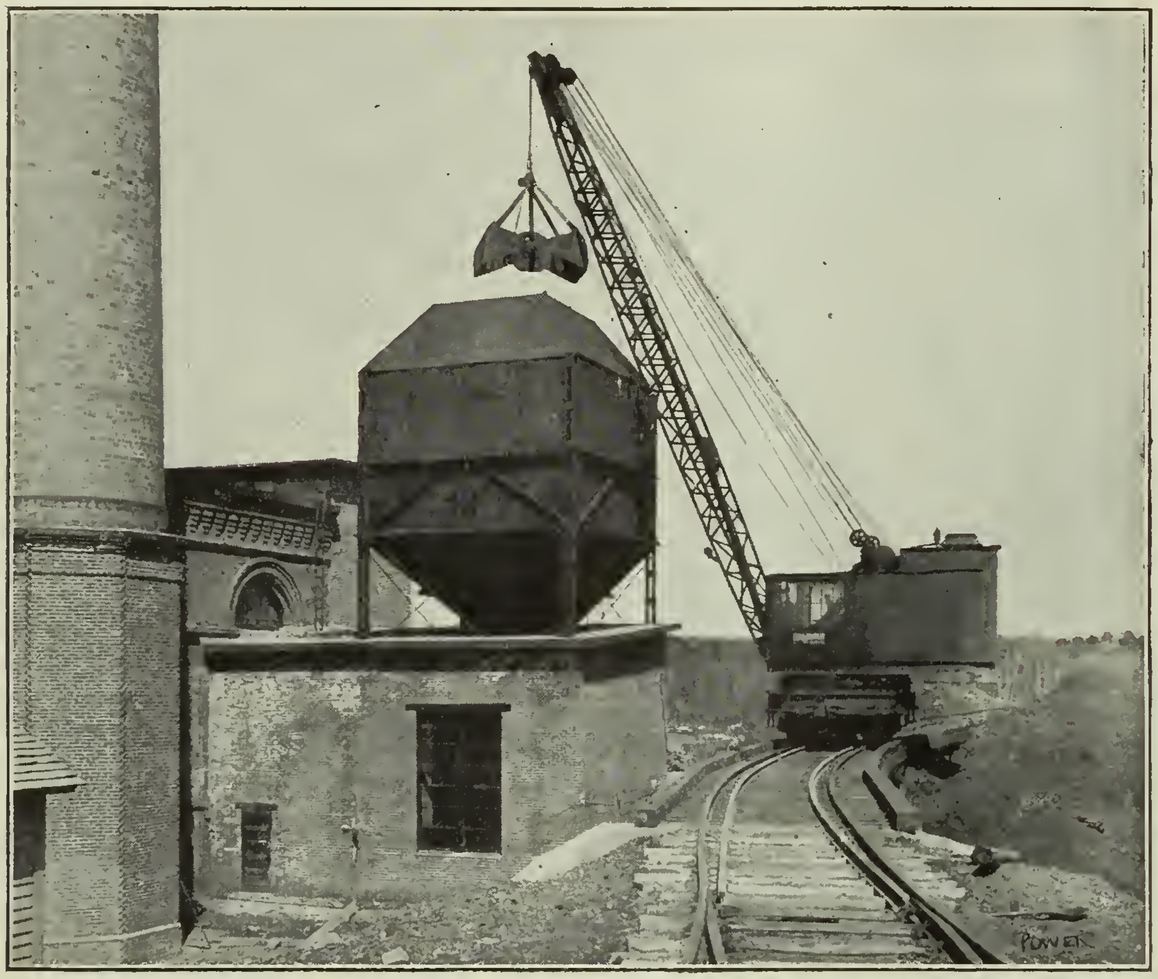

Fig. 4. Coal-handling Traveling Locomotive

arrester tower, where choke coils, disconnecting switches and lightning arresters are located. From the tower the wires pass under Madison street through underground ducts to the substation, which is made fireproof throughout and is constructed with a skeleton of steel with walls of brick and concrete. The win-

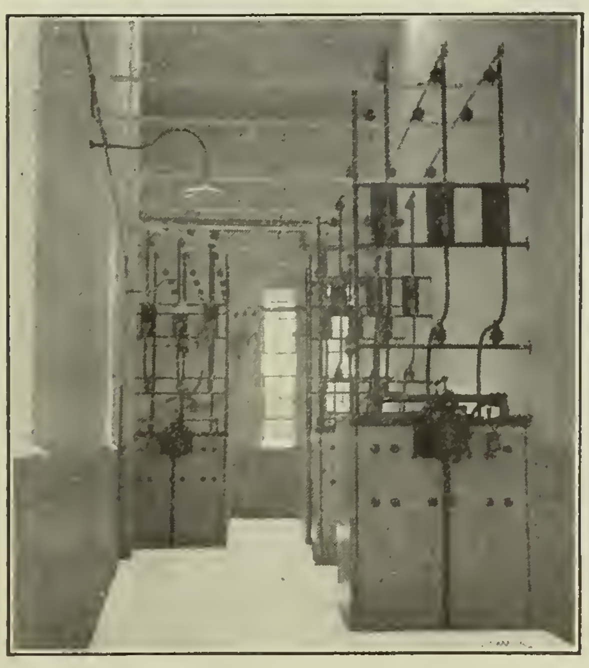

Fig. 5. Lightning Arresters and Oil Switches

dows, sashes and casings are also of steel, no wood being used in the construction of this building.

This is said to be the largest substation in New England. The building is 144 feet long, 35 feet wide, and is 60 feet in hight. There are two floors and a basement, the first floor being 27 feet high, the second floor 26 feet. A 20-ton electric crane has been installed in the converter room, and one of 10 tons capacity in the second story. The supply circuit from the lightning-arrester tower enters the basement in two insulated lead-covered cables, which are carried to the

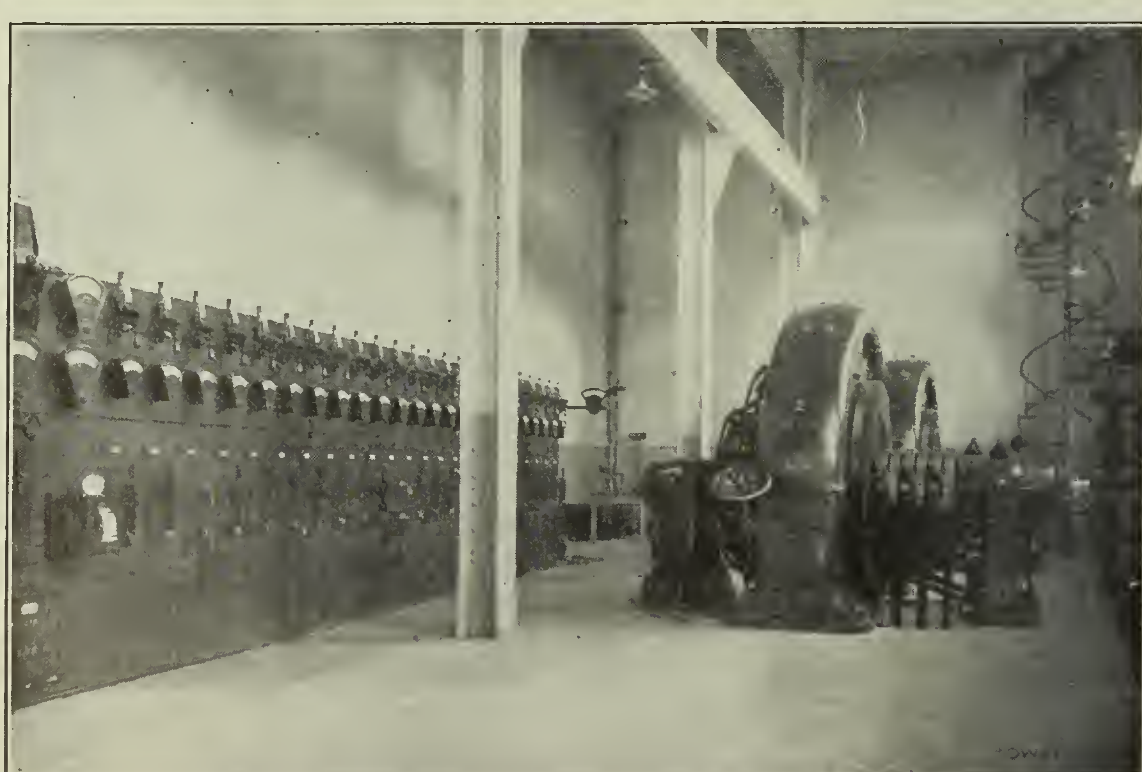

Fig. 7. Converter Room, Showing the Two 1500-kilowatt Rotary Converters

top of the building where they connect with the busbars. In this same room there are four oil switches, which are operated from the switchboard. These are shown in Fig. 5.

A separate room on the second floor contains the transformers, which are shown in Fig. 6. They are arranged in banks of three over a large concrete duct. Each rotary converter is served by one of these banks. Each is connected to a motor-driven blower which draws air from the duct below and drives it through the transformers to cool them. Each transformer has a capacity of 500 kilowatts and steps the voltage down from

Fig. 6. Section of the Transformer Room

13,200 to 430, the potential at which it operates the rotary converters.

These two converters are located on the ground floor, as shown in Fig. 7. They are each of 1500 kilowatts capacity. Space has been provided for the addition of three more converters with the necessary transformers and oil switches. Each machine has its separate starting switchboard, which is on the opposite side of the building from the main switchboard. This panel contains the main rotary switch, the reacting switch and the push button controlling the oil switch. A constant voltage of 600 is transmitted from the busbars to the outgoing lines.

The main switchboard has 27 panels: One station-instrument panel, two main rotary panels and a separate panel for each section of the feeder system, the city wiring having been rearranged for this purpose. This substation is the center of distribution, as the outgoing current from the rotary converters and the incoming current from the Freemont street power station are connected in parallel at the switchboard and switched onto the various lines.

Directly under the rotaries, in an open space in the foundation in the basement, the negative and equalizer buses are placed. Several lines of underground return wires enter through the basement walls and are connected to the negative busbar.

The substation is located at a point practically in the center of the city, which makes the distribution of current with but small loss a possibility.

The Effect of Vacuum at an Altitude

In a recent issue of POWER the question was asked, "At a hight of a mile is the vacuum in an engine cylinder as effective as at the sea level?"

And answered, "It is."

In an effort to be laconic the editor who wrote the answer failed to put himself into the mental attitude of the man who wrote the question. If the question asked no more than if a given force is just as effective to move a piston in Colorado as in New York his answer is right, but the question is not worth answering. Adding twenty inches of vacuum will add, in round numbers, ten pounds to the mean effective pressure, and this wherever the engine may be, but this is too obvious to be taken as the point in the question. The atmospheric line from which it is reckoned has slipped downward at the higher altitude.

Suppose an engine with an initial pressure of 100 pounds gage and a vacuum of 20 inches to be run, first with a 30-inch barometer, as there might be at the sea level, and then with a 25-inch barometer, as there might be at the altitude of a mile. To simplify the matter, since we are not after absolute results, assume 2 inches of mercury to be equal to one pound pressure.

Then at the sea level with the 30-inch barometer the atmospheric pressure would be 15 pounds and the absolute initial pressure 115 pounds per square inch.

With a 20-inch vacuum the absolute back pressure in the cylinder would be 30 − 20 = 10 inches of mercury, or 5 pounds.

The ideal diagram would be *A B C D E* of Fig. 1, which, with a ratio of expansion of 6, gives a theoretical mean effective pressure of 48.5 pounds.

On the mountain, with the 25-inch barometer the atmospheric pressure would be 12.5 and the absolute initial pressure 112.5 pounds. With a 20-inch vacuum the back pressure in the cylinder would be 25 − 20 = 5 inches of mercury, or 2.5 pounds absolute.

The ideal diagram would be *a b c d e*, represented by the dotted lines, and, with six expansions as before, would give a mean effective pressure of 49.8 pounds; 2.7 per cent. more than in the case of the same engine with the same initial pressure (gage) and the same vacuum at the sea level.

The effect of the condenser is to reduce the lower temperature level, to increase the head or fall of the heat between the temperatures of entry and rejection. A 20-inch vacuum on a mountain means a lower absolute pressure and a lower temperature of rejection than does the same vacuum at the sea level.

In the diagram, Fig. 2, hights represent temperatures instead of pressures, as they do in Fig. 1, but the area represents energy just as does the area of the other diagram. The diagram should be plotted with absolute temperatures, so that its real base is 460 + 338 = 798 units below the level *A B* and the area of the whole diagram would represent the energy in the form of heat which must be put into a pound of water to make it into a pound of dry saturated steam at the given pressure. The area *A B C D* shows how much of this heat a perfect engine, working in a Rankine cycle between the limits 338 and 162 degrees (100 pounds initial and 20 inches vacuum at 30-inch barometer), could convert into mechanical energy as against that convertible by a similar engine working between the limits 338 and 135 degrees (100 pounds initial and 20 inches vacuum with 25-inch barometer), as shown by the area bounded by the dotted lines.

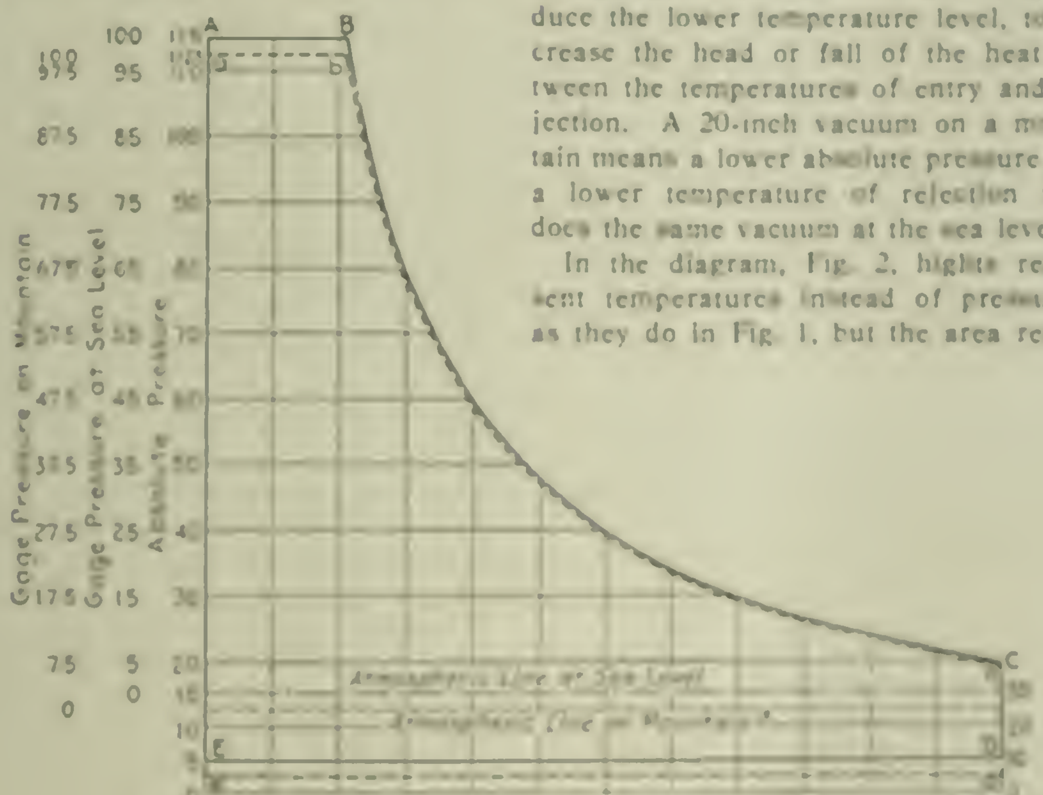

FIG. 1

A Dangerous Bag

By [illegible] T. Hume

A venerable engineer recently related the following interesting incident of a dangerous case of bagging:

In taking charge of an old plant that was considerably run down, the boilers were found to be badly scaled. A barrel of good boiler compound was procured. Orders were given the fireman to use it sparingly until after the first or second cleaning; then to increase the amount until the scale should be removed. Instead of paying attention to these directions, the fireman got the order of proceeding reversed and for the first few days fed the compound in large amounts.

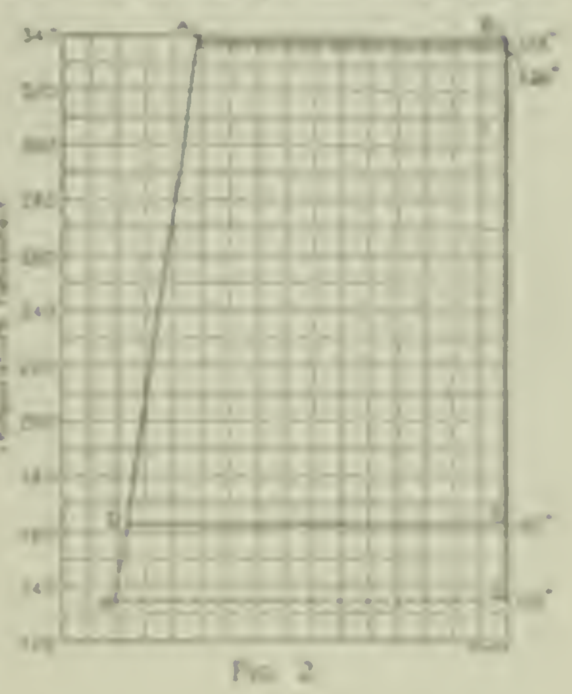

FIG. 2

At the end of the third day he called the attention of his chief to what seemed to be a leak in the boiler plate over the fire. An effort was made to run the boiler until Sunday but, the leak growing worse, it became necessary to shut down the boiler. Upon opening it, an accumulation of scale sufficient to fill a nail keg was found directly over the fire. The plate under this deposit had burned and bagged to a distance of 9 inches and over an area about 15 inches in diameter. The metal was drawn out to the thinness of brown paper and several small openings through the metal were in evidence. While the accumulation of scale caused the burning, it apparently stopped the leaks for the time being and saved the boiler.

A horseshoe patch was put on and the old boiler is still in service.

Letters Patent for Inventions*

By D. Howard Haywood

A general discussion of patent rights and the protection they afford; also some useful hints as to the scope of the claims to be made in applying for a patent.

*From a paper delivered before the American Society of Mechanical Engineers, at New York on May 9.

There is much confusion in the mind of the average man as to the nature of the rights conferred by letters patent of the United States. Upon their face they grant to the holder, for a specified term of years, "the exclusive right to make, use, and vend" the invention claimed therein. This would seem to grant to the owner the right to make, use, and vend the invention, coupled with the right to exclude others from so doing. Such, however, is not the meaning at all. Letters patent grant no right to make, use, or vend an invention, but only the right to prevent others from doing so, the so-called exclusive right being merely the right of exclusion. If the grantee has the right to make, use, and sell the invention, at the time he receives the patent, then the patent grant makes that right an exclusive one; but if he does not have that right at such time, the patent does not give him such right, but merely the right to exclude others therefrom.

This will be understood best by citing a concrete example. Assume A to be the original inventor of the steam engine; he has a natural right to make, use, and vend the same, regardless of any patent right. He, however, applies for and obtains a broad patent thereon and receives the right to exclude others from exercising the right which they would otherwise have had of making, using, or selling steam engines. Now assume that B at some time later invents a specific form of rotary steam engine, for the novel features of which he obtains a patent. At the time of obtaining the patent, however, A's patent is in force; hence B has no right to make, use, or vend a steam engine of any kind. B's patent gives him no right in this connection, for if it did the effect would clearly be in abrogation of A's rights of exclusion, already acquired. B's patent grants him the right to exclude everyone from making, using, or vending the specific form of rotary engine invented by him, and nothing more; he can prevent others, including A himself, from making, using, or selling the rotary steam engine, but having no right to the exercise thereof, he obtains none in his patent. It is to be noted also that B's right to exclude A from making the rotary steam engine that B invented, is in no way inconsistent with A's patent right.

The result of the foregoing may seem somewhat anomalous, but it is no less true that during the life of A's patent, neither A nor B can make, use, or sell rotary steam engines, except by permission of one from the other. Failing such permission B can only wait until A's patent right has expired, whereupon he will be free to exercise his natural right, and for the remainder of the term of his own patent will likewise be able to exercise his legal right of restraint against others.

Novelty Distinguished from Infringement

When application is made to the Government for letters patent of the United States, a search is made by the Government solely upon the question of novelty. The applicant for a patent right describes and claims what he considers he has invented, and the Government, through its officials in the Patent Office, proceeds to search through prior publications, records and patents, in an endeavor to find anything upon which such description and claims can be read, and if found, B's application is refused. In the example just given, however, there is no disclosure by A of any rotary steam engine, but merely (say) of a reciprocating steam engine, and it being assumed that no disclosure of a rotary steam engine is found elsewhere, the patent sought for by B is granted to him. The fact that A in his application claimed, and in his patent was given, an exclusive right in relation to all forms of steam engines, is not taken into consideration by the Patent Office at all. A search is made for the specific thing that B has disclosed and is claiming and as this is not found, a patent is granted to B.

Patent Rights Transferable in Whole or in Part

The holder of a patent may remit that right to one or more persons, firms or corporations at will. There are in general three ways of accomplishing this result: (*a*) by assignment, (*b*) by territorial grant, (*c*) by license. Assignments may be of the entire patent right held by the original grantee, or of a part thereof If of the entire right the situation is simple, the assignee merely being substituted for the original grantee, in which case the assignee assumes every right the original grantee had at the time he made the assignment. There is provision made for recording such assignments, and a statute provides that when recorded within a specified period, they become and constitute constructive notice to all of the transfer of title of the patent. If, on the other hand, the assignment conveys only a part of the right granted by the patent, the situation is not nearly so clear and is very often misunderstood.

Assume that *A*, the original grantee, assigns to X an undivided one-half interest in the patent, such assignment being unaccompanied by any partnership agreement. A has now broken up the complete right of exclusion and is sharing it with X. But as the right of exclusion necessarily carries with it the right of remission thereof, it follows that A and X can now, each of them, and the one independently of the other, remit that exclusion so far as anyone else is concerned, and that neither can interfere with the action of the other in this respect. The "exclusive right" or right of exclusion is thus utterly broken up and lost unless A and *X* act in concert. Furthermore, in an assignment unaccompanied by any restrictions as to a partnership agreement, it does not matter what proportion of the patent right is nominally assigned. An assignment of a one-hundredth part conveys exactly the same right in this respect as one-half or ninety-nine hundredths.

But few words need be said in relation to territorial grants and licenses. These instruments do not convey an undivided interest in the patent right, but the exact nature of the interest conveyed is dependent in each case upon the wording of the particular instrument, the nature of such interest usually being set forth in specific terms therein.

Part ownership of a patent right may also result from joint invention. In such a case application must be made in the name of the joint inventors and the patent is granted to them jointly. Each owner may operate independently of the other and may grant rights under the patent without the consent of the other.

As it is the claims which determine the breadth and scope of the patent protection granted, it follows that their wording is of extreme importance. It is upon the skilful drawing of the claims that the whole value of the patent depends. They should, where the nature of the invention permits, be broad and comprehensive, so that mere variations in structure will fall within them; yet they must not be ambiguous, uncertain or vague, for they would then be liable to be declared invalid by the courts. Also the claims must not touch upon any previously invented structure, for in such case they would be anticipated thereby and would have no validity. The first requisite, then, in the drafting of a claim, is an accurate knowledge of what has been previously accomplished in the same or similar lines, a knowledge, as it is aptly called, of the state of the art.

The next requirement is a true appreciation of the problem that the inventor has solved. It is not sufficient that one drawing a claim shall merely understand the specific structure for which patent protection is to be acquired, for in such case he would not be in a proper position to distinguish between the essential and nonessential features thereof. To illustrate this, conceive an appliance placed upon an engine such as would operate in connection with the valve mechanisms for both the inlet and the exhaust of steam. For convenience the inventor might apply it in this way, yet actually his problem is completely solved by the application of the device to the means for admitting steam. A failure to appreciate the fact that the application to the means for controlling the exhaust of the steam was mere surplusage, or at best a convenience, might lead to the drawing of claims in a way that would prevent others only from applying the mechanism to both inlet- and exhaust-valve mechanism, leaving them free to place it upon the inlet-valve mechanism alone, and thereby actually to attain the benefits of the invention.

After broad claims have been drawn such as comprehensively cover the invention generally, in such terms as to include all reasonable variations of the structure, it is then wise to insert specific claims: First, to the general specific structure shown, and, second, to any specific part of the structure such as may be deemed to be of particular importance.

Letters patent for inventions may cover: First, an apparatus, machine, structure or a device; second, a process or method; third, a composition of matter, such as a chemical compound, and, fourth, a design.

Under the first heading come such combinations of elements as are included, for instance, in steam-heating systems, steam engines, automatic machinery, etc., including practically everything which comes under the term mechanical arts. Claims drawn to these structures are in form for a combination of elements.

The Supreme Court of the United States has laid down the doctrine that the elements of claims must combine together to a single unitary result in order that the claims be patentable. The most famous case perhaps in this connection is the Faber pencil case in which a claim covering the ordinary form of lead pencil in use today, with the rubber tip thereon for erasing purposes, was held unpatentable. A patent had been actually granted upon this device but the Supreme Court of the United States declared it to be invalid. The Court said in effect that the pencil and the rubber each operated independently of the other as each had theretofore operated and that the mere assembling of them together was for convenience only, and did not constitute an inventive act. When so aggregated, the pencil was still used as a pencil and the rubber as an eraser, the pencil and eraser did not combine together for any single unitary result but, on the contrary, were separately employed for independent and individual results. Hence for a claim to be valid, all of its elements must combine together for a final result which is different in kind from that which would have resulted from the use of these elements individually or in individual subcombinations.

Under the second heading come processes or methods, and in this connection it is quite difficult to say with any degree of certainty what is capable of being protected by a patent right, and what is not. Anything new in which there is an elemental or chemical action is capable of this protection; while going to the other extreme, anything which is the mere function of a machine is not capable of such protection, the only possible way of protecting the process or method carried out in a machine being to patent the machine itself.

The requirement for patents under the third class, other than novelty, is that they constitute something more than a mere mixture of known ingredients, with no new result other than that which would naturally follow from such a mixture.

Design patents are granted for something new in ornamental configuration. Parts that have a new form merely for some mechanical purpose are not capable of protection under the design branch of the patent law, the requirement being novelty in ornamental configuration without regard to utility.

Fatal Economizer Explosion

By John S. Leese

An explosion of a Green's economizer resulting in the death of one man, recently occurred at the Pilkington Tile and Pottery Works, Clifton Junction, England.

The economizer was connected to a Lancashire boiler for which it heated the feed water and was installed in 1897. It had been periodically examined since its installation by the representatives of the makers and was apparently in good condition up to the time of the explosion. In the engine room was hung a list of instructions issued by the makers and the following paragraph was printed thereon in red ink under the caption "Repairs:" "When these are being executed it is imperative that the pressure be taken off and the economizer shut down by closing the inlet and outlet dampers and feed valves, allowing the heat to pass through the spare flue. Under no circumstances should any of the joints be interfered with while under pressure."

Howard was the night and Horsfield the day attendant of the boiler and economizer and the circumstances of the accident resulting in the death of Horsfield were as follows: At 11 p.m. on the day before the explosion Howard, who was on duty, noticed that the second cover joint from the inlet end of the lower branch pipe was leaking. He thereupon disconnected the economizer from the boiler and emptied it by means of the blowoff valve. He then removed the cover and remade the joint with rubber and canvas, and, after replacing the cover, reconnected the boiler to the economizer. At five o'clock the next morning he relieved the economizer of pressure by lifting the safety valve, and, with a spanner 18 inches in length, tried the nuts on the remade joint. He then placed the spanner on a branch pipe near the cover and lowered the safety valve. Howard was relieved at six o'clock by Horsfield to whom he related what he had done to the cover, telling him where he could find the spanner in case it should be again necessary to tighten the nuts. At a few minutes past seven the explosion occurred and Horsfield was found in the space occupied by the lower branch pipe of the economizer. The spanner was found 8 feet away from the place where Howard had left it, the cover referred to was on the ground and one of the two bolts which had held it was found to be broken.

The cover was held by two [illegible]-inch bolts. About three years ago Messrs. Green replaced, as standard on their economizers, two [illegible]-inch bolts with four [illegible]-inch bolts and later still these four bolts were replaced by four [illegible]-inch bolts. The boiler was worked at a pressure of 100 pounds per square inch and the economizer at a pressure of 110 pounds per square inch. According to the statement of the head of the inspection department of Messrs. E. Green and Sons, the number and thickness of the bolts had not been increased on account of any doubt as to the safety of using two bolts, but simply to guard against the possibility of employees ignoring the rules. He stated that two bolts were strong enough to withstand the pressure, but that, if one of them was sheared off, the other would not suffice to hold the cover on. With four bolts, in the event of one of them being broken, the other three would hold the cover in place. The above mentioned instructions had been issued to all economizer users in [illegible] as a result of an accident that had occurred in [illegible] to an economizer.

The cause of the fatality was, apparently, the breaking of the [illegible]-inch bolt by tightening it with the 18-inch spanner. The moral of the accident is, therefore, "When rules are issued by the manufacturers of power-plant apparatus, stick to them. They are [illegible] to know more about what it is safe to do and when to do it than you are and they will not put obstacles in the way of their sales department by [illegible]."

Symonds—Emergency Engineer

By F. L. Johnson

Some of the experiences of a bright young engineer who opened a "first aid" to injured machinery consulting office from which he directed personally conducted repair and replacement jobs.

John Symonds had a small office near the business center of a New England manufacturing town. On the glass of the single large bow window, by which he used to sit and think, or just sit if he had no thinking to do, was written in modest gold-leaf letters,

JOHN SYMONDS
EMERGENCY ENGINEER

I had known Symonds a number of years. In early manhood he was one of the engineers in the fire department of his city. I called on him to renew an acquaintance which had been interrupted by my absence from the East. He had not changed much, and except for a sprinkling of gray in the hair about the temples, twenty years had not altered his appearance. Of medium hight and rather lean, he looked like an athlete in perfect condition and his keen, alert glance was friendly and somewhat inquiring as we shook hands. After the usual greeting had been exchanged I said, "Emergency Engineer, what is that?"

"Oh," he said, "it is really a long story but I can make it short by just touching the high spots for I do not think you will care for the minor details. The fire department is no place for a live engineer. It is a soft job at fair pay, but the average man will go down hill both mentally and physically from the day he enters the service. I recognized this early in the game and got out. There was no job waiting for me so I advertised in a small way among the englneers and owners, that I was ready to substitute in engine rooms during the vacation, sickness and emergency absences of the regular man. I got plenty of work at the prevailing rate of pay. In many plants I found many opportunities to improve the operating conditions, to do quick repair stunts and a lot of first aid to injured machinery work.

"Somehow I got the nickname of Emergency Engineer, which stuck and as I had some ability in getting out of close corners I began to get calls to look after repair jobs, make changes and the like, which, with substituting, kept me pretty busy. I rather liked the title of Emergency Engineer and determined to earn it, so I stopped substituting and opened this office.

"Owners wanted advice and wanted work done. I was long on doing work but short on giving or selling advice. I loved to do things my own way a great deal better than telling how they should be done and though I could do a fair business as a consulting engineer within my limits I prefer that work which gives me physical exercise and trains my hands along with my brain. I have my office, congenial work and make a good living. What more can life offer?"

"But," said I, "what work do you do? What kind of jobs come your way?"

"I do anything which anybody wants done in a hurry in a steam plant. Why! last week—" Just here the telephone bell rang. After answering it he said,

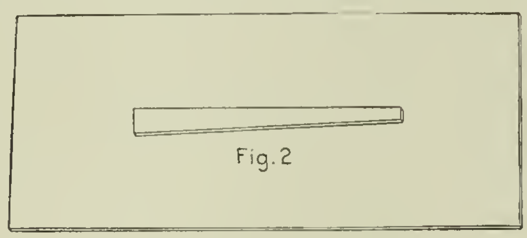

Fig. 2

Fig. 1

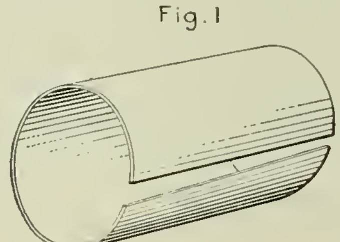

Fig. 3

Fig. 4

Fig. 5

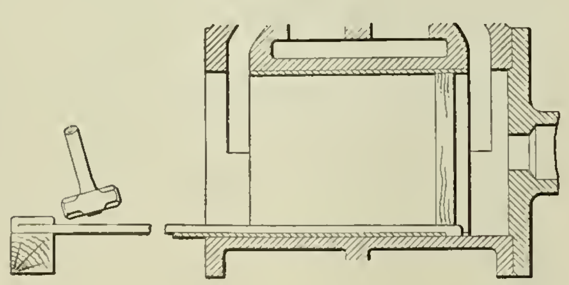

Fig. 6 POWER

"You asked what I do. A call has just come from Brown's that the air pump on the surface condenser has stopped. The engineer cannot start it and the engine will not carry the load noncondensing. I do not know what is wrong but as it is only around the block you can go with me and see what is wrong."

We went. The piston had stopped at about two-thirds of the stroke. Symonds pushed the valve to the other end of its stroke and opened the throttle slightly. The piston moved back to the end of the cylinder, the valve reversed and the piston started on the return stroke.

"Steam end apparently all right," he said softly, as he closed the throttle. He directed the engineer to take off the cylinder head on the water end. This showed why the pump stopped. The water piston was and probably had been for some months guiltless of packing. One of the set out segments had dropped to the bottom of the cylinder and had ploughed through the bushing near mid stroke and a sliver had rolled up, against which the piston struck and stopped.

Whistling, "It Beats All What You See When You Don't Have a Gun," Symonds got into overalls, cut out the obstruction, dismantled and took out the piston. Finding a short crowbar he drove it between the bushing and the cylinder wall at the worn part crimping it so that it was easily pulled out. He then calipered the cylinder. Next he went to a near-by carpenter shop and selected some soft-maple stock of about ½ inch thickness, from which with the band saw he made three packing rings for the piston. These he took back to the plant, put the piston on the rod, put in the wood packing, closed the cylinder and started the pump.

When the exhaust from the engine was turned into the condenser and everything seemed to be going along all right he said to the engineer, "This will run in good shape for months but I will be here Saturday at twelve o'clock to put in a new bushing and I will need one man with a sledge hammer to help."

On the way back to the office he said, "this is an example of the kind of work I have to do. It is my first call to handle a job of this nature. It goes without saying, however, that if all places were filled by first-class men I would not have much to do beyond a little substituting. But there are not enough, first-class men to go around and so long as such miserable wages are paid for engineers' services there will be little inducement for anyone to become an engineer."

I did not reply, but instead I said, "that pump was made out in Wisconsin and you promised to put in the new bushing Saturday. Today is Thursday. Do you expect to get it by telephone?"

"Well, not exactly, but I expect to make it tomorrow afternoon. Come around and take lunch with me and then we will make the bushing together if we can find any sheet brass suitable for the job."

After luncheon the next day he said, "that pump cylinder is 12⅜ inches in diameter and the piston is about 1/32 of an inch less than 12 inches, which shows that the bushing should be 3/16 of an inch thick and 16 inches long. It will take a strip about 39 inches long to go around the inside of the cylinder. It will take up some in rolling so we will go over to the boiler shop and see what we can find."

At the boiler shop some sheet brass 3/16 inch thick was found and from it he had two pieces cut. One piece 16 inches wide and 37½ inches long, one end of which was afterward trimmed diagonally, see Fig. 1, and another 20 inches long by 1 inch at one end and 1½ at the other, see Fig. 2.

The larger piece he had rolled to approximately a diameter of 12 inches, Fig. 3, and had the two pieces sent to the plant. While at the boiler shop he also had made from a bar of inch octagonal steel the two tools shown in Figs. 4 and 5.

After leaving the boiler shop we parted at the corner after he had said that if I still felt interested I would do well to come around to the plant the next day and see the job finished.

As Symonds suggested I arrived at the plant soon after 12 o'clock and found him already at work. The pump had been dismantled and he was driving the split bushing into the cylinder with a hide-faced hammer. When in place there was a tapering slot or gap where the sheet had been trimmed. Into this slot he drove the wedge-shaped strip until the rebound of the hammer showed that it was solid. This forced the side of the bushing outward against the cylinder wall. Then with a light hammer he "sounded" the bushing in several places to determine whether the contact between the bushing and the cylinder was perfect. Every spot touched gave forth the same sound, proving that the wedge had driven the bushing outward and that it was really expanded into perfect contact.

He then measured the distance from the small end of the wedge to the inner end of the bushing, which proved to be about an inch. He then took the bar shown in Fig. 4 and put the hook over the end of wedge and drove a strut of wood between it and the side of the bushing, as in Fig. 6, and with a block under the outer end of the bar to support it, the helper with the sledge struck on the gib of the bar which, with a few blows, pulled out the wedge.

This, after a thorough inspection, was dressed along one edge, narrowing it about a thirty-second of an inch which, according to Symonds' calculations would allow it with the same amount of driving to enter three-quarters of an inch further, leaving a quarter of an inch for the final driving. It was then narrowed slightly at the wide end to allow for the upsetting effect of the final driving. It was smeared on one side and both edges with a mixture of white lead and graphite to reduce the friction of driving.

After accurately locating the bushing and preventing a possible endwise movement from the effect of driving by a couple of distance blocks placed between the ends of the bushing and the inside cylinder head, the wedge was pushed into the slot and driven home with the drifting tool and sledge, Fig. 6. When the small end of the wedge came flush with the inside end of the bushing, the wide end was cut off flush with the end of the bushing.

The hard driving had raised a little bur or ridge along the joints which Symonds removed with a scraper. The parts were reassembled with new hot-water packing in the piston and the pump tried, and as everything appeared to be in good working order we walked back to the office.

Seated by the window again Symonds, as he held a cigar in one hand and a match in the other said, "that little job was just what I needed. It gave me the necessary mental and physical exercise which keeps me in condition. Sometimes nothing happens for a week and I have to take a cross-country walk to keep in shape. But that does not often happen. There are 200 steam engines in this town and I am sure to hear from most of them inside of a year. I do not keep a shop and have but few tools. I am always welcome to the use of any tools belonging to the shops in which I happen to be working."

Just here a man came in who wanted some advice about the purchase and repairs on an engine which had been slightly damaged by fire, so I took my departure after promising to look in on my next trip and see some more emergency repair work.

Driving Boilers at Economical Rates

By Alphonse A. Adler

A graphical method showing how the fixed charges, the cost of coal and the total operating cost of the boiler plant vary with the rate of driving.

The most economical rate of driving boilers, from the thermal and commercial standpoints, differ because the fixed charges are some function of the number of boilers in service, whereas the highest thermal efficiency occurs at a certain load per boiler and is independent of the number of boilers in service.

Before proceeding with the topic under consideration it might be well to define some of the terms used. The writer prefers the term "overall" efficiency to denote that efficiency ordinarily termed as "combined boiler and furnace efficiency." The efficiency of the boiler proper may be expressed as

$$\frac{\textit{Heat absorbed from combustible burned}}{\textit{Heat in combustible burned}}$$

and this ratio may be limited to one pound of combustible as its value is unaffected by the weight. The furnace efficiency may be expressed as the

$$\frac{\textit{Heat in the combustible burned}}{\textit{Heat in the combustible fired}}$$

This latter expression evidently indicates the combustible that is lost through the grate and that disposed of in the ashes. The product of these efficiencies gives the overall efficiency, or

$$\textit{Overall efficiency} =$$

$$\frac{\textit{Heat absorbed from combustible burned}}{\textit{Heat in combustible burned}} \times \frac{\textit{Heat in combustible burned}}{\textit{Heat in combustible fired}} = \frac{\textit{Heat absorbed from combustible burned}}{\textit{Heat in combustible fired}}$$

From the foregoing it will be seen that the overall efficiency is easy to measure as it is the ratio of the total heat in the steam to the total heat in the combustible fired. The overall efficiency is the one plotted in Curve 1, which is the characteristic curve for water-tube and probably, fire-tube boilers, under carefully guarded commercial conditions.

This curve shows the thermal efficiency of the boiler increasing to a maximum at about 3.25 pounds evaporation per square foot of heating surface per hour, then slowly dropping at higher rates of evaporation. Were only the thermal efficiency of importance, the most economical rate of driving would evidently be an evaporation of 3.25 pounds per square foot of heating surface. Consider first the heat absorption of the boiler, the heat transmission being a function of the time. At low rates of driving, the movement of the gases is slower, hence the transmission per unit of time is greater than at the high rates of driving. The water and the gas speeds are slow at low rates of driving, and the consequent absorption is low with a tendency to increase at higher rates of driving. The furnace operates at low efficiency at low rates of driving, increasing [illegible] as the rate of driving increases, due to better control of the air supply and consequent higher temperatures. The [illegible] of the [illegible] is more marked at the low rates of [illegible] bustion, as each particle has a well defined path through the boiler, and the formation of CO in the presence of O is readily detected. As soon as the speed

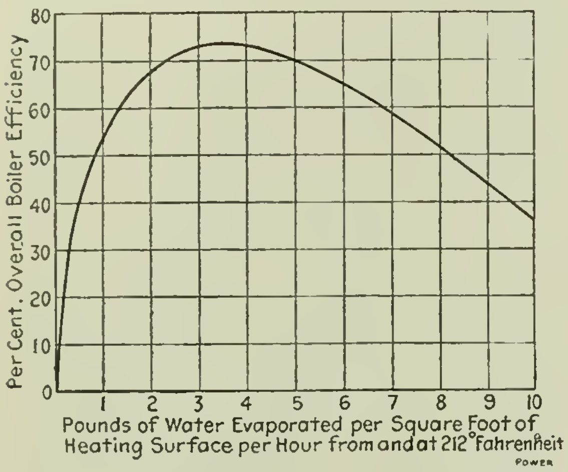

FIG. 1. EFFECT OF DRIVING UPON OVERALL EFFICIENCY

of the gas increases, the eddies formed give the gas a turbulent action and a more intimate intermingling results. The overall efficiency is the sum of these individual factors, some of which increase as the rate of driving increases, while others decrease under the same conditions.

In the analysis for a given plant, a curve similar to curve No. 1 might be drawn if accurate results are desired; otherwise, the one shown may be assumed as typical. For example, assume the following values:

Boilers at $15 per horsepower, or $4500 for a 300-horsepower boiler; floor space, 600 square feet per boiler; fixed charges on boiler house,* $1 per square foot, or $600 per boiler per annum; interest, depreciation, maintenance and labor at 20 per cent. of cost of boilers, $900 per boiler per annum; coal at $3 and $6 per net ton; heat value per pound of combustible, 14,600 B.t.u.; steam consumption, 24,000 pounds per hour; steam pressure, 150 pounds gage; feed-water temperature, 200 degrees Fahrenheit.

Service and conditions of operation as follows:

Coal at $3 per ton, 8 hours per day of 300 days per year; coal at $3 per ton, 4 hours per day of 300 days per year; coal at $6 per ton, 8 hours per day of 300 days per year; coal at $6 per ton, 4 hours per day of 300 days per year.

*These values represent the upper limits and are much higher than those met with in the average plant. In the curves, however, the actual conditions for any plant may be found by interpolation.

Adding the $900 for interest on the boilers, to the $600 for fixed charges on the building, the total fixed charge is $1500 per boiler of 300 horsepower. The assumptions are somewhat crude due to the 4- and 8-hour schedules, thereby ignoring coal for banking and variations in efficiency with variations in load. Present central-station practice indicates that reasonable results are arrived at by granting these assumptions, refinements in figures being a matter of personal taste. For convenience in plotting the curves, the fixed charges are reduced to

$$\frac{1500}{300} = \$5.00 \textit{ per boiler horsepower}$$

or

$$\frac{5.00}{10} = \$0.50 \textit{ per square foot of heating surface}$$

The total steam per hour from and at 212 degrees Fahrenheit is

Steam at given pressure and feed temperature × *factor of evaporation* = 24,000 × 1.0615 = 25,476 *pounds*

The number of boilers required at the most economical rate of driving from the coal standpoint alone is found from the expression

$$\frac{25{,}476}{3.25 \times 300 \times 10}$$

which figures out to be three boilers, allowing the customary 10 square feet of heating surface per boiler horsepower.

By reference to curve No. 1, the efficiencies at the different rates of driving can be tabulated as follows:

TABLE 1

Rate of driving in pounds of water evaporated from and at 212 degrees Fahrenheit per square foot of boiler heating surface....	1	2	3	4	5	6	7	8	9	10
Boiler efficiency.....	0.54	0.6775	0.73	0.73	0.70	0.65	0.5875	0.5175	0.44	0.36

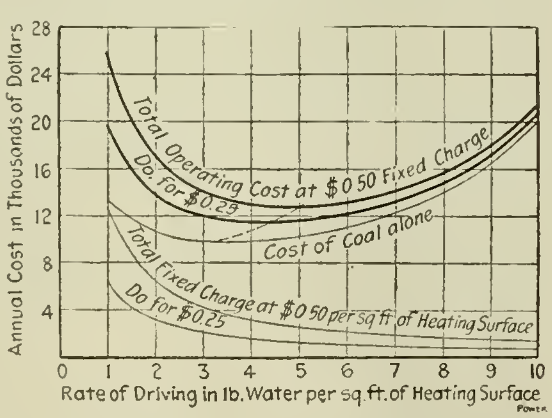

FIG. 2. EFFECT OF DRIVING UPON TOTAL OPERATING COSTS. SERVICE, 2400 HOURS, COAL $3 PER TON; SERVICE, 1200 HOURS, COAL $6 PER TON

The annual cost of coal for a given plant will equal

$$\frac{\left(\textit{Steam per hour} \times \textit{B.t.u. per pound of steam} \times \textit{hours of service per annum} \times \textit{cost per pound of combustible}\right)}{\left(\textit{Heat value per pound of combustible} \times \textit{boiler efficiency}\right)}$$

This for eight hours operation per day, and coal at $3 per ton, is expressed in Table 2.

TABLE 2

Rate of evaporation, pounds of water per sq.ft. of heating surface per hour	Cost of Coal per Annum
1	$\frac{25{,}476 \times 970.4 \times 2{,}400 \times 0.1765}{14{,}600 \times 0.54}$ = $13,300
2	$\frac{25{,}476 \times 970.4 \times 2{,}400 \times 0.1765}{14{,}600 \times 0.6775}$ = $10,600
3	$\frac{25{,}476 \times 970.4 \times 2{,}400 \times 0.1765}{14{,}600 \times 0.73}$ = $ 9,830
4	$\frac{25{,}476 \times 970.4 \times 2{,}400 \times 0.1765}{14{,}600 \times 0.73}$ = $ 9,830
5	$\frac{25{,}476 \times 970.4 \times 2{,}400 \times 0.1765}{14{,}600 \times 0.70}$ = $10,200
6	$\frac{25{,}476 \times 970.4 \times 2{,}400 \times 0.1765}{14{,}600 \times 0.65}$ = $11,000
7	$\frac{25{,}476 \times 970.4 \times 2{,}400 \times 0.1765}{14{,}600 \times 0.5875}$ = $12,200
8	$\frac{25{,}476 \times 970.4 \times 2{,}400 \times 0.1765}{14{,}600 \times 0.5175}$ = $13,900
9	$\frac{25{,}476 \times 970.4 \times 2{,}400 \times 0.1765}{14{,}600 \times 0.44}$ = $16,300
10	$\frac{25{,}476 \times 970.4 \times 2{,}400 \times 0.1765}{14{,}600 \times 0.36}$ = $20,000

In doubling the cost of coal it is necessary only to double the costs in Table 2, or, halving the hours of service, will be equivalent to dividing these costs by two.

TABLE 3

Rate of evaporation	Cost of coal per annum	Fixed charges at $0.50 per sq.ft. of heating surface	Total annual cost fixed charges at $0.50 per sq.ft. of heating surface	Fixed charges at $0.25 per sq.ft. of heating surface	Total annual cost fixed charges at $0.25 per sq.ft. of heating surface
1	$13,300	12,740	26,040	6,370	19,670
2	10,600	6,370	16,790	3,185	13,785
3	9,830	4,250	14,080	2,125	11,955
4	9,830	3,185	13,015	1,593	11,423
5	10,200	2,548	12,748	1,274	11,474
6	11,000	2,125	13,125	1,062	12,062
7	12,200	1,825	14,025	912	13,112
8	13,900	1,593	15,493	796	14,696
9	16,300	1,417	17,717	708	17,008
10	20,000	1,274	21,274	634	20,634

The annual cost of coal given in Table 3 is taken from Table 2. The fixed charges are determined as follows: At the rate of evaporation of 1 pound of water per square foot of heating surface from and at 212 degrees Fahrenheit, 25,476 square feet of heating surface are required. At a fixed rate of $0.50 per square foot of heating surface the annual charges become

$$25{,}476 \times 0.50 = \$12{,}740$$

For an evaporation of 5 pounds of steam per square foot of heating surface, the number of square feet of heating surface is

$$\frac{25,479}{5} = 5,095$$

Again, at the fixed rate of $0.50 per square foot of heating surface the annual charge becomes

$$5,095 \times 0.50 = 2,548.$$

In this way all the values in the third column have been computed. By halving these values those in the fifth column are arrived at, this amounting to a fixed

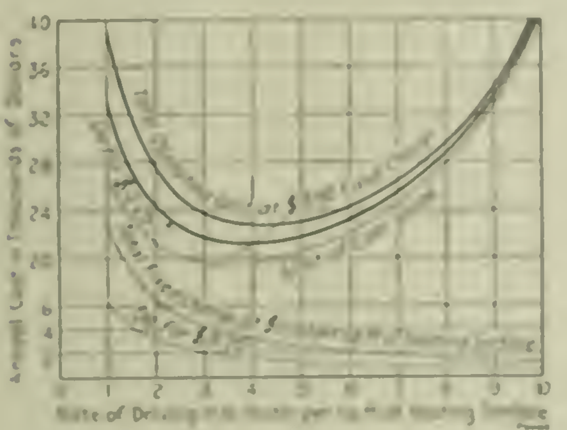

FIG. 3. EFFECT OF DRIVING UPON TOTAL OPERATING COSTS. SERVICE, 2400 HOURS, COAL $6 PER TON

charge of 0.25 per square foot of boiler heating surface.

By adding the fixed charges to the cost of coal the values in the fourth and sixth columns are obtained, these representing the total annual operating costs. The values in Table 3 are plotted in curve No. 2.

By doubling the cost of coal and using the same number of hours of service, the values in the second column, Table 4, become just double those of the second column, Table 3. The fixed charges remaining the same at rates of both, $0.50 and $0.25 per square foot of heating surface, the values are arrived at as before. These figures have been plotted in curve No. 3.

Assuming 1200 hours of service per year instead of 2400 hours, with the coal costing $3 per ton, the values in the second column, Table 5, are obtained; these are one-half the values of those in the second column, Table 3. As before, the fixed charges remain the same, and their addition to the cost of coal results in the fourth and sixth columns, which are the total annual operating costs. Curve No. 4 shows this in its final form.

Some attention might profitably be directed toward the change in the most economical rate of driving. When the coal cost and hours of service are low the rate of driving should increase. On the contrary, should the cost of coal be high and also the hours of service, then the point of maximum boiler efficiency should be approached. Curve 1 shows that there are two points that can have exactly the same efficiency at altogether different rates of driving. For instance, 60 per cent. efficiency is attained when evaporating 1.3 pounds and also 6.8 pounds of water per square foot of heating surface per hour.

TABLE 4

Rate of evaporation	Cost of coal per annum	Fixed charges at $0.50 per sq.ft. of heating surface	Total annual cost fixed charges at $0.50 per sq.ft. of heating surface	Fixed charges at $0.25 per sq.ft. of heating surface	Total annual cost fixed charges at $0.25 per sq.ft. of heating surface
1	26,600	12,740	39,340	6,370	32,970
2	21,200	6,370	27,570	3,185	24,385
3	19,648	4,250	23,898	2,125	21,773
4	19,660	3,185	22,845	1,593	21,253
5	20,400	2,548	22,948	1,274	21,674
6	22,000	2,125	24,125	1,062	23,062
7	24,400	1,820	26,220	912	25,312
8	27,800	1,593	29,393	796	28,596
9	32,640	1,417	34,057	708	33,348
10	40,000	1,274	41,274	637	40,637

TABLE 5

Rate of evaporation	Cost of coal per annum	Fixed charges at $0.50 per sq.ft. of heating surface	Total annual cost fixed charges at $0.50 per sq.ft. of heating surface	Fixed charges at $0.25 per sq.ft. of heating surface	Total annual cost fixed charges at $0.25 per sq.ft. of heating surface
1	6,650	12,740	19,390	6,370	13,020
2	5,300	6,370	11,670	3,185	8,485
3	4,912	4,250	9,162	2,125	7,037
4	4,915	3,185	8,100	1,593	6,508
5	5,100	2,548	7,648	1,274	6,374
6	5,500	2,125	7,625	1,062	6,562
7	6,100	1,820	7,920	912	7,012
8	6,950	1,593	8,543	796	7,746
9	8,160	1,417	9,577	708	8,868
10	10,000	1,274	11,274	637	10,637

The dotted lines on curves 2, 3 and 4 pass through points of maximum economy. The dotted line is also useful in estimating the most economical rate at other than these assumed values for fixed charges. Furthermore, should the max-

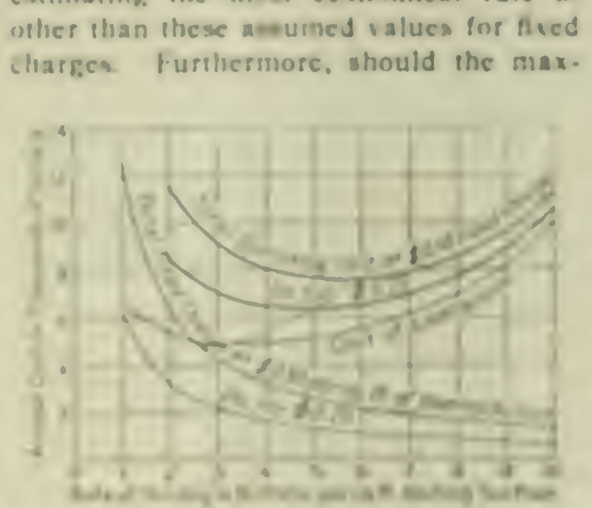

FIG. 4. EFFECT OF DRIVING UPON TOTAL OPERATING COSTS. SERVICE, 1200 HOURS, COAL $3 PER TON

imum boiler efficiency occur at, say, 4.25 instead of 3.25 pounds evaporation, the rate of driving would move in the same direction, that is, it would be about 1 pound higher than values obtained in curves 2, 3 and 4. Hence, even though the curves do not tell exactly the condition for any given plant, still with a little judgment, they may be of service in locating approximately the rate of driving for any plant.

In conclusion it may be said that the curves apply only to such cases where no spare boilers have been installed. When this is the case, the interest on the investment goes on, whereas there may be somewhat of a reduction in the labor charge. Also, it is better to keep boilers in service when light loads are being carried, as the variation in furnace temperature affects the life of the settings and may thus increase the maintenance charge.

Danger of Fire from Steam Pipes

The quarterly of the National Fire Protection Association of Great Britain recently presented some interesting notes on the danger of fire from steam pipes. It is generally admitted that steam pipes in contact with wood will cause an occasional fire. There is considerable diversity of opinion as to the circumstances under which such fires may be expected to occur, but the conclusions drawn by a number of investigators who attempted to produce fires by bringing steam pipes into contact with various combustible materials were, that any steam pipe, no matter how low the pressure, would in the course of time produce charcoal and that when this stage was reached, positive danger existed. Charcoal is unquestionably subject to spontaneous ignition due to its peculiar ability to absorb from the air many times its own volume of oxygen. The combination of this oxygen with the carbon may take place with sufficient rapidity to raise the temperature to the ignition point. Furthermore charcoal formed at a low temperature is known to have a low ignition point.

Some investigators seem to think that there is less danger from this source where steam is kept on a system continually than where it is on intermittently. The reason advanced is that when allowed to cool the charcoal has a better opportunity to absorb oxygen than if kept hot at all times.

There are two general methods of keeping steam pipes free from contact with combustible material, the first being through the use of an insulator, such as pipe covering, and the second by supporting them rigidly at a safe distance. Wherever pipes pass through concealed spaces the covering should preferably be carried for the entire length to avoid future contact with substances which may get into these spaces. On new installations solid covering and collars can be used; where the piping is already in place, split covering wired together and split collars make the partial taking down of piping unnecessary. If desired, metal supporting plates can be used at the ceiling instead of a collar.

The Cost of Industrial Power

By Henry D. Jackson

A rational discussion of the charges to be included in figuring the cost of industrial power, with special reference to the attempts of central-station men to boost these charges, as shown by Mr. Hibner's paper which appeared in the March 21 issue of Power.

It seems rather peculiar that all of the information available on power costs in industrial plants comes from the industrial engineers or sales engineers of the central power stations. It may be that these figures come from such sources because these people are the only ones sufficiently interested to go into the matter carefully and dig up figures which they can submit to a manufacturer and show him how enormously expensive his plant is and how much more it is costing him than it would cost if they were allowed to furnish power.

In Mr. Hibner's paper the statement is made that "Sometimes manufacturers retain consulting engineers on the basis of a percentage of the cost of the plant if it is installed. The dangers of such a practice are quite evident, as it is asking a good deal of human nature for a man to lose a neat commission on the sale of a plant by recommending the purchase of power." Yet Mr. Hibner would not hesitate to recommend this manufacturer to go to the sales agent or industrial engineer of a power company for the same information. Is not this latter method a far more dangerous practice? The consulting engineer does a large amount of work for his money. He not only determines whether or not it is advisable to install a plant, but if to his satisfaction and to the satisfaction of his client he has proved that it is advisable, he lays out the plant, supervises its installation and sees that it meets the requirements of the manufacturer. Does the sales agent of the power company do anything in this line?

The figures given by Mr. Hibner would not lead one to believe that his figures are as convincing or as nearly correct as would be likely if the figures were submitted by an engineer who was not biased in either direction, and no good engineer would be biased any more than would a good doctor. A man with a broken leg would not go to a carpenter because the carpenter has all of the tools necessary and knows how to saw off the leg or knows how to make the splints. He would go to a surgeon.

The question of whether to purchase power or to generate it, depends entirely upon the relative cost of the two methods. In most cases it is a question not only of power, but also of supplying steam for heating and other purposes in addition to the power, resulting in the plant operating noncondensing with more or less back pressure during the winter months. The steam economy is not as good as would be expected from a condensing plant, but there is no reason why the steam consumption should be excessive or an uneconomical type of engine purchased.

Taking up the specific points of the discussion, Mr. Hibner considers a shoe factory of approximately 250x60 feet general dimensions, four stories high and built of brick. In the portion of the country selected, that of Toronto, heat is required for approximately seven months in the year; and, according to his figures, an average of 45 boiler horsepower is required, with 90 horsepower during zero weather and probably considerably over this during exceedingly cold weather. According to Table 1, the coal required for heating alone is 475 tons.

TABLE 1

Heating Plant Investment		
Boiler, piping and auxiliaries (*A*)	$1500.00	
Building and stack (*B*)	2500.00	
Total investment	$4000.00	
Fixed Cost		
Interest at 6 per cent. on $4000	240.00

Additional for power		$1,830.00	
Operating Cost of Power Plant			
240,000 Kilowatt-hours			
Coal at 7.39 pounds per kilowatt-hour, 887 tons at $3	$2,661.00		
Banking, 181 tons at $3	543.00		
Night heating, 202 tons at $3	606.00		
Engineer at $18 per week	936.00		
Fireman at $15 per week	780.00		
Water	100.00		
Oil, waste, supplies	150.00		
Repairs	200.00		
		$5,976.00	
Operating cost of heating plant		2,305.00	
Additional for power		$3,671.00	
Total additional for power		5,501.00	
Cost per kilowatt-hour		0.0229	
Cost per horsepower-year		51.40	

In Table 2, however, it will be noted that 202 tons are allowed for night heating, leaving a total of 273 tons for day heating. If it requires 202 tons of coal for heating a plant which is entirely closed, as a plant is at night, and where no changes of air take place other than leakage, it certainly would take more than 275 tons of coal to accomplish the same results where there is at least one change of air per hour as well as open windows, doors, etc. It would be better to figure 475 tons of coal for day heating and 202 tons of coal for night heating, making a total of 677 tons of coal for heating during the year. Therefore, it will be noted that in estimating the cost of heating alone, Mr. Hibner has neglected the heating during the night, which he has been very careful to consider in estimating the heating in connection with the complete power-plant equipment. In Table 1, the investment and fixed costs may be left as they are, but the operating cost will increase in the ratio of 677 to 475 on the coal, making a considerable difference in the operating cost of the heating plant. Table 1-A would represent the revised figures.

TABLE 1-A

First Cost and Fixed Charges Same as 1

Operating Cost	
Coal, 677 tons at $3	$2031.00
Fireman at $15 per week	780.00
Supplies and repairs	100.00
	$2911.00
	400.00
Total operating and fixed charges	$3311.00

There might also be added to this operating cost, according to his own paper, the cost of the coal required to generate the steam which is required at high pressure during the entire year, for which no allowance has been made, although the time of the fireman has been figured for this period. Besides, it is advisable to note that since steam at a high pres- [illegible] is required for industrial purposes, [illegible]e boiler plant, piping, etc., must be purchased for high-pressure service.

Now consider what it will actually cost to install and furnish power from a power plant.

TABLE 2-A

100-kilowatt generator and engine	$[illegible]
Boiler, piping and auxiliaries	[illegible]
Buildings, stack and foundations	4,000.00
	$11,000.00
Steam heating plant	4,000.00
Additional for power	$7,000.00
FIXED CHARGES	
Interest, 6 per cent. on $11,000	$660.00
Insurance and taxes at 2 per cent.	220.00
Amortization, 3 per cent. on total	330.00
Profit (to help out Mr. Hibner)	[illegible]
Fixed charge on heating plant	[illegible]
Additional for power	$1,100.00
Total fixed charges	$1,840.00
OPERATING CHARGES	
Coal, 6 pounds per kilowatt-hour, 720 tons at $3	$2,160.00
Night heating, 150 tons at $3	450.00
Engineer at $20 per week	1,040.00
Fireman at $15 per week	780.00
Oil, waste, water, repairs, supplies	[illegible]
	$[illegible]
Operating charges for heating	2,210.00
Additional for power	$[illegible]
Total for power, fixed charges	1,100.00
	$3,730.00

Table 2-A gives the first cost, fixed charges and operating charges according to my estimate. There certainly seems to be no reason why a 100-kilowatt plant using noncondensing engines and apparatus moderate in price, should cost over $110 per kilowatt; and, although these figures may appear small to Mr. Hibner, I have recently installed a 200-kilowatt plant at very nearly these relative figures, as well as a number of 100-kilowatt plants.

The profit item shown in these tables requires explanation. If the profit is to be considered at all, it should be considered on everything that a manufacturer owns; and if taken in this light, very few manufacturers would own anything; they would prefer to rent everything. Therefore, it would seem that this item should not be taken into account in the fixed charges on the plant. I should prefer to use this item as an item of profit in favor of utilizing my own plant, and not as a charge against my plant, using it to pay off in a greater or less time the total cost of the installation, thus making the installation entirely a profit from an operating standpoint. Therefore, I should deduct this 5 per cent. from Table 2-A and make the fixed charges $1210 instead of $1840, making the additional charge for power $810 instead of $1100. This would make the total fixed and operating charge for power additional over what is required for heating, $3380 instead of $3730, or 1.41 cents per kilowatt-hour.

An explanation may be necessary for the reduction of coal from 7.30 to 6 pounds per kilowatt-hour. While an evaporation of 7 pounds is not bad for a heating plant, it is probable that a power plant which is in continuous operation would do better than 7 pounds; hence, an evaporation of 8½ or 9 pounds is not excessive. It would have been better had Mr. Hibner given some idea as to the quality of the coal, as good coal would probably do better than 7 pounds and poor coal might do much worse.

I have under observation three plants requiring a maximum of 140 horsepower and an average of about 110, all operated by Corliss engines which, in spite of their age, something over 15 years, are in good condition. These plants operate noncondensing with a back pressure during the winter months of approximately 2 pounds. The buildings are of wood and heat is kept on all night during the winter, yet the coal bills are something less than $2400 for the year, in spite of the fact that the coal costs $4.50 a ton instead of $3, as given by Mr. Hibner. It might be well to add, however, that there is more or less leather burned in all of these plants, and the same would be true in the factory under discussion by Mr. Hibner, unless he has some means of disposing of this leather more profitably, which is doubtful.

It is hard to account for the necessity of the 181 tons of coal which Mr. Hibner has assumed for banking purposes. For about seven months of the year there is night heating, for which he has allowed 202 tons of coal. During the other five months of the year he would not require over 300 pounds of coal a night for banking purposes, should it be found advisable to bank the fires, which is by no means true in all cases, for the plants referred to find it is cheaper to allow the fires to go out each night. Mr. Hibner figures 1.45 tons of coal per night for banking purposes. I would like to ask how he succeeded in getting this coal upon the grate; and further add that a good-sized plant can readily be operated on 1.45 tons of coal per day.

Such figuring as this would lead one to believe that it is far safer to trust to the consulting engineer for figures, even although he be paid upon the percentage basis, than upon the figures of the sales engineer of a central power plant, for it is apparent that the latter does not take average conditions but extreme cases. The consulting engineer, however, figures on a conservative basis from plant tests and results obtained in actual practice on good plants.

The great difficulty most manufacturers have in taking up the matter with the central-station man is in getting fair figures. Everything is given an artificial value, in order to make the power cost as high as possible; and, as Mr. Hibner states, when the manufacturer is not an engineer, he has great difficulty in determining where the central-station man is at fault, or in translating the contract of the central-station man so that it means anything to him. It is true that the load factor has an important bearing upon the cost of power, not only as generated by the manufacturing plant, but also when purchased from the central station. Very few power-company contracts give a flat rate regardless of the load factor, and most of them are on a sliding-scale basis, so arranged that the cost of power as purchased increases far more rapidly as the load factor decreases than would the cost of power if generated. Particularly is this true when there is a fixed charge per horsepower of motors installed, and other methods of charging which call for a fixed monthly rate regardless of the power used.

The consulting engineer is by no means adverse to so laying out a plant that it can be operated by purchased power for a sufficient length of time to prove to the manufacturer that his estimate of power cost under conditions of purchased power is correct, and at the same time so arrange the plant that a power installation can be later installed, if necessary. This arrangement gives the central station a fair chance, and by a proper arrangement of the buildings it will enable the new power installation to be installed with no excess cost over what would have occurred had it been installed at the same time the plant was laid out for purchased power.

Emergency service is more a theoretical necessity than a practical one. The central-station man claims that such service is absolutely necessary. A study of the conditions existing throughout the industrial world would hardly bear out this opinion, as for years the majority of manufacturing plants have been operated from a single unit, some of these operating 24 hours a day for six days out of the week, with hardly a shutdown in the entire life of the plant. A good reliable engine and boiler plant, well installed, is more free from the possibility of breakdown than is power from any central station. There are hundreds of factory plants which operate six days out of the week without a breakdown or shutdown, year in and year out; but I do not believe there is a single central station in the country that has not had power off its lines for a greater or less period of time at least once a year, ever since it was installed, and I know of a number of plants that have been off from three to five such times, varying in length from 15 minutes to 3 hours, in the last few years. In one case, that of a large central plant, power was off nearly all day, and in every case the transmission lines were short and most of the trouble was with the lines. There was also trouble in the plants themselves.

Central-station service is, as a rule, good, but as regards reliability and continuous service, it is not to be compared to that of the individual power plant if the apparatus purchased is good and properly installed.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

An Endurance Test of Aeroplane Engines

An official 24-hour test of aëroplane gasolene engines was made recently by the National Physical Laboratory, which is under the control of the British government, though not relying entirely upon government support. All the research work of the official advisory committee of aëronautics is carried out at this place, where a very fine testing plant is gradually being amassed. Originally six builders entered the competition, but only three actually presented their motors for test. Two of these failed in the endurance test, leaving a single competitor to complete the full schedule of the trials.

To prove the trustworthiness of the engines it was stipulated that they should make a run of 24 hours at full load with not more than three stoppages nor a total duration of stoppages exceeding 30 minutes. While the engine was running the only adjustments permitted were those that could be made by the levers for ignition and carbureter control. Handling of the engine for any other purpose was forbidden. Oiling by hand, for instance, was not permitted.

An additional test had to be undergone to determine whether the motor would work satisfactorily when tilted about an axis transverse to the shaft. Two runs of one hour each were made at an angle of 15 degrees, first one end and then the other being elevated.

The motors had to be designed to give 35 brake horsepower and not to weigh more than 245 pounds; that is, 7 pounds per brake horsepower. The weight, however, included not only parts necessary for ordinary running, but also the cooling apparatus with its accessories, such as fans, etc. Neither gasolene, water nor oil was reckoned as motor weight, nor was the gasolene tank.

Among the most interesting and practical conditions were those relating to the air current and the propeller thrust. The test was made without propellers, but to represent the thrust an artificial load of 175 pounds was applied to the thrust bearing. To represent aërial conditions the tests were made in an artificial air current of 30 miles an hour delivered from a horizontal pipe six feet in front of the motor and 4x4 feet in cross-section.

In order that no possible bias may be allowed to enter into the description of the engine trials, the results are given herewith as they appear in the official report just issued (Government Booklet Cd. 5453).

Wolseley Engine: After a preliminary run the test was commenced at 1:11 p.m. on September 12. The engine ran very smoothly, doing 36 brake horsepower at 1443 revolutions per minute for two hours. It was then discovered that a copper oil pipe leading from the pump to the oilwell was leaking. The maker's representative decided not to stop, and, after 20 minutes, disconnected and blanked off this pipe while running. It appears, however, that this change interfered with the oil supply to the bearings, for the engine commenced to run irregularly and finally stopped at 4:13, when it was found that the white metal of one of the connecting-rod bearings had melted. In accordance with the regulations, the engine was therefore disqualified.

The representative of the maker, however, expressed the desire to repair the engine that it might again undergo a 24-hour trial. In view of the nature of the failure and the value of having as complete a test as possible of the engine, it was considered desirable to accede to this request. A new bearing was accordingly fitted and another trial was started at 9:50 a.m. on September 15. The engine ran very well for four hours and then began to run irregularly. After five hours of the test a stop was made and a new spark plug was fitted to one cylinder. This was repeated after another hour's run but without improving matters, the trouble being apparently due to faulty action of the radiator.

After six hours of the test there was a stop for 50 minutes. The radiator was emptied and refilled. After restarting, the engine ran for six hours and then failed. After three more short runs, of

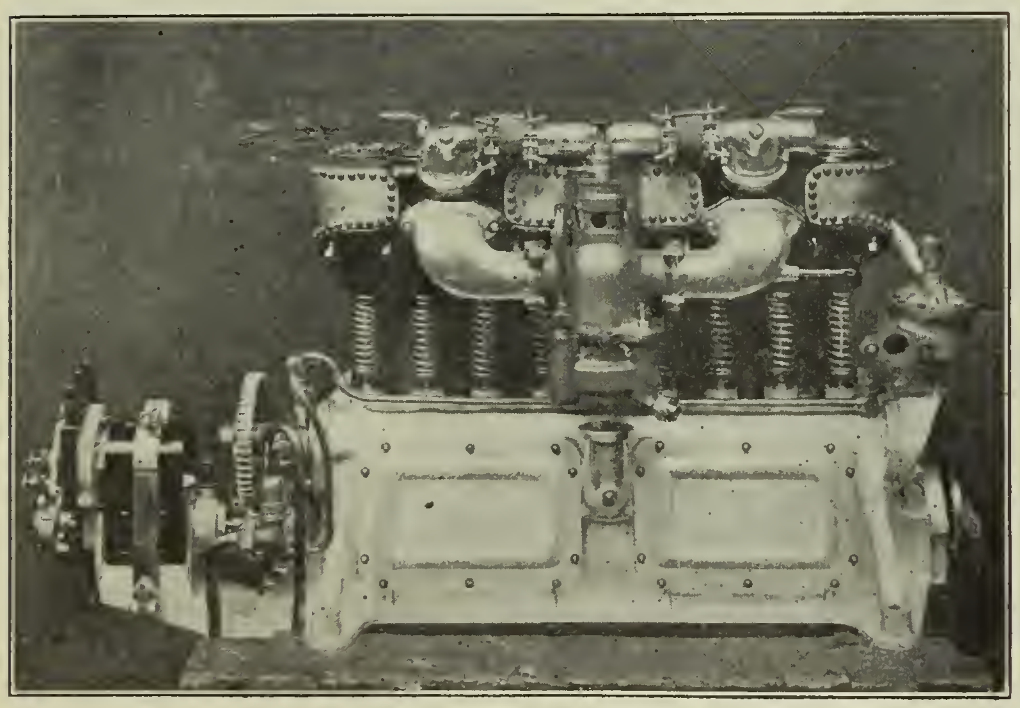

Fig. 1. The Wolseley Engine

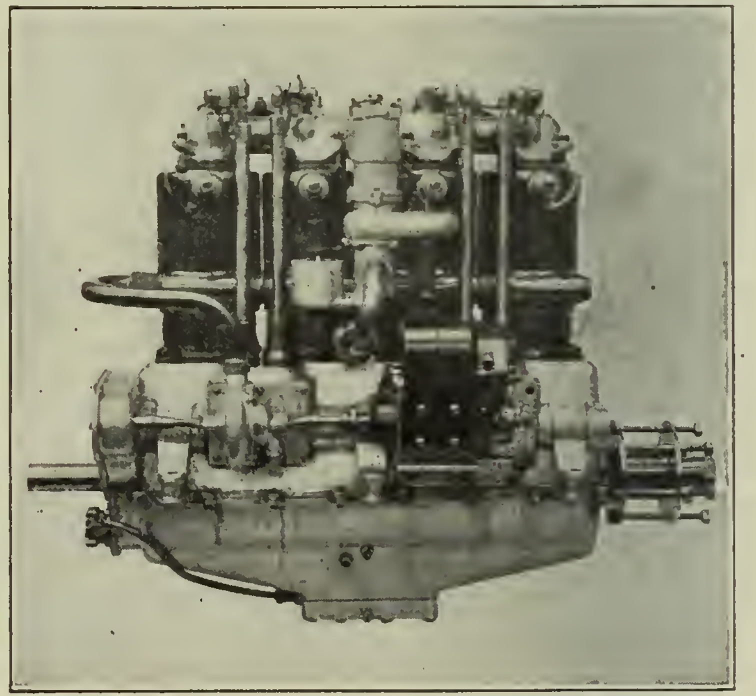

Fig. 2. The Humber Engine

23 minutes, 92 minutes and 38 minutes, respectively, it was observed that the cooling water was rapidly disappearing. The engineer in charge then decided to stop and examine the cylinders. On applying water at about five pounds pressure to the jackets, it was found that the water was making its way into all four cylinders through cracks in their upper ends. The test was therefore discontinued after a total run of 17 hours and 41 minutes, including seven stops aggregating 2 hours and 18 minutes. The cylinders were taken to the works the next day, September 16, and on September 17 the Wolseley company withdrew from the competition.

Humber Engine. The erection of this engine was commenced on September 19 and a preliminary run was made on September 21. On September 22 the maker's representative asked for permission to install another radiator, as the one sent with the engine was inadequate. He was informed that the committee might take a serious view of such an alteration and that the company must make any alteration on its own responsibility. On September 23 another radiator was put on and, after a preliminary trial, the endurance test was commenced on September 26, at 9:45 a.m.

After running for 16 minutes, as the ignition in one cylinder was not satisfactory, a stop of two minutes was made and a new spark plug put on. The engine then ran steadily, doing 37 brake horsepower at 1224 revolutions per minute for 11¼ hours, when the engine suddenly failed; on inspection it was found to be completely wrecked, with one of the cylinders broken off. The only attention to the engine during this period was the addition of 12 pints of oil seven hours after the commencement of the trial and 50 pints an hour later. On the following day the engine was examined more in detail and it was found that, in addition to the fractured cylinder, two connecting rods were buckled and the big end caps torn off, several holes were made in the crank casing and the crank shaft was damaged. This accident, of course, brought the test of the Humber engine to a conclusion.

Green Engine. A preliminary run of the engine was made on October 17 and the endurance test was commenced at 10:30 a.m. on October 18. The engine did not run very satisfactorily during the first hour, owing to difficulties with the ignition, and after one hour's run a stop of ten minutes was made, during which new spark plugs were fitted. On restarting, the engine ran much better and continued running at approximately 31.5 brake horsepower at 1213 revolutions per minute, until the completion of the 24 hours' run on October 19. The only attention to the engine during this period was the addition of 42 pints of oil 17 hours after the commencement of the trial and an additional 21 pints five hours later.

The maximum horsepower which could be maintained for seven minutes was determined on the same day without any overhauling of the engine, except grinding in the valves. The horsepower obtained was 36.4 at 1380 revolutions per minute.

To determine whether the engine would work satisfactorily when tilted about an axis transverse to the shaft, two runs of an hour each were made on the engine when tilted at an angle of 15 degrees, first one end and then the other being elevated. The makers did not wish to run the engine at full load during this test and maintained the load at approximately 18 brake horsepower throughout both trials. The engine ran steadily in both cases, but it was noticed that the exhaust was decidedly smoky, apparently indicating overlubrication.

The general steadiness and freedom from vibration of the engine when running were so marked that it was not considered necessary to test it when running on elastic supports.

On the completion of the trials the engine was dismantled and the working parts thoroughly examined. Very little wear could be detected in the crank-shaft and connecting-rod bearings and the state of the cylinders and valves appeared to be quite satisfactory. The ball races of the thrust bearing at the propeller end of the crank shaft were, however, considerably worn. In the crank-shaft bearings one of the aluminum caps was cracked right through for about one-third of its length. It was not certain that this crack had originated during the tests, as there was some evidence that it existed before these trials began, but it appeared probable that the crack became larger during the tests. It was found that the sleeve inside the small end of one of the connecting rods had rotated so that the oil way to the pin was blocked up; also, that the gudgeon pin had shifted endwise and had been rubbing against the side of the cylinder.

The Engines

A beautiful piece of work indeed was the Wolseley engine. It had, of course, been especially designed for aeroplane work, but the main consideration kept in mind has been not the reduction of weight, but the production of a reliable motor. The engine which was entered for the contest had four cylinders of 3¾-inch bore by 5½-inch stroke and was rated at 30 brake horsepower at 1100 revolutions per minute or 37 brake horsepower at 1400 revolutions per minute. The weight was 205 pounds complete with magneto, carbureter and all piping, but no flywheel. The cylinders are cast in pairs with each head and liner in one piece. All the valves are on the same side of the motor and operated by hardened-steel tappets, as shown in Fig. 1. A special feature is the use of four water jackets of planished sheet metal.

In appearance, the Humber engine is strongly reminiscent of a motor-car engine, the copper water jackets being the only apparent feature of difference. The cylinders are of cast iron, machined all over, with a bore of 4.33 inches and a stroke of 4.725 inches. Both the inlet and the exhaust valves are overhead and operated by concentric push rods from a single cam shaft in the upper half of the crank case. The outer push rod carries at its upper end a light bracket, by means of which the rocker arm for the inlet valve is moved. The carbureter is of the single-jet type with an automatic auxiliary air valve opened by the usual adjustable spring. The crank shaft is hollow and supported on ball bearings of large diameter; one bearing is provided between every adjacent pair of cranks. The connecting rods are of chrome-nickel steel of very light section, and the pistons are turned from solid bar steel. Forced lubrication is provided through the hollow crank shaft to the big-end bearings of the

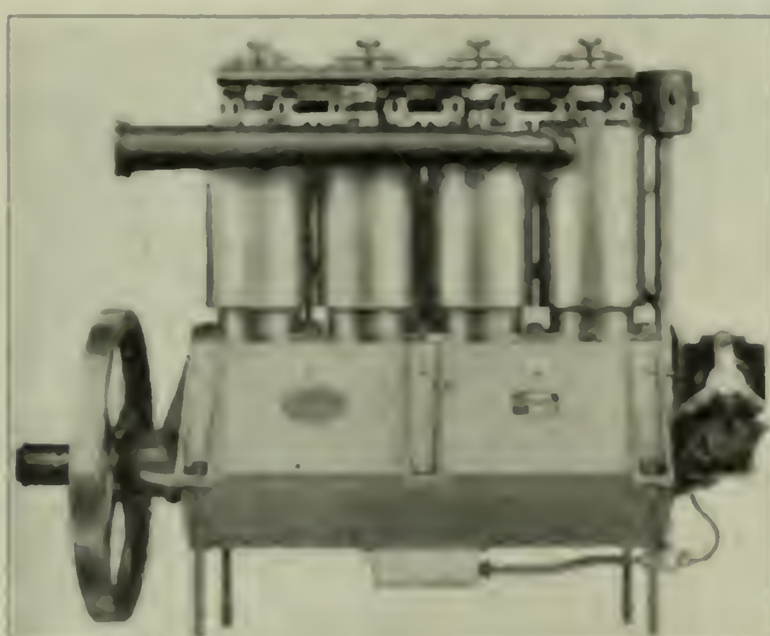

Fig. 3 THE GREEN ENGINE Fig. 4

connecting rods; the oil pump is of the gear-wheel type. Complete with its piping and magneto the weight of this engine is 232 pounds, and 42 horsepower is developed at 1200 revolutions per minute; the weight per horsepower is, therefore, 5.5 pounds.

It is an odd fact that the Green engine, which made the best showing in the contest, was designed and built before the recent developments in aëroplanes. It was

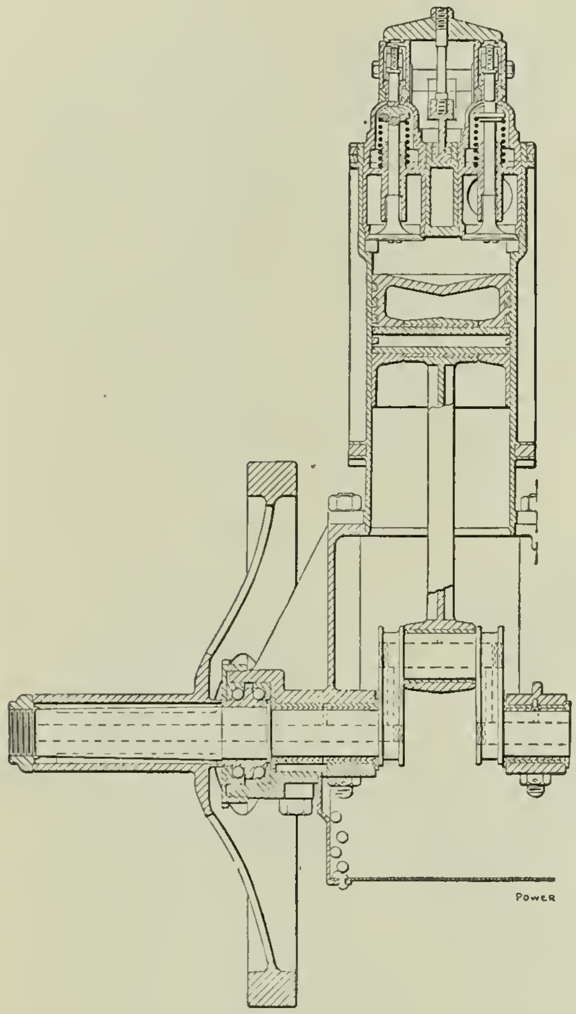

Fig. 5. A Green Cylinder

shown at a small exhibition as long ago as 1905, but at that date was, of course, regarded as a freak. It does not come within the category of extra light engines. The contest model, which develops 32 horsepower at 1220 revolutions per minute, weighs 181 pounds with all pipes, connections, carbureter and flywheel, but excluding ignition apparatus; that is almost 5.7 pounds per brake horsepower.

Unlike the majority of aëroplane engines, the Green motor is practically of orthodox automobile design, the weight being reduced by the judicious choice of material and not by ingenuity in the arrangement of the working parts. Each cylinder, with its head, is cast in one piece of steel and is machined inside and outside. The water jacket is made of thin polished copper and the greatest body of water is distributed unobstructed around the valves and the head. The cylinders are offset with respect to the crank shaft and the latter is provided with five bearings. The lower part of the crank case is made of sheet aluminum and makes a tongue-and-groove joint with the upper part of the crank case, which is a casting.

The crank shaft is made hollow for the sake of lightness; for the same reason the crank cheeks are grooved in an unusual manner (see Fig. 5). One end of the crank shaft receives the propeller and from the other end the pump and magneto are driven through spiral gears. A vertical shaft inclosed in an aluminum oil-tight case takes the drive to the overhead cam shaft and down to the oil pump, as indicated in Fig. 4. The cam shaft is driven through bevel gears and runs in four bearings in an oil-tight case; each cam with its rocker arm is also completely enclosed. The valves are in removable cages and are prevented from falling into the cylinder by ledges below the valve seat, as may be seen in the accompanying section of one of the cylinders, Fig. 5.

One of the most interesting features of the engine is the floatless carbureter, designed to work equally well at all angles. The supply of gasolene and air is controlled by the engine suction. Fig. 6 is a sectional elevation of the carbureter. There is a small clearance between the head of the choke cone *D* and the head of the gasolene valve *Y*. This permits a tight joint between the gasolene

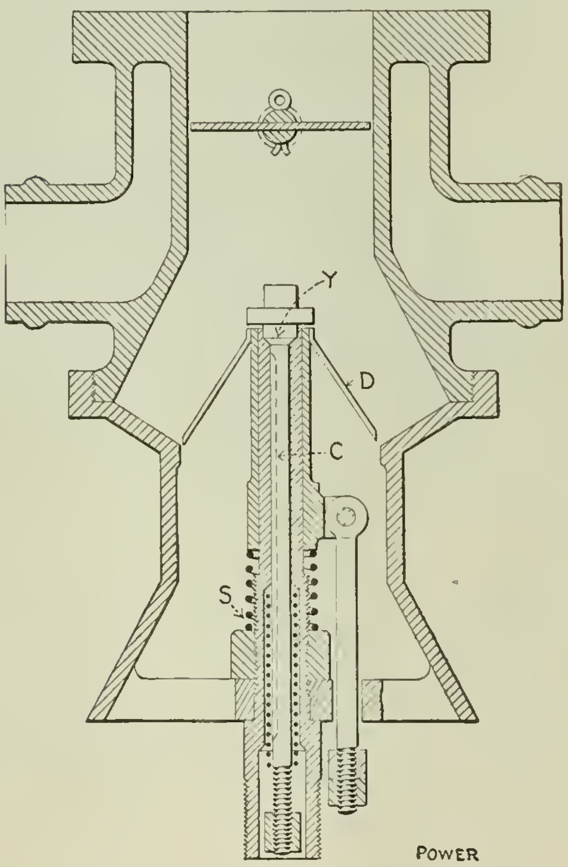

Fig. 6. Green Carbureter

valve and the end of its casing when the valve is down. As soon as suction takes place the choke cone, after taking up the clearance, commences to lift the gasolene valve from its seat, the force of the suction determining the extent of the lift. The gasolene is fed through the milled channel *C* in the side of the valve stem; this channel diminishes toward the seat of the valve and therefore passes more gasolene at high suction than at low, but beyond a certain point there is no increase in the opening. The spring *S* acts in the capacity of a flexible stop for the choke-cone sleeve when it drops.

Engineers for Gas Engines

By M. W. Utz

Mr. Hamilton's article on this subject in the April 25 issue was especially interesting to me, possibly because I happen to be familiar with a typical case of the no-engineer fallacy. A small manufacturing establishment was formerly equipped with a 65-horsepower slide-valve steam engine supplied from an 85-horsepower tubular boiler, the excess boiler capacity being used for steaming raw material before manufacturing. This plant was not very economical in operation, so when a gas-engine salesman began to quote figures on the cost of installing and operating a gas engine, the owners were all attention, especially as to the claims made by the salesman that "the labor cost would be practically nothing, because they would not need an engineer; an ordinary laborer could fill the oil cups and start the engine in a few minutes, and this was all that would be necessary till time to shut down again." The salesman was also rash enough to promise that the exhaust of the gas engine would evaporate enough water to steam the raw material.

The steam plant was taken out and the gas engine installed in its place and when everything was ready for operation the steam engineer was discharged and one of the owners undertook to look after the gas engine and do the office work. A man from the builder's shop started the engine, which seemed to run very satisfactorily, but the exhaust would not evaporate enough water for their requirements, so they had to buy and install a 10-horsepower boiler. After a short time trouble began, and finally the engine could not be started at all, the compressed air going straight through. A man sent by the builder promptly found the exhaust valve stuck open. Later on, the cooling water stopped circulating and the engine got hot, of course. When the water was turned on again the cylinder cracked; that meant a new cylinder. When cold weather set in, the jacket of the small engine which drives the air compressor was not drained, so it froze up and burst; the rotary pump which supplied the jacket cooling water did likewise. At another time, after putting in a new exhaust valve, the engine failed to give the required power and when a man from the factory was called to see what was wrong, all he did was to grind-in the exhaust valve, which they had put in without grinding. So it kept on, a man from the shop being called on to adjust or correct some small matter which a good engineer would have handled without difficulty and saved his salary in doing it.

The service became so uncertain that the central station was appealed to and motors were installed to drive the most important machinery; the arrangement is such that when the engine balks the motors can drive these machines only, leaving the rest of the plant idle until the engine can be started again. It looks as if the central station will soon be running the entire plant.

Now, this engine is of a well known make and would give good service if properly taken care of as it could be by a capable engineer. The man who attends to it now, or tries to, is inexperienced and is the fourth one in about a year. He has so many other duties to perform that if anything goes wrong with the engine it is generally shut down before he can get to it.

If this firm had kept the old steam engineer, who was a practical man and would have no doubt made a good gas engineer, and not burdened him with so many other duties that he could not have given the engine proper attention, it would have doubtless been a success and the central station would not be supplying motors there today.

In most cases, the steam engineer makes a success with the gas engine, having the advantage over the common laborer of a general knowledge of machinery and experience gained in the engine room of his steam plant.

Over 75 per cent. of the successful gas engineers that I have met were formerly steam engineers, and enthusiastic ones at that, which, I think, leaves little doubt as to who will be the coming gas engineer.

Gas Engineering in the Oil Fields

By H. H. Daniel

About the time when the gas engine was being introduced in the oilfields of Pennsylvania for pumping purposes, we were called upon to make repairs on all sorts of engines, and some of the experiences we encountered were comical; others were far from entertaining. A complaint came in to our shop once to the effect that a two-stroke engine which had been recently installed did not work satisfactorily. When I arrived at the engine house, a couple of pumpers from neighboring wells were on the job and had built a nice hot wood fire under the cylinder of the engine "to warm her up so she would start." We dispensed with the warming-up expedient and after a brief investigation found that the spring on the automatic inlet valve had been screwed up so tight that it was necessary for one of the men to relieve the tension by pressing on the valve stem with a lever in order to get the engine started.

The tension of the spring was relaxed to the proper point but it was found that the gas pressure was too low to furnish the engine with the necessary amount of fuel to carry the load, so we advised the pumper to look over the line for leaks. Following the line, he arrived at an abandoned shanty which stood between the engine house and the wells and, as the room was rather dark, he struck a match. Three very noticeable events occurred at exactly the same time: a loud report, an elevation of the roof of the shanty about six feet above the walls and the projection of a dark object through the door of the shanty. Upon examination we found that the dark object was the pumper, not hurt much but badly scorched and more badly scared. We went into the shanty (without a light) and found that the side outlet of a ¾-inch tee was open and out of this the gas was freely flowing. A stove had been used in the shanty and when it was removed, the detail of plugging the tee had been ignored. After we plugged it the engine was started and ran very nicely.

An Ingenious Crank Pin Oiler

The accompanying engravings illustrate the method finally adopted for de-

Fig. 1. Crank-pin Oiler

livering oil to the crank pin of a Lammert & Mann 8x10-inch gas engine after trying almost everything else that could be found.

The arrangement consists merely of a pair of telescopic tubes attached at one end to a Nugent swivel joint on the crank end of the connecting rod and at the other end to a similar fitting mounted on the cylinder housing. A stuffing box is provided on the end of the large tube where the smaller one enters it but no packing is used on the swivels; the joint between the fixed and oscillating members is closed by a ground metal-to-metal joint and is held in contact by a flat spring. This construction is more clearly shown in Fig. 2. Oil is delivered to the stationary end of the arrangement by a force-feed pump.

The speed of the engine is 300 revolutions per minute and we are informed that this made it impracticable to use a wiper cup; most of the oil was distributed impartially over everything within range except the crank pin. The application of

Fig. 2. Crank-pin Oiler

the telescopic feeder here illustrated is said to have effected an amazing reduction in oil consumption and to keep the crank pin thoroughly lubricated. It was made by W. W. Nugent & Co., Chicago.

LETTERS

Wanted: Suggestions for Distilling Water

The plant under my charge includes a suction gas-producer equipment of two 100-horsepower units and three 100-horsepower engines driving dynamos which are used to charge storage batteries. The proposition has been put to me to find out whether or not I can make distilled water with the apparatus now in use. Can some other reader of Power suggest a practical method of doing this?

Albert A. Simony.

Washington, D. C.

[Whether there is sufficient exhaust heat to distill all the water required depends, of course, upon the work done by the engines, the efficiency of the still and the quantity of water to be distilled per day or week. Suggestions from other readers as to the quantity of water that can be distilled with exhaust heat per brake horsepower-hour of engines' work will be welcome.—Editor.]

We are reliably informed that Diesel engines are being built by the Krupp works, in Germany, and by Schneider & Co., of Creusot, France, which develop as high as 1000 horsepower per cylinder. Multi-cylinder engines of about 10,000 horsepower are under construction for the equipment of war vessels.

Electrical Department

Especially conducted to be of interest and service to the men in charge of the electrical equipment

Changing Generators from Compound to Shunt Wound

By H. R. Mason

In a large power plant in the West which supplied a three-wire system at 120 + 120 volts through a number of shunt-wound rotary converters of a combined capacity of about 1500 kilowatts, the peak load increased recently until it required the full capacity of the converters and left no reserve to be used in case of trouble.

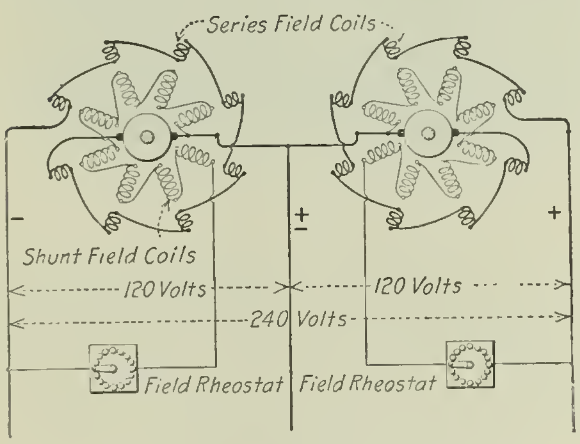

Fig. 1. Original Connections

Before the converters were installed, the system had been supplied by engine-driven compound-wound dynamos and one of the units was left in the station, but it was found impossible to operate this unit in parallel with the rotary converters; it would either pick up load until it was dangerously overloaded or else drop all of its load, when it would reverse its polarity and knock out the entire system. The unit consisted of a 14x24-inch twin Corliss engine direct connected to two 200-kilowatt, 120-volt direct-current dynamos mounted on a common shaft. A diagram of the electrical connections as originally installed is shown in Fig. 1.

In an attempt to make use of the twin unit, the series field windings were disconnected and a load put on the generators, using the shunt field windings only, but it was found that the field had insufficient strength to maintain the voltage with more than one-quarter load. It was found impossible to operate the unit at a high enough speed to produce the necessary voltage, so in its present condition it was of no practical use. As it became imperative that it be put into operating condition, the construction of the dynamos was investigated with a view to making changes in them. The shunt windings were found to contain 370 turns of No. 6 wire on each of the eight poles and passed a current of 40 amperes at 120 volts when all of the field resistor was cut out, making 14,800 ampere-turns on each magnet core. The expedient of connecting the shunt winding of each of the dynamos across the outside wires of the system, at 240 volts, with additional resistance in series, was tried, but it was found that the increased current necessary to maintain the desired voltage overheated the coils excessively.

The series windings had four turns each and carried 1600 amperes at normal load, making 6400 ampere-turns on each magnet core in addition to the 14,800 furnished by the shunt coil adjoining it. Upon measuring the space occupied by each coil of the series winding, it was found that additional shunt coils could be substituted for the series coils (see Fig. 2), each containing 370 turns of No. 8 wire. It was calculated that each coil would contain 1480 feet, making 11,840 feet on each of the 8-pole field magnets, and the wire table indicated that about 20 amperes would flow through that length of No. 8 wire at 120 volts, allowing for the same temperature rise as in the old coils. This would afford 7400 ampere-turns per pole to take the place of the 6400 formerly supplied by the series fields and would accomplish the double advantage of enabling full voltage to be maintained at all loads and reducing the speed somewhat.

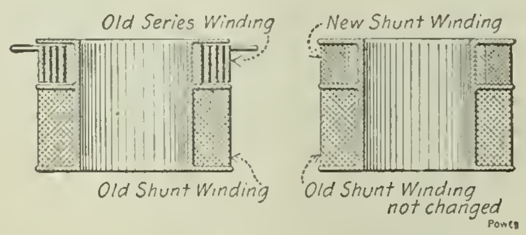

Fig. 2. Old and New Windings

Accordingly, all of the series coils were removed and additional shunt coils substituted, connected in parallel with the old shunt winding, as shown in Fig. 3. As the total field current was increased from 40 amperes in the original winding to 60 in the two, the field rheostat had to be remodeled and this was done by using standard street-railway motor resistor grids connected to the old faceplates. Of course, care was observed to connect the extra shunt field winding in such a manner that the current through it flowed in the same direction as in the old one. When the unit was started it fulfilled all expectations; it could be caused to carry as much as 30 per cent. overload at the maximum required voltage and one further experiment was tried upon it.

Occasional interruptions of the three-wire service were caused by short-circuits or by converters flashing and it was thought that the service could be resumed with less delay if this unit could be caused to take up the entire load upon starting, avoiding the delay necessary to restart and synchronize the rotary converters. The engines were capable of carrying 200 or 300 per cent. of their rated load in an emergency and, as the generators seemed liberally designed, it was thought that the load of 3000 to 3500 amperes would not damage them during the few minutes they would be called upon to carry that load, though 1600 amperes was their normal rating. The 120-volt field windings were again connected across the 240-volt busbars with additional resistance in series, but it was found impossible to maintain the voltage with a load of more than about 2500 amperes, or about 60 per cent. overload, as the field-magnet cores were then practically saturated and further increase of current through the coils had little effect on their magnetism.

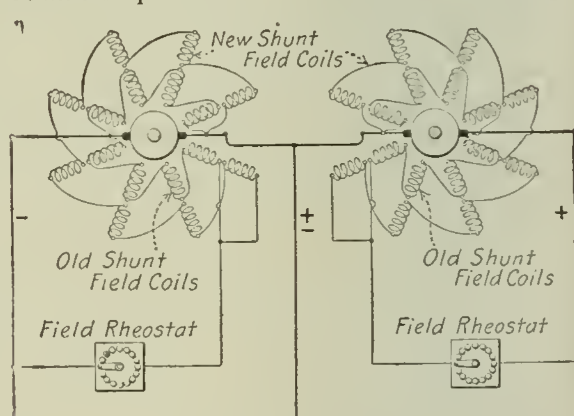

Fig. 3. Additional Shunt Coils Connected in Parallel with Old Winding

The unit has served to prevent several serious interruptions to the service since these changes were made and has been used to improve the station economy by taking part of the load from the rotary converters at times, allowing less efficient units to be shut down earlier.

Regulation of Rotary Converters

By R. A. Cultra

To allow the direct-current voltage of a rotary converter to be altered by adjusting the field rheostat or automatically by field compounding, a reactance coil is usually connected between the low-tension terminals of the transformers and the collector rings of the converter. Without such a reactance the maintenance of the same voltage at full load as at no load entails excessive leading and lagging currents and consequently excessive heating in the converter armature, unless the resistance drop from the source of constant potential is small, or the natural reactance of the circuit is unusually high. If the converter field is weakened a lagging current is set up which causes a voltage drop in the reactance coil. If the field is strengthened a leading current is set up which gives a rise of voltage in the reactance coil. Under a heavy load, the series winding of a compound-wound converter tends to produce leading currents, which tendency is practically balanced by the reactance, improving the power factor of transformers, lines and generators when loaded. The standard reactances are rated in kilovolt-amperes and are usually equal to 15 per cent. of the kilowatt rating of the converter.

The heating of converter armature conductors is greatly increased by the presence of leading or lagging currents. The series field winding of a compound-wound converter considerably increases the excitation at full load over that at no load; for this reason compound-wound converters should be adjusted to take a considerable lagging current at no load, which will be corrected by the action of the series field winding at normal load, thereby giving a good power factor and cool running when loaded.

For interurban railway service with low load factors, the converter should take about one-fourth of the full-load current at no load and this current should be lagging. The character of the current can be determined by the adjustment of the field rheostat. If the weakening of the field by cutting in more of the rheostat increases the alternating-current input, the current is lagging; if it diminishes the alternating-current input the current is leading. If the converter does not give the desired direct-current voltage with the desired setting of the field rheostat, the alternating-current impressed voltage should be altered by adjustment at the power house if possible; if not, by changing the primary taps of the step-down transformers feeding the converters.

For compound-wound converters with steadier loads having a high average load factor, the lagging alternating current at no load should be greater than 25 per cent. of the rated full-load current; somewhere around 35 to 50 per cent.

The no-load current of a converter should be measured when the equalizer switch is open if other converters are in operation in the same station; otherwise the current from the other machines will affect the excitation of the machine under investigation.

Rotary converters must not be operated above their rated voltage without proper adjustment of the transformer taps and alternating voltage. Overheating of the armatures is almost certain to occur with compound-wound converters run above normal direct-current voltage if a high average load is carried.

The ratio of the voltages at the alternating- and direct-current brushes of a converter varies slightly in different machines, due to differences in design. The best operating conditions exist when the desired direct-current voltage is obtained with unity power factor at the converter terminals when loaded.

Three-phase and six-phase converters require different voltages from the transformers on account of the difference between the connections of the armature taps. The no-load alternating voltage delivered from the transformers best adapted to compound-wound converters designed to carry variable loads is 61½ per cent. of the direct-current voltage for a three-phase converter or 71¼ per cent. for a six-phase converter. These ratios give a lagging alternating current at no load, a leading current on overloads and unity power factor at about the average load.

CORRESPONDENCE

Paralleling Two Phase and Three Phase Alternators

In the April 11 issue of Power I noticed an inquiry from D. M. Grove as to the operation of three-phase and two-phase alternators in parallel. I have charge of two power stations, one of which supplies two-phase currents at 2200 volts and the other three-phase currents at 13,200 volts, both at 60 cycles. The generating equipment at station No. 1 consists of two 180-kilowatt machines with closed-coil revolving armatures, similar to those described by Mr. Grove, and with compensating field windings and rectifiers, one 150-kilowatt revolving-field alternator, and one 300-kilowatt revolving-field machine. At station No. 2 there are two 600-kilowatt, three-phase machines with Y-connected armature windings. The transmission line from this station extends 17 miles to a substation which is three miles from station No. 1. Here the two lines are put in parallel through Scott-connected transformers, wound for 13,200 to 2200 volts.

These two stations operate in parallel without any trouble and with very little cross currents. Of course, it is necessary to adjust the field rheostats very carefully and in the case of the machines having compensating windings the adjustment of the rectifier brushes requires a good deal of care, otherwise cross currents may run up very suddenly and blow the fuses or open the circuit-breakers. The accompanying diagram shows the circuit connections between the machines just described. There is also a 300-kilowatt alternator at the substation which is operated as a rotary condenser (overexcited synchronous motor), and this is a great help in keeping up the power factor.

Where trouble is experienced in operating alternators in parallel it is usually found to be in the speed regulation of the motive power. To avoid "hunting," the governors should not be too sensitive; in some cases it is found necessary to dampen their action by means of dashpots. In the case of slow-speed engines it may be found necessary to increase the flywheel weight in order to absorb the impulse received at each stroke.

Diagram of Circuit Connections Between the Machines of Each Station

Thomas Hynes

West Chicago, Ohio.

The Electrical World states that the energy from Niagara Falls, including the stations on both sides of the falls, is used at the rate of 125,000 horsepower for electrochemical process, 58,000 horsepower for railway service, 38,000 horsepower for lighting and 54,840 horsepower for various industrial services, the total being 275,840 horsepower. Since the water of Niagara Falls represents probably 7,000,000 horsepower, it would seem that only about 3.9 per cent. of the available power is being utilized at present.

Inspectors Disagree

The conditions that prevail in Massachusetts, whereby old boilers are allowed to be operated so long as they hold their shape and comply with the requirements of the Massachusetts Board of Boiler Rules, are again illustrated in the case of a boiler owned and operated by a manufacturing company in that State.

The boiler is of the vertical tubular type and is described by the inspection certificate hung in the boiler room as follows: "Pressure allowed, 90 pounds; age, 21 years; length, 17 feet 6 inches; diameter of base, 60 inches; diameter of waist, 43 inches; tensile strength, 60,000 pounds; number of tubes, 96; diameter of tubes, 2½ inches; length of tubes, 14 feet; longitudinal joint, double-riveted lap; per cent. of strength of joint, 61 +; location of fusible plug, in tube."

On April 15, a State inspector visited the plant and ordered the boiler out of service until the following repairs had been made: A new ring in the frame of the furnace door; all tubes renewed and beaded; two patches put on, one on each side of the furnace-door frame; and the changing of the steam-gage pipe connection, which was tapped into the shell of the boiler slightly above the ogee seam, to be run from a tee at the top pipe connection of the water column.

The owner, believing that the extent of the repairs ordered by the State inspector was excessive, submitted the boiler as a risk to the steam-boiler insurance company whose inspector inspected the boiler on April 22 and recommended the following repairs to be made before the boiler could be accepted as a risk by the company: Ten tubes renewed; the ring in the furnace-door frame strengthened by fastening a flat piece of iron across the bottom (similar to a dead plate); one patch near the furnace door and the changing of the steam-gage pipe connection as was ordered by the State inspector.

These repairs being completed, the certificate of inspection was issued and so far as the parties directly interested are concerned the incident is closed.

In view of any possible failure that may occur to the boiler it looks as though the State inspector had all the best of the argument, inasmuch as he was endeavoring to give the owner and the public the benefit of the lesson taught by a recent disastrous failure of a boiler of this type. It is regrettable that when two eminently competent inspectors disagree as to the extent of repairs necessary to put a boiler in a safe working condition, that the law should be so worded as to allow the least of the recommendations to be accepted.

A rule that is printed in large type in the instruction book issued to railroad trainmen, "When in doubt, take the safe course," might well be followed by boiler inspectors when determining needed repairs.

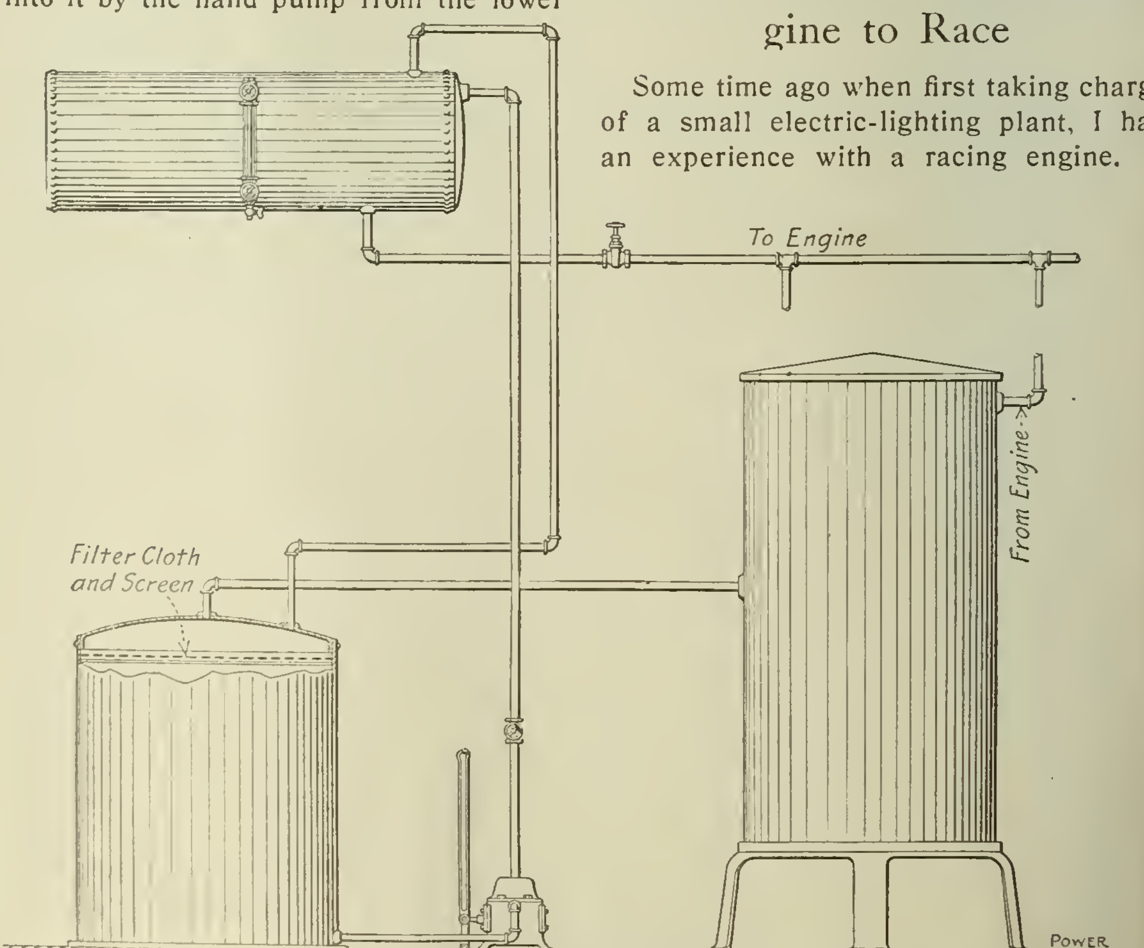
Clogged Overflow Pipe Caused Trouble

The accompanying illustration shows an oiling system that gave trouble. The gage glass on the overhead tank would fill to overflowing when oil was pumped into it by the hand pump from the lower tank. As it was known that there was not enough oil in the system to fill the tank it was concluded that there must be something wrong. In about 15 or 20 minutes the gage glass would be completely empty, although the oil was flowing freely to the engine bearings.



PIPING TO TANK AND FILTER

The chief finally investigated and found that the pipe leading from the overhead tank to the lower tank, which serves the double purpose of overflow and air relief, had become stopped up by the oily filter cloth that was on the screen in the lower tank, thus making the overhead tank air tight except for the little vent hole in the cap of the gage glass. As the oil was pumped up in the overhead tank a slight pressure was created which forced the oil up into the gage glass, and made it overflow through the vent hole; then, as the oil flowed to the engine, a partial vacuum was created in the tank, which caused the oil in the gage glass to flow back into the tank, completely emptying the glass. Upon taking down the overflow pipe and shortening it about 3 inches so it would clear the filter cloth, the trouble was cured once and for all.

Loose Setscrew Caused Engine to Race

Some time ago when first taking charge of a small electric-lighting plant, I had an experience with a racing engine.

This plant ran from dusk in the evening until the next morning. During the first few evenings the engine ran nicely; then, one evening there came several sharp pounds from the front end of the engine, and suddenly it began to race. By the time I had reached the throttle the voltage had got so high that the circuit-breaker tripped, leaving the building and town in darkness. This, of course, relieved the engine of all load, which had been gaining speed with every revolution. I thought there was a yard of threads on that throttle-valve stem before I got the valve closed and it seemed an age before the engine began to slow down.

By the time the engine came to a standstill and two-thirds of the population of the town had rushed to the plant, I had found that a setscrew which held a pin in place in the link of the governor had worked loose, allowing the pin to work out of the link. This put the governor out of commission, which allowed the engine to take steam full stroke.

The governor was soon adjusted and the engine started again, but the next morning, after shutting down, the setscrew was found to be loose again. This, I was told, had occurred before, so I hunted up a setscrew a little longer than the old one and put on a lock nut, after which there was no more trouble. However, I never started that engine again without first inspecting the governor, to be sure it was in good working condition.

Draft Regulation

A 125-horsepower horizontal tubular boiler furnishes steam for a small factory. The fire is burned out at 6 o'clock each night, and the setting on one side and the rear end is exposed to the outdoor temperature. A fire is started in the morning between 4 and 5 o'clock. During the night the leaking damper allowed a draft of cold air through the furnace and tubes which cooled the setting and the boiler. This reduced the steam pressure to about 25 pounds at 4 o'clock.

In order to prevent this cooling effect, a cleaning door in the flue between the smoke box and the damper is opened each night at closing-up time. This has the same effect as the opening of the flue doors, for the boiler and furnace are kept so hot that now there are about 25 pounds more steam pressure in the morning than there was before this method was adopted. There is also a saving in fuel, less expansion strains on the boiler and setting, which means less repairs.

Feed Water Problem

Here is a problem that recently came to my attention, which may be of interest to readers of POWER.

A boiler has two sources of supply of feed water. Each one is ample for the needs of the boiler for the greater part of the year, but for a month or two during hot weather it is necessary to use water from both sources in order to get the required quantity. One supply is from a stream and the other is from a well. When the water from the stream is in use alone, it is found necessary to clean out the boiler every eight weeks. When the water from the well is used alone, the boiler has to be cleaned out every three weeks. The quantity of water to be used from the stream is 1600 gallons in a given time, and the quantity to be used from the well in the same time and mixed with the stream water, is 900 gallons.

The question is, in how many weeks must the boiler be cleaned out while using the combination water, assuming that quantities of sediment, etc., remain the same for both waters and that no new elements occur from such combination?

At first sight this may appear difficult to some, who might let the problem go because they think it can only be solved by algebra. But it is not as difficult as it looks and it may be solved by arithmetic. There are different ways in which it may be solved, two of which are worked out herewith. The first is as follows:

Assuming that the deposit of material in the boiler is a certain measure when cleaning is necessary, then, in one week, when using the water from the stream, the deposit will be 1/8 measure, and when using the well water, it will be 1/3 measure. The length of the run is not given in the question, but there is the proportion of the two waters which is 16:9, hence, a run of any length of time may be taken in order to find the deposit per week, or the rate of deposit. Therefore, suppose that the stream water is used for 16 weeks and that the well water is used for nine weeks, then the deposit in 16 weeks, using stream water, would be

$$16 \times \frac{1}{8} = \frac{16}{8} = 2 \text{ measures}$$

Using the well water for nine weeks would give a deposit of

$$9 \times \frac{1}{3} = \frac{9}{3} = 3 \text{ measures}$$

This makes a total of

$$3 + 2 = 5 \text{ measures}$$

in 9 and 16, or 25 weeks, or one measure in five weeks. The boiler should therefore be cleaned out once in five weeks when using both waters together.

Perhaps the other solution will appeal to some as being simpler. It is as follows:

Assume that 1600 and 900, or 2500 gallons of water, are required for one week. With the stream water alone, one-eighth of a full measure of deposit will occur in one week, and with the well water alone one-third of a full measure will occur in one week. But when combining the two waters in the proportion of 1600 to 900 gallons, there is for the stream water

$$\frac{1}{8} \times \frac{16}{25} = \frac{2}{25}$$

of a full measure in one week, and

$$\frac{1}{3} \times \frac{9}{25} = \frac{3}{25}$$

of a full measure in one week.

Then

$$\frac{2}{25} + \frac{3}{25} = \frac{5}{25}$$

of a full measure in one week, when using both waters, as $\frac{5}{25}$ equals 1/5 of a full measure the full measure will require five times as long, or five weeks.

How many other ways can the problem be solved? It is of some practical value at least.

CHARLES J. MASON.

Scranton, Penn.

A Soil Pipe Repair Job

There are several large buildings at the institution where I am employed as engineer. We are about 12 miles from any town which can boast of a plumbing shop, so when repairs about these buildings are necessary I make them myself, rather than allow things to get messed up while waiting for a plumber.

One morning the branch pipe of a sewer connection began leaking, due to choking up of the sewer. I took a coil of messenger cable, which was on hand, bent a knock on one end and by this means located the obstruction about 75 feet away from the building and managed to knock it out with the wire cable.

I had supposed the leak in the branch was due to the cap not fitting into the threads tight enough, but upon examination found the pipe itself to be split for about 3 inches. I cut a sheet-iron disk to fit on the inside of the pipe, drilled a hole through both cap and disk for a 3/8 x 1 1/2-inch bolt, on which was slipped an iron washer, to stiffen the disk.

All was put in place and the space between the disk and the end of the pipe filled with putty. The cap was then screwed into place with the threaded end of the bolt extending through the hole in the cap. The bolt nut was then put on and tightened.

Only a few minutes were needed to make the repairs and it proved water and gas tight.

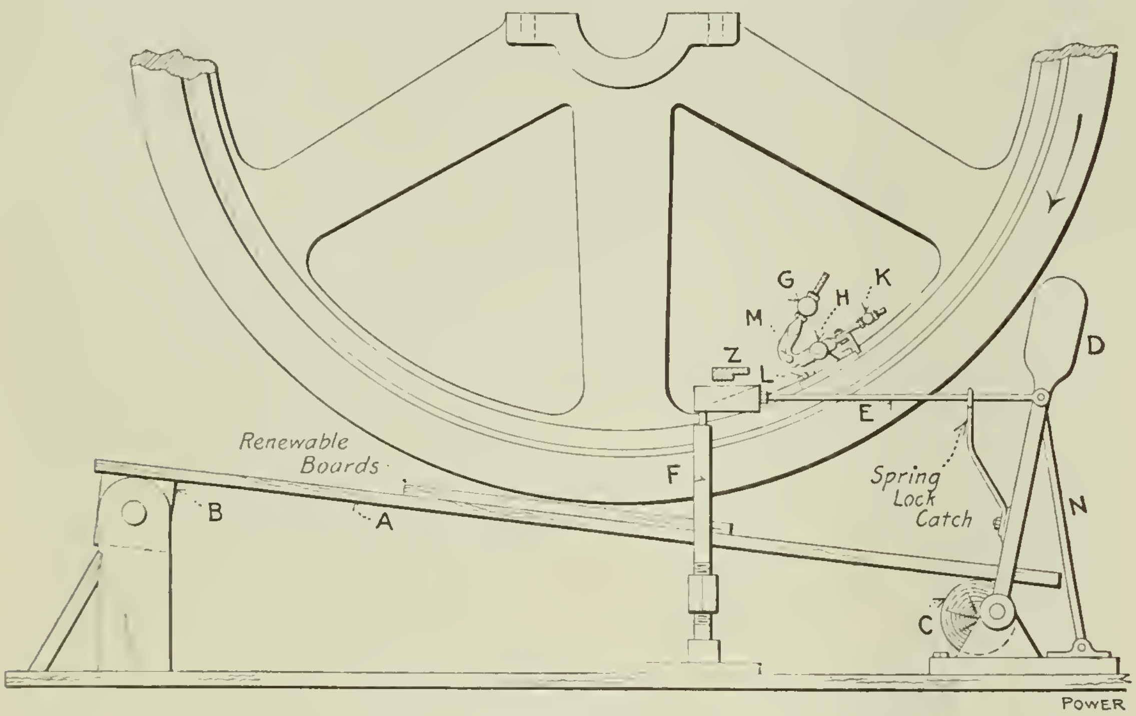
Columbia Falls, Mont.

Stopping the Engine Off Center

A 24x48-inch single-eccentric Corliss engine, direct connected to a generator, had a habit of stopping on the center, due to a tight piston, leaky steam and throttle valves and lack of judgment on my part. My predecessor had made arrangements with several men in the mill to ring a bell whenever he wanted help to move the crank off the center and, believing the arrangement to have been instituted after other methods had failed, I continued the practice. But no amount of bell ringing would bring anyone to the engine room at shutting down, for the men dashed for home as soon as the whistle blew and would not reappear again until it was time to start up. Thus, about 15 minutes were lost, during which time from 300 to 400 persons were idle.

One day when (from pure cussedness) the engine had stopped with the crank on the center twice in succession, I was



Details of Stopping Device

called to the manager's office and presented with a slip of paper on which appeared a lot of figures arranged, *"à la* Uncle Pegleg," as follows:

"This mill is operated 300 days in the year; the engine is, therefore, started 600 times and stops 24 times on the center. The average time spent in getting started again in 15 minutes; therefore, the mill is idle from this cause a total of six hours in the year. The pay on the average to 300 operators is 20 cents per hour. Each man then receives $1.20 per year without giving its equivalent in work, a total of $360. This is a net loss. The loss in production is many times this amount. Think this over and see what you can do about it."

Think it over I did, and finally evolved the scheme illustrated herewith. The idea was obtained from watching the showman stopping his swings. *A* represents two 7-inch planks laid side by side and connected by a piece of 4x4-inch joist *B*, through which a 1½-inch pipe passes to the upright posts shown to form a pivot. *C* represents two iron-bound wooden eccentrics, the fulcrum shaft of which passes through the bearings, as shown, and is firmly secured to the upright lever *D*. The club end of the lever is hollow and is filled with shot to form a weight. Its purpose is to cause the planks *A* to bear against the rim of the wheel with a certain tension due to the amount of shot placed in the head. It is supported in place by the reach rod *E*, the head of which latches to the upright *F*.

To the inside of the rim of the wheel is attached the automatic detaching mechanism operated by lack of inertia. It consists of a weight *G*, supported at a certain position on a bent arm pivoted at *H*, and more or less counterbalanced by the small movable weight *K*. The position shown is that assumed when the flywheel is in motion. When it is about to stop, the gravity of the weight *G* overcomes the inertia and the arm drops to rest on the pin *L*. It will be easily understood that the rim of the wheel needs to travel but slowly to cause the weight *G* to fly out. Secured to the bent arm is the pin *M*, the purpose of which is to slide under the head of the rod *E* at the proper time and release the weighted head *D* which manipulates the brake. The latch head of the rod *E* is shown enlarged at *Z*.

The right position on the rim for the releasing governor, with reference to the crank pin, was ascertained only after repeated trials. My method of shutting down the engine is as follows: After closing the throttle, a half-inch valve on a drip pipe leading to the valve chest is opened. Then the brace rod *N* which prevents the brakes from being set when starting up the engine is released. When the engine has slowed down to the speed that is just sufficient to keep the weight of the releasing governor in its outward position, the half-inch valve is closed, and the brake does the rest. The number of stoppages on the dead center was greatly reduced and the device, according to the manager's figures, saves the company $270 yearly.

Screwed Down the Safety Valve Spring

Recently a large fire flue collapsed in a traction-engine boiler of the Scotch type. The engine had been in service for several years and was of 12 horsepower capacity.

The engineer had been running the engine for several years. Three days before the explosion, he took the safety valve apart to clean and after putting it together he believed that he had turned the screw down as many turns as it took to loosen it. At the same time the steam gage was out of order.

When getting up steam on the morning of the accident, the engineer had turned on the blower and when the safety valve popped he started to shut off the blower. Just then the flue collapsed.

An examination showed that the rivet in the flange and lap seam of the flue had given away and ripped most of the rivet heads.

I got the safety valve and tested it under a pressure of 205 pounds before it opened. The engineer supposed he was carrying about 120 pounds pressure.

Covington, O.

Engine Ran with Broken Crank Pin

In a large cotton mill in one of the Southern States there is a center-crank engine which is used for driving a dynamo that supplies the lights for the mill. It runs at a speed of 175 revolutions per minute. One morning a short time before the engine-room lights were due to be switched off, the oiler noticed them dying out. Looking over at the small engine, he saw that the drivewheel which was belted to the dynamo had stopped, while the other wheel, containing the governor and eccentric, was running along apparently the same as usual.

He shut the engine down, and on examination discovered that the cast-iron crank pin was broken off flush with the face of the disk on the side next to the driving pulley. The other flywheel, which carried the governor and eccentric, had continued running the same as if nothing unusual had happened, being operated as a side-crank engine with only one bearing. The break was almost square across and flush with the face of the disk. The only damage other than the broken pin was a slightly cracked bed between the pillow blocks.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Sulphur for Hot Bearings

In a note on page 639 of the April 25 number, I note that someone recommends sulphur as being good for hot bearings. During a series of bearing-metal tests conducted by the writer, the matter was tried out with results not pleasant under service conditions at least. A bearing was perfectly surfaced, then loaded until the frictional heat developed was about 120 degrees, or about the temperature at which an ordinary operator would commence to get busy. Powdered sulphur mixed with oil was then fed into the box, with the result that the motor was very soon stalled, and when the blue brimstone smoke had cleared away, the condition of the bearing surfaces was the worst I ever saw.

It would seem that the application of a mild abrasive like sulphur is a matter requiring good care and judgment, if a hot box is developed. In such a case, the writer would not attempt to use it without shutting down the machine and starting cold, using the sulphur very cautiously with large quantities of lubricant. I would not use it in any case, unless it was the only thing for the purpose available, on account of its chemical ability to produce tremendous heat, once the boundaries of safety are passed.

A better method, recommended by several erecting engineers of long experience and thoroughly tried out with uniform success in my own experience, is to shave off powder from a cake of sapolio or Bon Ami, whichever is most available, mix it with good oil until a very thin mixture is secured and feed it slowly into the bearing, *after* it has been cooled down, if possible; if not possible to do this at least reduce the speed or pressure, remembering at all times that you are using a mild abrasive; hence while cutting off the high spots you are developing more heat and therefore require more lubrication than usual. This treatment should be applied to bearings one has reason to believe are running warm because of ill fitting or roughness caused by previous overheating.

Sometimes an old bearing will heat because of an accumulation of dirty or gummy oil. In such cases, a liberal application of brine or salt in the oil will cut out an amount of dirt and corruption that will be an eye opener to the novice. Once thoroughly cleaned the bearing will cool down quickly. An application of dilute acid, if available, will often work a similar cure; of course, in all cases, liberal lubrication should be employed.

I should like to read the experiences of others with hot bearings, especially with regard to the use of sulphur. Aside from my own case, I have found men of wide operating and erecting experience very slow to recommend it.

H. B. McDermid.

Minidoka, Idaho.

Feed Pipe Scaled

In looking through the issue of April 4, I noticed a letter entitled "Feed Pipe Scaled," by I. H. Stacey. If Mr. Stacey had arranged his feed pipe to provide two means of feeding the boiler, the trouble he relates would not have occurred. The pipe could have been arranged so that the boiler would receive feed water through the front head and also through the blowoff pipe. Then, should one of the feed pipes become scaled, the other could be used until repairs could be made at a convenient time, thereby preventing a shutdown of the plant.

I have my feed pipe arranged in this way and have not experienced any trouble. The feed pipe which goes through the front head runs above the top row of tubes within 24 inches of the rear head, then runs across the tubes up to the center row of tubes, where the water is discharged.

This boiler has been in service about three years and is practically clean, except where the feed water discharges between the center rows of tubes. In order to prevent any more accumulation of scale at this point I have changed the pipe so that water is discharged between the tube and shell. This was done about six months ago and the scale between the center rows of tubes is peeling off nicely. By the time all this scale has disappeared, there will probably be an accumulation at the new place of discharge, but it will simply mean changing back the piping to the old place.

H. A. Jahnke.

Worn Pump Screws

The reader has noticed an article in Power of May 2, and is rather interested in some points that are not fully explained. The reader has been in charge of a plant containing large triplex pumps and would like to procure information in regard to the screw pump so as to gain some comparison as to the relative upkeep of the two kinds of apparatus.

Is it possible to pack the screw type of pump on ordinary time; that is, not on Sundays or nights when the plant is shut down?

How often is it necessary to pack the screw pump?

What has been your experience in regard to the expense of the packing of this type of pump?

In packing a triplex pump against big pressure it is easy to set the packing down too tight so that the electric power required to drive the pump is very much increased. Do you have the same trouble with the screw pump?

The reader would also be interested to know whether or not this type of pump requires continuous attention in regard to its oiling system.

George H. Thomas.

Glen Ridge, N. J.

Special High Pressure Valve

The valve illustrated by A. Wind on page 574 of April 11 issue of Power is a very good large-size type of valve. A few years ago I operated an engine with a throttle of this type. It was a 10-inch valve, and differed from the one shown, in that the valve stem was reversed. That is, it pushed the valve off the seat instead of pulling it off, with

Valve with Internal Bypass

the advantage that when the valve was closed the pressure came off the valve-stem packing.

Omaha, Neb. S. C. Kinsey.

Specialists

The letter entitled "Specialists," by James Scotch, appearing in the issue of March 21, is, in my opinion, too critical and unwarranted. He blames the engineer in the small plant for exposing the mistakes of the specialists and dubs these engineers as "dinkies."

Mr. Scotch is apparently mistaken in reference to the object these engineers have in writing of such mistakes. I believe they write to warn unwary engineers of such pitfalls and not to pose as pedants or to unjustly criticize any specialist. There is always the young engineer starting in the business who will profit by the simple letters in POWER. He must start at the bottom and read carefully the simple questions asked in POWER every week—simple to those to whom they are familiar.

The fact that the bricklayer or machine erector probably has been doing such work for years, as Mr. Scotch states, does not make him infallible nor does it prevent the little engineer from knowing something about the business that the specialist does not know or happen to notice. To verify these statements I will relate an experience I had with one of these specialists.

An old locomotive-type boiler was to be inspected for the first time after I became engineer of the plant. I gave the boiler a good cleaning out, removed the grates, cleaned all the ashes and iron rust from the furnace sheets and found some very bad cases of rust on the lower parts of the water leg. A light blow with the peen of the hammer would dent the sheets.

This boiler inspector was really an expert, or specialist; he had worked many years at the boilermaking business before he became an inspector. Knowing this, I believed it would not be necessary for me to give him any instructions in his line of business. However, "a hint to the wise is sufficient" and I ventured to tell him to be a little bit particular and he might find something the matter with her.

When he got through he said that the boiler was all right except for some oil on the rear head at the upper row of tubes and told me that when I scraped it off I might run her as usual with 105 pounds to the square inch.

I then called his attention to the water leg. He started to pound it and feel for the thickness of the sheet; then started marking oblong figures on the sheets with white chalk. When he got through he took off his glasses, looked at me and said: "Don't start that boiler until there are seven patches on her and I have inspected her again."

The boiler was not started but was taken out and a new one replaced it.

My advice to all engineers in charge of plants is to keep your eyes open when other men are doing work in your plant, and for your own protection see that it is done right. The men doing the work may be careless or inexperienced, or they may be first-class mechanics but crowded with work and anxious to get at the next job or home on a short visit after an absence of several months. In any case, they are not infallible and will bear watching.

It is not necessary to be an expert in all branches of steam engineering in order to be able to detect whether a job is done right or radically wrong. Common sense, combined with the degree of intelligence that every engineer ought to have, should be sufficient.

JAMES W. BLAKE.

New York City.

Isolated Plant Engineering

The article published in the May 2 issue of POWER under the heading "Isolated Plant Engineering" is undoubtedly the strongest argument yet presented to show the true conditions which engineers in general have to face.

It is indeed a sad state of affairs that a large majority of men employed in steam plants are not permitted to know what the various expenses connected with the plant are, yet there are those who are kept in absolute ignorance of the price that is being paid for coal, oil, waste and supplies in general. Under such conditions as these, what chance has a man to know what it is costing to do certain work?

Furthermore, I would like to say that a big mistake is made when managers or superintendents who are not themselves engineers, but who have the hiring of such men, try to tell these men what to do, because any man who has had the necessary experience to fit him for the position knows far better than this type of manager what his duties as engineer are. Oftentimes much trouble and friction could be avoided if these men would allow the engineer to run his own department, and then if he was not doing his full duty in that respect the cost of maintenance would very soon make it known.

In regard to making suggestions for the betterment of the plant, I would like to say that many good engineering kinks submitted by the engineer are often credited to the manager later on when the work is carried to completion.

A little experience of mine was as follows: I had charge of a very poorly designed one-pipe heating system in an uptodate office building and found that a number of the rooms could not be properly heated on account of poor circulation. After considerable trouble and thought, I concluded that to overcome the trouble with the least expense it would be necessary to run the returns from the risers to a suitable tank and then pump them into the boiler instead of putting them into the sump, as had formerly been the practice. I submitted this arrangement to the agent, who took about a year to consider whether it was worth the expenditure of $100 or not, and after much agitation he consented to let me proceed with the work.

The work was completed just in time for the commencement of the heating season, and from the start the tenants remarked how much more comfortable their offices were.

After the installation had been working long enough to prove its reliability, the agent brought in several of his friends and explained how he had conceived the idea of saving so much good, hot water with a corresponding decrease in feed water as well as coal.

Writing for the Technical Papers

Referring to the advice offered by Mr. Williams, in the issue of April 25, to a recent correspondent on this subject, it would appear that the suggestions, in the main, might be materially improved. When you have a message, deliver it by all means, but in the delivering there is distinctly a right course and a wrong one; wrong, not only in point of view to the journal to which the matter is to be forwarded, but a greater wrong to oneself, inasmuch as each contribution should be an improvement over the one which has preceded it for personal benefit of its author. If one is deficient in some of the functions of letter writing and the like, there is no time like the present to endeavor to correct, and, in exercising a little care in the preparation, one not only has a possibility of having an article accepted, but he has a positive assurance that each one executed is helping to better his natural condition, is assisting in a general knowledge of the proper usage of words, correct spelling and the like.

Mr. Williams' statement, "Do not waste your time in rewriting; simply make all corrections in the first draft—" embodies a wrong principle. All know that "time is money," but time spent in a careful preparation of copy is far from wasted. Editors, as a rule, do not keep a "puzzle department" and one of the most important essentials for a just consideration of a contribution is its readableness, its ability to be quickly deciphered. A rough pencil draft should be made of matter which is to be presented, which one should try and divide into distinct parts, as introduction, or head, description, or body, and end, or tail, instead of a jumbled mass of material entirely out of order. This method is easy and simple and will not only help the writer in collecting what he wants to say, but will help the reviewer for publication in learning if what he has to say is worth while. In writing one should be brief and direct, make the letter read with full common sense in the fewest possible words; this does not mean "telegram" style, but, as steam is usually supplied to an engine by the shortest and best route, so should words be applied to the manuscript.

When matter is so collected in a rough draft, it should be copied plainly, on one side of the paper, of course, and with all neatness possible. This is not time wasted, this is time well spent. A rewriting in this manner shows, many times, how arrangement and wording may be improved, and it all helps; it shows where one can "cut" or add to good advantage. A little reasoning, such as "if I did not know this, would my reading of this article show me plainly," in description work, will oftentimes prove effective in bringing out little points not thought of and which may be necessary for completeness. Sheets should be numbered, as Mr. Williams states, but a title on the first page with a name and address on the last, and the whole held together with a common paper fastener, is far better and simpler than repeating such on each particular sheet.

An entirely wrong idea is obtained from "Do not be afraid of your spelling —," from this letter. Because a man is engaged in power-plant work in the operating end, is it any excuse why such carelessness should be shown in spelling, an elementary study compared with what his occupation demands? Is there any reason why he should not be fully as competent to spell simple words as a clerk or anyone else? A dictionary today is a cheap article, a small one, suitable to all practical purposes, may be obtained for a trifling sum, reference is an easy matter and a continual misspelling of the same word, with no attention given, shows the spirit that one is not alive to a betterment of his condition. Not only for contributions, but in record work and private correspondence to allow this "don't care" manner to predominate is unjust to oneself. When once a proper spelling is known, especially when it is looked up, it will come thereafter very easy.

In a paper such as POWER there is always a place for an article whether it be long or short, if it is worth while, if the matter is interesting or novel, if it is going to help its readers. If one knows something good, a kink, layout or otherwise, that he has not seen in print, he should write it up. Time-worn subjects unless presented in a particularly new and bright dress do not usually find place. Let the contribution work from both ends, make it serve two purposes; if it adds one dollar to the bank account, let it add many times this amount in value in perfecting system, neatness and an appreciation for the simple rudiments of the English language in its author. These are some of the things which help in getting the job higher up.

Los Angeles, Cal.

Coal Defined

Mr. Bement has an interesting article on "The Coal Problem Analyzed" in the April 25 number, but I must protest against his definition of the word "coal" as "that part of the fuel minus ash and moisture for which the term pure coal has been devised." It is all right for him to use the term "pure coal," if he likes it, to signify what others call "ash-and-moisture-free coal," since this term is not likely to be used with any other meaning, but it is all wrong to take the word "coal" which has had for hundreds of years a well known meaning, and limit it to mean only a part of what has hitherto been known as coal, and to invent for the latter a new term or terms, such as "fuel mixture" or "coal fuel."

The meaning that technical writers should give to a commonly used word is the meaning that is ordinarily given to it in commerce and literature, and that is found as the common definition in a modern dictionary.

Example: Coal (Century dictionary). "A solid and more or less distinctly stratified mineral, varying in color from dark-brown to black, brittle, combustible, and used as a fuel. Coal always contains more or less earthy matter, which is left behind in the form of ash after combustion. Sulphur is rarely if ever absent."

In other words, coal is the stuff that is called coal in the market. In the "Mechanical Engineers' Pocketbook," page 789, eighth edition, it is said that coal is composed of four different things that may be separated by proximate analysis, viz., fixed carbon, volatile hydrocarbon, ash and moisture. The late Eckley B. Coxe, in one of his papers on coal, once said, "Coal consists of two things, coal and dirt," meaning by dirt the visible pieces of slate and dirt which should be removed from the coal before shipping it.

Mr. Bement's Table 2 reads:

TABLE 2. PROXIMATE COMPOSITION OF COAL.

Pure Coal = Combustible Elements + Non-combustible Elements.
Dry Coal = Pure Coal + Mineral Matter.
Moist Coal = Dry Coal + Water.

I would change it to read as follows:

TABLE 2. PROXIMATE COMPOSITION OF COAL.

Coal = Dry Coal + Water.
Dry Coal = Pure Coal + Ash.
Pure Coal = Combustible Elements + Non-combustible Elements.

WILLIAM KENT.

New York City.

Engineers and Boiler Inspectors

In the April 25 issue I read Mr. Eaton's article on engineers and boiler inspectors. This brought to mind the question asked in an article in the April 18 issue, "Do you ever take time to examine the boilers of which you are in charge?"

Mr. Eaton writes that he does not touch anything inside of a boiler until the inspector has had an opportunity to see it in its operating condition. Would not this naturally lead the shrewd employer to think that the inspector and not the engineer, is the brainy one in the plant? It is because some engineers neglect to make examinations that most of our license laws are passed. These laws are safeguards for the public against explosions.

Some time ago I was in charge of a plant which apparently was in first-class condition. After an examination I found a defective boiler. This fact I made known to the office. The boiler had a number of leaking tubes and over the fire the seam showed up burned for a space of 2½ feet of the circumference of the shell. Stretched rivets and a crack in the plate showed up between two of the rivet holes to the edge of the plate, also a burned and buckled fire sheet which was subsequently straightened out with hot plates, sledges and flatters. The flange and rivets of the head were then calked tight and no trouble from leakage was afterward experienced. The rivets were in such bad condition that I insisted on their being replaced with new ones. Notwithstanding the condition of the seam over the fire, the only satisfaction I got from the superintendent of the plant was the statement that the boilers were insured and that the leakage would probably take up. I, therefore, immediately reported to the Hartford inspector of the district. New tubes were soon put in and a patch put on the defective seam over the fire.

The inspector's task is not always a pleasant one and the salaries of some are less than the salaries of chief engineers. It is unfair, therefore, to compel the inspector to stand four or five hours scraping scale off the seam and tube ends, crawling under boilers full of ashes and soot in search of fire cracks and other defects, which are visible only after every inch of the surface has been cleaned and scraped. Some engineers are in charge of boilers for long periods, without knowing that the feed pipe is partly plugged up or disconnected from the bushings in the front head. I always have our boilers cleaned out regularly. The back connections, tubes and head are cleaned, as well as the bottom of the shell, the seams, flues and stay braces. Thus, I am always ready for the inspector. I am in a position to report all defects as soon as he enters the boiler room. Only in one instance did it require more than an hour for an inspector to examine our boilers.

Inspectors should be cultivated, for they are great aids sometimes in getting unsafe boilers repaired. Engineers should care for their plants and see that the boilers are kept clean and in a safe condition, without having to be told to do so by the inspectors. This is the best proof of their ability and gives them a reputation, not only among the inspectors, but keeps them in good standing with their employers.

Cambridge, Mass.

The Benefit of Organization

Mr. Wallace, on April 4, opposing Mr. Gotstein's plea of March 14 for an organization, said, "Organization never raises wages." How, then, would he explain the substantial increases granted to every mechanic, except the engineer, during the last few years? I am positive that men with intelligence, aware of current events, would not honestly say that organization never raises wages. In one city alone, through organization, the wages of 68 engineers were raised $7 a week, for an eight-hour day.

The history of industrial battles for the last 50 years against oppressive methods of employers, proves conclusively that organization alone has reduced the hours of labor and increased wages.

Wherever and whenever an organization has had any semblance of strength, there has been a demonstration of its power. Surely no man is so lost to the trend of the times as to believe that Mr. Rockefeller, Mr. Carnegie, Mr. Morgan and others of their class made their millions by their own unaided efforts. It is a fact that will bear no contradiction that our millionaires now hold their positions by the aid of the most iron-clad organization the world has ever known.

Mr. Wallace states that engineers are not like other mechanics, and work under different conditions. Let us see if he is correct.

An engineer depends upon the sale of his brain and brawn for so many hours a day for wages. With these wages, which is the price paid for the use of that brain and brawn for eight, ten, twelve or more hours a day, he buys food, shelter, clothing, recreation, establishes a home and educates his children. Other mechanics sell the same things for the same price—wages—and purchase the same essentials for a normal working-class life. So far as the sale and the reason for the sale are concerned there is absolutely no difference between the engineer and other mechanics. The wage received is expended in precisely the same manner. Thus, there is a continuity of interests between all mechanics of all classes in both the sale of their brain and brawn and in the expenditure of the price received.

Mr. Wallace states that an engineer receives what he is worth without the aid of organization and quotes a few acquaintances who are receiving high wages. This is not at all a wonderful thing, confined alone to the ranks of the engineer. The same thing is true wherever there are unorganized mechanics.

In all important things of life the material interests of all mechanics are identical. The sole difference between engineers and other mechanics is that 90 per cent. of the engineers are holding down one-man jobs while other mechanics work in groups.

It is true that engineers are expected to cover a wider range of effort than other men, but this is due principally to the isolation of their positions. Oftentimes between whistle and whistle the engineer performs the duties connected with a dozen different trades. If he refuses, or is unable to perform them, he is either no good or lazy, or both.

This isolation, with the constant and insistent calls upon his knowledge and mechanical ingenuity, has bred in the engineer an egotism that is monumental. It is this very isolation that makes organization necessary for the engineer.

To be an engineer—a real one—requires years of study and experience, a close study of new mechanical devices which are day by day being placed on the market, physical strength, a cool, clear head, nerves of steel, the ability to act quickly, the courage to face death or injury in the interest of his employer, the endurance to work hour after hour without rest or sleep and the willingness to do so whenever necessary. And for these attainments he is paid less and is obliged to work longer hours than the members of a dozen other trades which are organized.

Mr. Wallace, to prove the uselessness of organization, points out one man who, when he was not satisfied with his pay, stepped out and secured a $6000-a-year job. This is one man of abnormal ability. We are not, however, dealing with abnormalities, but with the average normal, brainy, everyday engineer. Were all engineers like the gentleman Mr. Wallace cites, possessing just as much push and ability, there would be no $6000-a-year jobs. Wages are not based upon what the highest-priced man receives but what the most needy will consent to accept.

If organization is good for our employers, good for other mechanics, for doctors and lawyers, why in the name of common sense is it not good for engineers?

Therefore, as we are now living in an age of organization, from the lowest to the highest, including billionaires and tramps, it behooves the engineers of this country to keep abreast of the times, and organize.

Let me say to Mr. Gotstein that he need not look around for an organization; it is already at hand. Get into it. Keep your eyes open and help to place your fellow engineers where they belong.

GEORGE G. HALL.

Dorchester, Mass.

Standpipe on Heating System

In the letter published under the above heading in the May 9 issue, the statement is made that "The system is made up of 1-inch pipe." The sentence should have read, "The system is of the one-pipe design."—EDITOR.

Remarkable Overload Boiler Test

Referring to the article in the March 21 number on "A Remarkable Overload Boiler Test," some data are given below on a test of a Parker downflow boiler at the plant of the Colorado Fuel and Iron Company, Segundo, Colo. If the tests published in the March 21 number are considered remarkable for overload, the test of the Parker boiler at 234 per cent. of its rating should be of interest.

Kind of boiler	Parker Water Tube
Heating surface, sq.ft	2,650
Grate, Roney Stoker (8′3″x7′9″) sq.ft	63.9
Duration, hours	7
PRESSURES (Average)	
Barometer, inches	23.3
Steam gage, lb	102.64
Draft gage, inches, comb. chbr	1.119
Draft gage, inches, furnace	0.308
TEMPERATURES (Average)	
Boiler room, deg. F	92.55
Escaping gas, degrees F	506.57
Feed water, degrees F	66.3
FUEL	
Kind of fuel	Frederick slack
Per cent. moisture	1.2
Per cent. ash of natural fuel	19.4
EVAPORATION	
Evaporation from and at 212 degrees, per lb. natural fuel, lb	7.90
Evaporation from and at 212 degrees, per lb. dry fuel, lb	8.000
Evaporation from and at 212 degrees, per lb. combust., lb	10.279
Evaporation from and at 212 degrees per sq.ft. grate, lb. per hour	335.21
Evaporation from and at 212 degrees per sq.ft. heating surface, lb. per hour	8.98
HORSEPOWER	
On basis 34½ lb. from and at 212 degrees	621.16
Builders' rating for boiler, h.p	265
Overload, per cent. rating	234
Efficiency of boiler and furnace, per cent	59.1

No account of steam furnished stoker and fan engines.

The boiler tested is rated at 265 horsepower, having 2650 square feet of heating surface. It is equipped with a Roney stoker 8 feet 3 inches wide by 7 feet 9 inches long, 63.9 square feet. The duration of the test was seven hours, and it was conducted by a representative of the stoker company. Attention should also be given to the fact that the coal used in the test was of an inferior quality.

B. DIECKHAUS,
Parker Boiler Company.

Longing for Old Times

The relative difference between the standing of the old-time engineer and the man who has charge of the modern steam plant is self-evident, even to the layman. And the steam plants that are operated by the two types of engineers stand apart in a marked degree, showing the difference between the old and the new.

A man who operates a small steam plant, does his own firing and attends to the chores about the place does not and never will hold a very exalted position among his fellow craftsmen. He may be all right for the place, but in the engineering world the place is not recognized.

It is but natural that the modern engineer should tower head and shoulders above the old-time runner, who is altogether too frequently a young man using old-time methods in an old-time plant because he does not bestir himself and know enough to hold a better job.

Although there is no attractive comparison between the two types of engineers, it is exceedingly strange that a correspondent should recently write a letter bemoaning the fact that the old-time men, who only knew how to start and stop an engine and shovel coal, are being ousted by men who understand electricity, hydraulics and the other subjects that are necessary for the successful engineer to know.

Such an attitude is not only unprogressive, but it is foolish. What engineer worthy of the name would go to work in some of the steam plants that boast of one engine and boiler? What incentive can there be for an ambitious man to long for the chance to work in a steam plant, starting an engine and firing coal? Nothing much to do, not much responsibility and very poor pay.

One might as well long for the days when houses were lighted by the flames in an open fire place, when the steam engine was used in its crudest form or when knives and forks were unknown.

No progressive man regrets the fact that he has been obliged to know about a number of engineering branches in order to assume charge of a modern steam plant.

Such knowledge has made him a better man in every way. More liberal and broader minded in his views, more conservative in his opinion and a more observing, careful, painstaking engineer.

All of this has perhaps cost him self-denial and long hours of solid study that might have been spent in pursuit of pleasure. There is, however, no gainsaying that the benefit has been all his own.

It is about time that engineers got away from the idea that they are an overworked and abused set of men. Because the design of the steam plant has been improved faster than some engineers have improved in engineering science is no reason why there should be regrets on the part of anyone that old conditions are passing away.

Let them pass. Get ready to take charge of the new power plant. Throw the old homemade box chair out of the door and get ready to take a place at the new plant and know how to hold down the cushioned armchair before the engineer's desk.

Radiated Heat

Popular belief regarding the insulating effect of a hollow furnace wall seems to have received a severe jolt as a result of the recent investigations of the Geological Survey, mentioned in the May 23 issue.

Heat may be transferred in three ways: by conduction, by convection and by radiation. The conductivity of air is known to be low, and where convection is eliminated by stopping leaks and preventing the circulation of air currents, an air space between the walls of a boiler setting is generally regarded as affording the greatest protection against the loss of heat to the boiler room. In view of the investigations, however, it appears that notwithstanding the low conductivity of air, its effect upon the transfer of heat is small as compared with that of radiation when high temperatures are considered. This is because the transfer of heat by conduction varies directly as the temperature difference between the two inner surfaces of the walls and the resistance of the intervening air, whereas the radiation varies directly as the difference between the fourth powers of these surfaces.

This may appear somewhat startling at first, but when it is considered that the heat given to the earth by the sun is transmitted by radiation alone, the significance of this factor is at once apparent. Furthermore, when standing in front of an open fire the heat is felt upon the face, yet the temperature of the intervening air may not be materially increased; but if a piece of paper or other shield is placed in front of the face the heat will not be felt. This shows that it is radiated heat. Also, the heat from an incandescent lamp is radiated as the bulb contains very nearly a perfect vacuum.

Some may find it hard to harmonize this with the fact that there are certain vessels on the market for keeping things hot or cold, which have double walls with a partial vacuum between. The fact is, however, that the walls of these vessels are polished and reflect the heat. If it were practicable to do this with furnace walls, one source of heat loss might be greatly minimized. The whole subject is one of unusual interest and should evoke profitable discussion.

Room for Improvement

Ever since Newcomen started his first pumping engine it seems to have been understood that the engineer would stand for more overtime and other undesirable conditions than anyone else around the plant.

It is taken for granted that he will be the first on the job in the morning, the last to leave at night; that he will spend all day Sunday at the plant and work for laborers' wages. This has gone on until after two hundred years' of precedent and practice the bargains that some employers are able to drive with their mechanical help seem almost beyond belief. The following is an example:

This is the case of an "engineer" who runs a machine in a shop. He is an expert on the machine and, although he has some other duties to look after, he turns out nearly as much work as his companions who keep steadily at their tasks. These "other duties" consist of wheeling the coal, firing, and hoisting the ashes for a two-hundred-horsepower heating boiler and attending to a gas engine which runs the shop. The engine runs night and day, shutting down a half hour for the noonday lunch and a half hour in the evening for a change of shifts.

During lunch time the "engineer" tinkers around the plant between mouthfuls and sees to it that the machinery is started for the afternoon run. At night he remains to put the plant in operation for the night run. On Saturday afternoons he works on the engine, getting it in shape for the next week's work, and comes down on Sunday to work around the boiler, lace belts, rebabbitt the line shafting or do any odd jobs of plumbing on the heating system.

For his extra duties he receives twenty-five dollars per month, which helps to pay the rent, and he makes up the rest of his living by hustling on the machine. As an example of industry he is a model; as an example of poor engineering conditions his case could not well be improved upon.

It has often been remarked that this country affords a wonderful field for activities of every description; that there is scarcely a line in which one may enter but what virgin soil may not be encountered.

This is particularly true of all those organizations which have for their object the betterment of the individual. Each is endeavoring in one way or another to better the condition of its members and incidentally the profession in general, and in this work there is no question but that great good is accomplished.

Much time and hard work are necessary to dig down into the depths and reach some individual cases, but with such conditions as cited above existing the possibility of reward is always present; the horizon is limitless; the field has hardly been scratched.

All in the Spirit

One of the arguments frequently advanced in favor of the enactment of engineers' license laws and ordinances is that it will act as an incentive to the engineer to study the fundamental principles of his calling. This may be true of the man who is an engineer because accident led him to the power plant in his search for something to do in order to get a living and who still works for a living and nothing else. It is not true, however, of the engineer who follows his vocation because he loves it. He strives and studies not because of the spur of the license but to fit himself for the highest position possible. His ambition is not alone to hold a license, but to become better educated, a better engineer and a better citizen every day of the year. He does not expect that a law, which unless properly administered will not eliminate the unfit, will place an arbitrary value on his services, for he aims to give value received for every dollar paid by perfecting himself in both the theoretical and practical knowledge of his work.

There were good engineers before the days of license legislation and there are good engineers in those States and cities where there are no license laws. It will be found, however, that it is the progressive and able engineer who is always advocating the passage of license and inspection laws. His knowledge of the dangers attendant on the operation of steam boilers and engines, his appreciation of the possibilities in the loss of life and limb and the damage to and destruction of property and his regard for the safety of others make him the foremost of all advocates for rational license and inspection laws and their administration in the spirit for which they are intended. He does not advocate license laws for the purpose of limiting the supply of competing workers in his field, for none can be found more ready to give effort and time to help another than the real engineer, but because he loves and honors his calling. It is his chosen work and he gives to it the best that is in him and all of it, because to him to be an engineer is to live.

Boiler Horsepower

The new value for the heat of evaporation from and at 212 degrees throws out the American Society of Mechanical Engineers' standard for a boiler horsepower. That standard is 30 pounds of water at 100 degrees evaporated per hour into steam at 70 pounds pressure above the atmosphere.

Or 34½ pounds, evaporated per hour from and at 212 degrees.

Or 33,305 B.t.u. per hour. The first two never did agree and with the corrected heat values the evaporation of 34½ pounds from and at 212 degrees means 33,478.8 B.t.u. instead of 33,305.

Why not leave any consideration of the horsepower of boilers out of the forthcoming (?) report. It is an anachronism and ought to have no further official recognition. Let them be rated in direct terms of the water which they will evaporate from and at 212 degrees per hour. We do not buy condensers by the horsepower.

At the experiment station of the United States Bureau of Mines, Pittsburg, Penn., several trial runs have been made with an experimental gas producer, using coke as fuel, with which limestone has been mixed in varying proportions, the purpose being to flux the ash, and form a liquid slag, thus avoiding clinker and ash troubles and consequent shutdowns. Liquid slag has been readily made which runs freely from the producer. The high temperatures necessary are very efficient in the generation of gas.

It seems that our numerous references to the self-contained outfit which the Europeans call the Locomobile and with which they obtain such wonderful efficiencies have had their effect. It is said that a number of large American companies are considering their manufacture.

The weather has now reached the point where the back door can be kept open, all ready for the speedy exit of the man who tries to sell you one of those gas engines that "require no attention."

Just because warm weather is coming is no reason why you should close your books and let your studies go for another six months.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Flow of Air through an Orifice

A vacuum of 7½ inches of mercury is maintained in a tank while air rushes in from the outside, passing through five ½-inch openings. Required the velocity of the air through the openings and the quantity of air entering per minute.

G. H. W.

The velocity in feet per second is obtained from the equation:

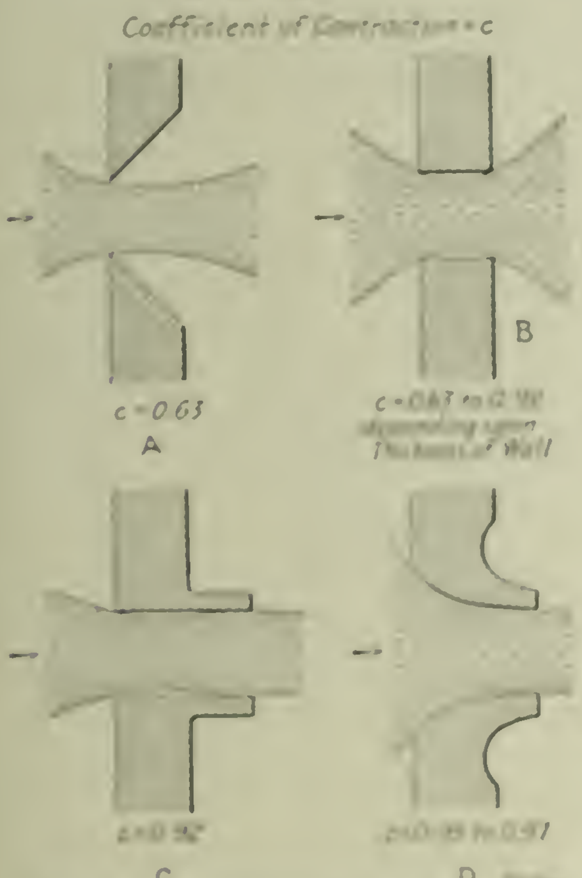
$$\frac{v^2}{2g} = \frac{k}{k-1} p_0 V_a \left[1 - \left(\frac{p}{p_0} \right)^{\frac{k-1}{k}} \right] \quad (1)$$

where,

v = Velocity;

p_0 = Atmospheric pressure in pounds per square foot;

p = Pressure in tank, in pounds per square foot;



JETS WITH DIFFERENT COEFFICIENTS OF CONTRACTION

V_a = Specific volume of air at atmospheric pressure and temperature t_a degrees Fahrenheit;

g = 32.18;

k = Ratio of specific heat at constant pressure to that at constant volume.

With the barometer at 29.92 inches,

p_0 = 14.7 × 144 = 2117 *pounds per square foot*

Corresponding to a vacuum of 7½ inches of mercury,

p = 11.01 × 144 = 1585 *pounds per square foot*

The value of V_a depends on the temperature and the humidity of the air. Leaving aside the effect of humidity, 12.83 cubic feet equals the volume of one pound of dry air at 50 degrees Fahrenheit; then

$$V_a = \frac{12.83 \times (460 + t_a)}{460 + 50}$$

Substituting this value of V_a in equation (1),

$$v^2 = \frac{2 \times 32.18 \times 2117 \times 12.83 \times (460 + t_a)}{510} \times \frac{1.41}{1.41 - 1} \left[1 - \left(\frac{1585}{2117} \right)^{\frac{1.41 - 1}{1.41}} \right]$$

Whence,

$$v = 30.85 \sqrt{460 + t_a} \text{ feet per second}$$

The volume flowing per minute through a ½-inch opening equals

$$60 \times \frac{d^2 \times 0.7854}{144} \times v \times \text{coefficient of contraction}$$

expressed in cubic feet of air at p pounds per square foot pressure or at 7½ inches vacuum.

To obtain the volume of free air at atmospheric pressure and a temperature t_a, let t be the temperature in the tank; then

$$t_a - t = \frac{A \times v^2}{c \times 2g}$$

where,

A = Heat equivalent of work = $\frac{1}{778}$

c = Specific heat of air at constant pressure = 0.2375;

$$t_a - t = \frac{v^2}{0.2375 \times 778 \times 64.36} = \frac{v^2}{11,892}$$

The tank temperature is

$$t = t_a - \frac{v^2}{11,892}$$

The volume V discharged into the tank at the temperature t and pressure p is equivalent to a volume V_a of free air at a pressure p_a and temperature t_a,

$$V_a = \frac{V \times (460 + t_a) \times p}{(460 + t) \times p_a}$$

cubic feet per minute.

Joint Resistance of Parallel Circuits

If a conductor of 20 ohms resistance, one of 22 ohms and one of 25 ohms be connected in parallel and 110 volts applied to the terminals, what current will flow in each one and what will be the joint resistance of the three?

C. H.

The current in each conductor will be exactly the same as though the other two did not exist. By Ohm's law,

$$\frac{\text{Volts}}{\text{Ohms}} = \text{Amperes}$$

therefore, the current in the three branches will be 110 ÷ 20 = 5.5 amperes, 110 ÷ 22 = 5 amperes and 110 ÷ 25 = 4.4 amperes, respectively. The total current in all three branches will be 5.5 + 5 + 4.4 = 14.9 amperes, and the joint resistance, therefore, is 110 ÷ 14.9 = 7.38255 ohms, or practically 7.4 ohms. The joint resistance can also be figured by adding the reciprocals of the three resistances and taking the reciprocal of the sum. Thus, the reciprocal of 20 is 0.05; the reciprocal of 22 is 0.0454545; the reciprocal of 25 is 0.04. The sum of these is 0.1354545, and the reciprocal of that is 7.38255.

Boiler with Little Water

Supposing a 60-inch by 16-foot horizontal-tubular boiler with 58 four-inch tubes was fired up with several inches of water in the boiler. The water at about 100 degrees. Would it be possible for this water to be evaporated into steam and cause the safety valve loaded at 80 pounds to blow off. In other words, would it be possible for the small amount of water in the boiler to be expanded into steam to cause a pressure of 80 pounds, providing the boiler held tightly; also, would this be likely to happen within 20 minutes from the time of starting the fire, coal being used as fuel?

O. C. D.

A boiler 60 inches by 16 feet with 58 four-inch tubes has a capacity of 200 cubic feet. Steam at 80 pounds gage pressure weighs 0.2198 pound per cubic foot. Therefore it will require the evaporation of 0.2198 × 200 = 43.96 pounds of water to fill the boiler with steam at 80 pounds pressure. A depth of water of one inch at the bottom of the boiler would contain 40 pounds or enough to blow the safety valve and then have some water left. It should be an easy matter to boil so little water in much less than 20 minutes with a good coal fire.

Refrigeration Department

Principles and operation of ice making and refrigerating plant and machinery

Charging a Refrigerating System

By F. E. Matthews

How should a refrigerating machine be charged, and how is it possible to tell when it is sufficiently charged; also, when it needs recharging? What are the various systems? What will prevent brine from freezing in the pipes, and how can they be opened after freezing?

Although not specifically stated in the question, the machine is probably of the compression type, and on this assumption proceed as follows: Connect the shipping drums of anhydrous ammonia, one at a time (or more if the plant is of large capacity or the initial charge is being put in and one wishes to save time), to the charging valve usually placed between the master expansion valve on the liquid line, where it leaves the receiver, and the expansion coils or brine cooler. This connection is most easily made by a special fitting built up with two swing joints, one end threaded to fit the valves on the shipping drums and the other provided with a flanged or threaded end to connect to the charging valve. When the connection has been made the air in the pipe may be expelled by slightly opening either the charging or the shipping-drum valve and loosening the flange swing joint nearest the opposite end.

The connection having been carefully made, the main valve on the receiver is closed and the low-pressure side is "pumped down" by allowing the compressor to continue operation after the liquid has been shut off. By the "pumping down" process the ammonia in the expansion side of the system is compressed and discharged into the compression side of the system, where it is condensed and flows to the liquid receiver which it may fill as well as the lower pipes of the condenser.

When the low-pressure gage indicates that the pressure in the expansion coils has been reduced to zero, or atmospheric, pressure, the charging valve may be opened wide and then the valve on the shipping drum may be "cracked," allowing a small stream of the liquid to pour into the system. The valve on the drum virtually becomes the expansion valve of the system and its manipulation should be governed by the same rules that govern the other expansion valves when the machine is in normal operation, except that it is better not to carry the back pressure quite as high as usual. This pressure may be anything above atmospheric, but it is not advisable to go below atmospheric as the vacuum would tend to draw air into the system through the charging connection when the drum is disconnected if the charging valves are not absolutely tight. A considerable inrush of air is not so easily detected as the slightest leak of ammonia outward.

When an open connection is made between the shipping drum and the system, the liquid is forced out of the drum into the system by the pressure of the gas above the liquid just as water is forced out of the blowoff of a boiler by the steam pressure above the water. The only difference is that it requires a higher temperature than that of the atmosphere in the engine room to raise steam pressure, while any temperature above zero will give a pressure above atmospheric in the case of ammonia. The pipe line from the drum valve will frost while there is liquid flowing. The melting and dropping off of this frost is an indication that the drum is empty. Frost may also appear on the bottom of the drum. The end opposite the valve is usually slightly elevated so that the liquid will flow to the outlet pipe which enters the head and turns down within about an inch of the cylinder side. When one drum is emptied, shut both valves and disconnect the pipe connection; then place another drum in circuit if more liquid is needed.

In systems of medium and large capacity it will be found necessary to slow down the compressor during the charging operation to prevent the pumping of a vacuum.

It is easier to form an opinion as to the amount of ammonia that the system needs while it is operating than it is to determine when a sufficient amount has been added. Except in initial charges, in which case the company supplying the machine calculates the amount of ammonia required from the number of feet of pipe on the low- and high-pressure sides, it is better to add a comparatively small amount of ammonia and then operate the system for a sufficient length of time to restore normal conditions. The hight of the liquid in the gage glass of the receiver, or the general performance of the plant when no gage glasses are used, will give the engineer an idea as to whether more ammonia is required. There should always be sufficient liquid ammonia in the receiver to insure a solid stream at the expansion valve. It should be remembered that refrigeration is produced by the absorption of the heat required to change the liquid ammonia to a gas and since it takes only a very small amount of heat to raise the temperature of any gas that passes the expansion valve in company with the liquid, little cooling effect can be expected from the gas. The passage of gas with the liquid can usually be detected by the intermittent whistling sound at the expansion valve, the flow of the liquid being almost noiseless.

Refrigerating systems may be classified first, as to the working fluid, and, second, as to the method of operation. The most common refrigerating fluid is ammonia, the next is carbon dioxide, after which come air, sulphur dioxide, Pictet fluid, sulphuric ether and a few others little used in practical refrigerating systems.

Ammonia systems are operated either according to the compression or to the absorption system, the former being far in the majority. Either of these may be operated on the direct-expansion principle in which the working fluid is conveyed direct to the rooms or tanks to be cooled, or by the brine-circulation system, in which the refrigerant is used in a suitable brine cooler for cooling either salt or calcium-chloride brine which is then circulated through the rooms or tanks to be cooled.

These systems might be further classified as to the type of apparatus employed for converting the refrigerant from the gaseous to the liquid state and the means of utilizing the heat-absorbing power of both the primary (the refrigerant) and the secondary (brine) cooling media. Where brine is employed as a circulating medium, it is usually chosen because it can be more conveniently handled in the compartments to be refrigerated than can the primary refrigerant and because the primary refrigerant can be expanded more efficiently in a single brine cooler especially designed for the purpose than it can in a number of dissimilar expansion coils scattered throughout the various rooms; also, where a brine-storage tank of large capacity is employed, it permits a considerable amount of refrigeration to be stored away during the periods of operation of the system, to be used during periods of rest, as, for instance, where it is desired to operate the principal mechanical equipment of the plant during the daytime only.

Brine is employed instead of water (which would otherwise be used on account of its cheapness) because its density may be so increased by the addition of salts that it will not freeze at the usual temperatures required for cooling. Water will transmit more refrigeration per pound pumped than brine and may be used where cooling at a high temperature only is required and the operating pressure of the primary refrigerant can be carried sufficiently high to insure against the water freezing. This condition could not be realized in the majority of cases, as any pressure of the ammonia below 47 pounds gage will produce a corresponding temperature below 32 degrees Fahrenheit, the freezing point of water. For lower temperatures salt brine is employed, its maximum density being sufficient to insure against freezing at temperatures above zero where tank systems are employed and the brine is kept in circulation. When still lower temperatures are required calcium-chloride brine is employed which at its maximum density is safe against freezing at all temperatures above 25 degrees Fahrenheit. At their maximum densities salt brine and calcium-chloride brine contain by weight respectively 25 per cent. of salt and 33 per cent. of calcium chloride.

To insure against freezing of brine, care must be taken to see that the solution is sufficiently strong to have a freezing temperature above that which will ordinarily be produced by the refrigerating machine. Care must be taken to see that this strength is maintained, as in the case of ice tanks a considerable dilution occurs through the replacing of wet cans and possible overflows due to occasional failure of automatic can fillers to shut off the fresh water at the proper time.

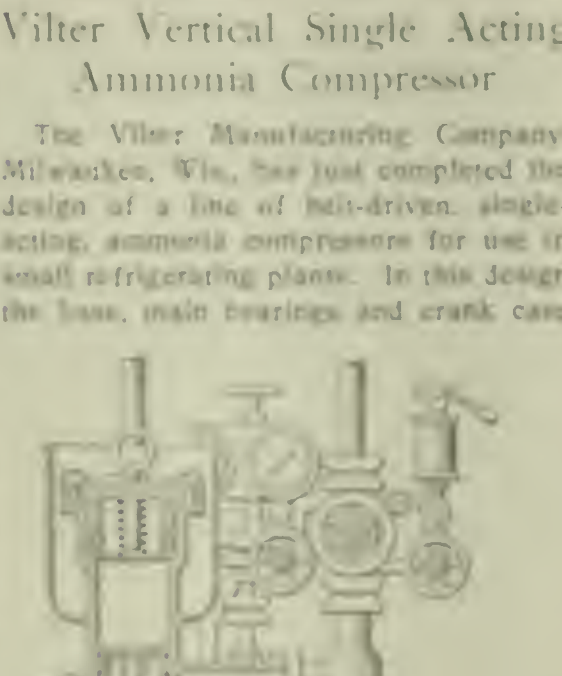
In the case of brine tanks slight freezing of brine on the outside of the expansion coils has no worse effect than that of insulating the pipes, reducing both their efficiency and capacity for cooling until the expansion can be shut off and the brine temperature allowed to rise sufficiently to melt the ice.

In the case of brine coolers a solid freeze may burst the pipes, allowing the refrigerant to escape into the brine and the brine into the refrigerating coils if the system is pumped down while leaks still exist. In both the brine tank and the brine-cooler system care should be taken to insure against abnormally low back pressures being carried when the brine pump is not in full operation. While it is always better to work on a safer margin, it is nevertheless a fact that brine can be circulated at its freezing temperature provided sufficiently brisk circulation is kept up to carry it away from the brine-cooling surfaces before the liquid brine, between any ice crystals that may form, has time to congeal.

When coils have been allowed to freeze up solid the temperature in the cooler should be allowed to rise until the coils are freed, care being taken to see that the brine pressure is kept lower than that of the refrigerant so that the brine will not be forced into the system if leaks have been produced by the freezing. A careful examination of the brine flowing from the coils will show whether or not the higher-pressure refrigerant is escaping.

Vilter Vertical Single Acting Ammonia Compressor

The Vilter Manufacturing Company, Milwaukee, Wis., has just completed the design of a line of belt-driven, single-acting, ammonia compressors for use in small refrigerating plants. In this design the base, main bearings and crank case



Vilter Single-acting Ammonia Compressor

are in a single massive casting, making possible rigid construction and a low center of gravity. These units are built in six different sizes from [illegible] to [illegible] inches of compressor displacement and require a small amount of head room and floor space for their rated capacity.

The compressor water jacket, suction and discharge pipe are cast as a unit, the suction entering the cylinder at a point near the center of the bore and meeting the trunk of the piston.

As will be evident in the sectional drawing, the piston is of the double-trunk design, having long ports between the upper and lower sections, which register with the suction-gas inlet at all points of the stroke, allowing ample gas passage to the compression end of the cylinder but preventing entrance of liquid or gas to the crank case.

The suction valve, contained in the piston as shown, is made of hammered steel, finished and ground to its seat. All superfluous metal is hollowed out from the disk and the valve stem is drilled the full length in order to lighten the valve and render it responsive.

The discharge valve is a light weight cup-shaped, pressed-steel member, housed in a semisteel cage and fitted into the upper counterbore of the cylinder. Both valves are extremely light in proportion to their size, are large with relation to the cylinder bore and give full area of opening from [illegible] to [illegible] inch extreme lift, thus insuring full cylinder charging and noiseless operation.

For lubrication a hand-oil pump is furnished for the upper part of the cylinder. An oil cup or grease box is supplied on the bearing next to the band wheel, while the main bearing, crank pin, wristpin and lower part of the trunk piston are automatically lubricated by oil splashed from the crank case. A gage glass is used to indicate the level of the oil in the crank case.

A strong feature of the design is the accessibility of all parts. By the removal of the large crank-case cover and the cylinder head the entire mechanism may be inspected or the parts disassembled. The same controlling features are used as are furnished with the larger machines of Vilter manufacture.

Repairing Pipe Insulation

How can the sweating of pipe be prevented? In the plant I am operating it has caused the partial disintegration of the 3-inch cork covering. Will wrought-iron pipe painted or galvanized pipe remedy the trouble?

Unless the pipe has actually rusted through, the moisture encountered does not come from the inside. There is no such thing as sweating through a pipe. The so called sweating of cold surfaces is due to the cooling of the surrounding air by contact with the cold surface. Air always contains a certain amount of humidity, or in other words, there is always mixed with air a certain amount of water vapor. The capacity of the air to carry this vapor depends directly on the temperature. The warmer the air the more vapor it will hold; the cooler, the less. When air is saturated with vapor, that is, when it has absorbed all the vapor it can at a given temperature, the slightest drop in temperature will produce precipitation, or a throwing down, of a part of the moisture. If air other hand, the temperature rises, the air will no longer be saturated, and a capacity for absorbing more moisture will have been created.

The temperature at which air becomes saturated to the point of precipitating its moisture is known as the "dew point." When drops of water appear on a cold brine pipe, or, in fact, on a pitcher of ice water, it is because the layer of air immediately surrounding the cold surface has been chilled below the dew point and thus gives up a part of its moisture.

In the case of a cold pipe insulated with cork or other kinds of covering, the liability of the air to be cooled to the dew point is greatly reduced, since the temperature of the outside of the covering is not nearly so low as that of the pipe. Nevertheless, a condition of atmospheric humidity will sooner or later exist when contact with a surface only a degree or two colder than the air will produce precipitation. If there is even the smallest opening through the waterproofing on the outside of the covering, air will enter, and, since the further it passes into the covering the lower the temperature encountered, the more likelihood of precipitation.

When the moisture has once been precipitated in the small openings through the waterproofing, it has limited exposure to the air for reëvaporation and unless there is a rise in temperature to increase the absorptive power of the immediately surrounding atmosphere, it will remain there. If the temperature of the insulation finally falls below 32 degrees, the moisture is frozen and in so doing expands, cracking the insulation still further, and into these minute cracks the moisture flows when another rise in temperature melts the ice. A recurrence of the freezing operation still further tends toward the disintegration of the insulation and the more the moisture penetrates toward the pipe and the more frequent the variations in temperature the more rapid will be the destruction of the insulation.

The place for the waterproofing, or more accurately, air proofing, of all kinds of cold insulation is where it comes in contact with the air and not at the point most remote from the point of attack, as in the case of the application of waterproof paper, paint, etc., next to the surface of cold pipes, where the only possible function of such waterproofing would be to prevent the pipe from rusting after the insulation had been penetrated and rendered useless by moisture.

If the present pipe covering is badly disintegrated and shows signs of being frozen, it should be removed and replaced. If it only shows deterioration in places, it can possibly be dried out. If there is any time of year when the pipes are not in service for a considerable length of time, they may be disconnected and the drying operation accomplished by passing steam through them. When the insulation has been thoroughly dried, the outside should be given a good coat of rubber sealing compound, supplied by the manufacturers, or several coats of quick-drying asphalt paint.

LETTERS

Corrosion in Refrigerating System

In the issue for April 11, comments are invited on the rapid deterioration of a brine-concentrating coil and tank, such as are used in connection with wet-air coolers. The following suggestions are offered for annihilating or at least greatly reducing the difficulty:

The first improvement that can be made is to pass only hot water or at most exhaust steam, not live steam, through the heating coil, so that the temperature of the brine will not exceed, say, 110 degrees Fahrenheit. This will prevent rapid formation of salt crystals on the pipes.

Secondly, the tank should have a large brine surface so that the surrounding atmosphere can absorb the rising water vapor as fast as possible. Let drafts of air pass over the surface, and do the work of concentrating when the humidity of the air is low. If the brine can be kept in motion by means of an agitator or circulating pump it will be an advantage, as it hastens the process of evaporation.

Third, arrange the heating pipes in form of an upright coil in the pan over the brine level, with a V-shaped distributing trough along the top, in the same manner as with an atmospheric type of condenser; and with a small pump keep circulating the warm brine over the coil until the solution has attained the proper strength. It is evident that under this method the atmosphere has a good opportunity of assisting in the work. With steam the heating surface of the coil should not be less than 0.11 square foot per ton of refrigeration; with hot water this surface may have to be doubled.

Fourth, for hygienic reasons it is objectionable to use the same stale brine over and over again; a slight overflow should be permitted to waste and this must be replaced with fresh brine. This can best be prepared by means of a box or barrel fitted with a false bottom, perforated. The water enters the barrel below the false bottom, rises through the salt above it and passes out as strong brine at the overflow pipe near the top of the barrel. This outlet must have a filtering screen to prevent obstructions from getting into the pipe. As it is frequently the impurities which cause rapid corrosion, the fresh brine should next be passed through a filter so as to remove these impurities. As a further precaution, the brine should be allowed to settle for some time in a tank of large area, where more impurities will precipitate to the bottom. At this opportunity it would be well to neutralize the corrosive properties of the solution by adding, in the case of salt brine, one to two pounds of carbonate of soda per 100 pounds of salt used, or one-half pound hydrate of soda per 100 pounds of calcium used in the case of chloride of calcium brine.

Fifth, as the expense for heating the brine and evaporating the water is considerable in a large plant, an economy can be effected by letting the hot discharge gas from the compressor pass direct through the concentrating coil. The coil should be made of extra-heavy pipe, galvanized on the outside only, and of sufficient cross-sectional area so as not to impose undue resistance on the gas. This plan will require very little attention and saves heat and condenser water.

Sixth, if this arrangement is not convenient the efficiency of the plant can be improved by means of a heat exchanger, in which the cold brine coming from the air cooler exchanges heat with the warm brine leaving the concentrator, in the same way as is done with the liquors of an absorption-refrigerating plant. In order to be able to advise as to the surfaces needed for a heat exchanger, one must know the temperatures and quantities of each medium available per hour, also the relative densities. In this connection it is well to bear in mind that it is important to work with brine just dense enough to prevent formation of ice on the ammonia coils. In order to see that this is the case, one must test the specific gravity of the solution every day by means of a hydrometer, and be guided by a table which gives the correct relations between specific gravity, freezing points and working temperatures of the salt or calcium brine used in the system.

CHARLES H. HERTER.

New York City.

With reference to the article, "Trouble with Refrigerating System," in the issue of April 11, the author has had trouble with brine rusting the boiling tanks and coils. Most of the trouble is caused from the fact that the brine does not let the tank dry when empty and the air rusts the moist iron. If the tubes fail at the fittings, it is due to electrolysis in the brine solution, which does not leave the tubes when they are apparently dry. If the tank is covered and copper coils used or perhaps a jacket, the trouble from corrosion of the tanks or from electrolysis will disappear.

F. G. WHEELER.

Trenton, Mich.

The Ohio Society of Mechanical Electrical and Steam Engineers

The twenty-third meeting of the above society was held at Youngstown on May 18 and 19, in the auditorium of the Elks Club, the privileges of which were extended to the visitors during their stay in the city. Six excellent papers were presented and discussed, of which those of interest to POWER readers will be treated in the columns following and in a later issue.

Inspection trips were made to the works of the Youngstown Sheet and Tube Company and to the Ohio works of the United States Steel Corporation, and outside of the formal program visits were arranged to the power station of the Youngstown Consolidated Gas and Electric Company of which Vice-President H. L. Patterson is mechanical engineer, the works of the William Tod Company and other local industries.

The next meeting will mark the tenth anniversary of the organization of the society, and will be held in November at Canton, where the first meeting took place.

Hydroelectric Developments in Ohio

BY PAUL M. LINCOLN

Reliability and continuity of supply is the first requisite for any power development. In former years the grist mill or sawmill was more or less common on many of the streams in Ohio. These operations required a comparatively small amount of power, and the continuity of supply was, under the conditions then existing, not absolutely necessary for success. However, most of these small developments of power have fallen into disuse.

A study of the rainfall and runoff conditions that apply to the Middle West is essential in arriving at a proper valuation of water powers. Table 1 shows the mean rainfall and runoff as recorded for the Muskingum River basin at Zanesville, O. This record covers the eight years of 1888 to 1895 and also shows the average of the same quantities for the three dry years of 1889, 1894 and 1895.

For the three months of August, September and October, the runoff reaches a comparatively low figure. A better idea of the conditions will be obtained by referring to the curves in Fig. 1, which show in dotted lines the average for the three dry years and in solid lines the average for the eight years. Referring to the months of August, September and October of the three dry years, it will be noted that the average monthly runoff amounts to 0.131 inch. Considering that this is the average for nine months (three consecutive months of three different years) it is certainly not too radical to assume that one cannot depend upon a continuous amount of water at the minimum flow of the stream of more than 0.1 inch per month. As a matter of fact, it is quite probable that this estimate is higher, rather than lower, than what would actually be obtained.

The table shows that the average rainfall, if distributed equally throughout the whole year, would amount to about 3.3 inches per month and that the average runoff for the same conditions would be about 1.1 inch per month.

One square mile with a runoff of 0.1 inch per month, falling through a head of 1 foot, will give a theoretical energy of about 0.01 horsepower. Taking into account the efficiencies of the waterwheel and such other apparatus as is necessary to utilize this power, it is evident that a continuous supply can be obtained of not more than 0.005 kilowatt for each square mile of drainage area for each foot of fall over which this water can be used. For instance, if it were possible to obtain a point at which the runoff from the entire State of Ohio (41,000 square miles) could be utilized over a 10-foot fall, it would be possible to obtain a continuous power supply of only about 2000 kilowatts at the minimum flow point. This seems an astonishingly small result but is nevertheless true when it is conceded that a runoff of 0.10 foot per second per square mile is all that is available.

CURVES SHOWING RUNOFF OF MUSKINGUM RIVER

The foregoing figure is for a continuous power supply. As a matter of fact, actual conditions do not demand a continuous supply throughout all hours of the day. Considerably more power is demanded at certain hours than at other hours, and for an ordinary lighting load a 30 to 40 per cent. load factor might be expected. Only a relatively small amount of pondage is necessary for equalizing a continuous supply of water so as to take care of the variations in daily load demanded by a daily load factor of 30 to 40 per cent. This would increase the maximum power which would be available at certain hours of the day by conserving the water for the remainder of the day. A 30 per cent. load factor would mean that 3⅓ times the continuous supply can be depended upon at the maximum demand.

There are two plans which may be adopted for the utilization of such water power as is available in relatively flat and variable rainfall localities. The first is to build reservoirs for the purpose of impounding the water during flood periods and releasing it during the low-water periods; the second, to use water-power plants as auxiliaries for steam operation, depending upon each kind of plant as a relay for the other.

Referring to the first of these remedies, suppose, for instance, that it is desired to increase the runoff available from 0.1 inch per month, which represents about 45 per cent. of the average runoff. The curves in the figure indicate in a general way what is necessary. The line *C* shows the low-flow period of the stream, namely, 0.1 inch per month. The line *D* is drawn at the average flow point of 0.5 inch per month, and the area *e f g e* represents the amount of water which would have to be released during the summer months of the average dry year to raise the flow from what records show really does exist during such years to the 0.5 inch per month. In order to release this amount of water, it would be necessary to impound an amount of water indicated by the area *e h i f e*. On account of the losses which necessarily take place by evaporation and seepage, it would be necessary that the amount of water stored exceed that released by about 20 per cent.

If the water-power plant be considered simply as an auxiliary to a steam-power plant, it at once becomes necessary to install duplicate machinery for a considerable part of the load. Steam-driven machinery must be provided to carry the load during the periods of insufficient water. The question at once arises, will the installation of a water-power plant pay? In order to get a basis for answering this, assume first that the duplication of machinery is complete, that is, that there is an available water power during a part of the year and that it is therefore necessary to have a steam plant that can carry the entire load during such period. A brief consideration will show that practically the only saving that can be obtained by the operation of a water-power plant as an auxiliary to a steam plant is the saving of the fuel which would be burned if the water plant were not operated. The item of labor for attendance will certainly not be reduced. In fact, the attendant expense is apt to be increased, since during a considerable part of the year both plants would have to be operated, necessitating practically a double crew. Supplies, such as oil, waste, etc., would not be reduced by the operation of the double system, nor would maintenance and repairs be reduced as the upkeep on the steam plant is apt to be even higher if run intermittently than if run continuously.

Another feature which plays an important part is the load factor. The lower the load factor, the smaller will be the number of kilowatt-hours turned out per kilowatt capacity of machinery installed; also the smaller will be the fuel bill per kilowatt of machinery installed. Table 2 indicates, in the first column, the load factor, and in the second column, the total number of kilowatt-hours which a plant will put out for each kilowatt-hour of maximum load; the third column shows the cost of the fuel for each kilowatt of maximum load at 0.5 cent per kilowatt-hour, and the fourth column, the maximum amount of money per kilowatt that should be put into a water-power plant for the conditions assumed. The figures in this column are arrived at by considering that the annual fixed charges on the water-power plant must not exceed the annual fuel bill, if the steam plant produced all the power. The fixed charges on the water-power plant are taken at 13 per cent. per annum, which is obtained by assuming 5 per cent. for interest, 6 per cent. for depreciation and 2 per cent. for insurance and taxes.

TABLE 2

Load Factor in Per Cent.	Kilowatt-hour per Year for Each Kilowatt of Capacity	Yearly Cost of Fuel per Kilowatt of Capacity at 0.5 Cent per Kilowatt-hour	Limiting Cost per Kilowatt of Auxiliary Water-power Plant
20	1750	$ 8.75	$ 67
30	2630	13.10	100
40	3500	17.50	135
50	4380	21.90	169

In arriving at the cost of a water-power plant, one should take into consideration not only the hydraulic development and the cost of the machinery but also the cost of transmitting the power from the plant to the market. This last item is very often an important one, since it is usually necessary to make the hydro-electric development at a considerable distance from the market, therefore making the cost of transmission high.

The figures in Table 2 were based upon the assumption that the water-driven plant will save all the coal. Reference to the curves in the figure will show, however, that this is much more than can actually be saved unless the stream be developed for the minimum flow only. If more than the minimum flow is developed, all the coal that would have been used by the equivalent steam plant could not, of course, be saved. To correct for this, the figures in the fourth column of Table 2 would have to be increased, the amount of this increase running as high as 33 per cent. for the conditions indicated by the cross-hatching on the curve.

In conclusion, it would seem that where load factors are low, the question of developing a water-power plant in a region such as Ohio is one that demands a very close scrutiny. The cost per kilowatt of a water-power development is a variable quantity, but it seldom runs below $100 per kilowatt, and sometimes runs to four or more times this figure. The amount spent in a water-power plant can therefore easily exceed the economic limit.

The Coming Chicago Convention of American Institute of Electrical Engineers

The annual convention of the American Institute of Electrical Engineers will be held in Chicago on June 26 to 30, inclusive, in the new Hotel Sherman, the most recently completed of Chicago's group of modern hotels. While the list of papers to be presented at the convention is not complete, the following partial list of papers that will probably be presented shows the diversity of subjects to be considered: "Economical Design of Direct Current Magnets," by R. Wikander; "Catenary Span Calculations," by W. L. R. Robertson; "Currents in Inductors of Induction Motors," by H. Weichsel; "Multiplex Telephony and Telegraphy by Means of Electric Waves Guided by Wires," by Major G. O. Squier; "Electrolysis in Reinforced Concrete," by C. E. Magnusson; "Induction Motor Design," by T. Hoock; "The High Efficiency Suspension Insulators," by A. O. Austin; "The Electric Strength of Air," by J. B. Whitehead; "Electrification Analyzed, and Its Application to Trunk Line Roads," by W. S. Murray; "Telegraph Transmission," by F. F. Fowle; "The Cost of Transformer Losses," by R. W. Atkinson and C. E. Stone; "The Costs of Railway Electrification," by B. F. Wood; "Induction Motor for Single-Phase Traction," by E. F. W. Alexanderson; "Magnetic Properties of Iron at 200,000 Cycles," by E. F. W. Alexanderson; "Electric Storage Batteries," by Bruce Ford; "The Characteristics of Isolated Plants," by P. R. Moses; "Elevator Control," by T. E. Barnum.

New Coal Region Being Developed

To those who are looking forward with so much apprehension to the time when the coal supply shall have been exhausted, the announcement that a large tract of land in Kentucky is about to be developed will prove welcome news.

The Consolidation Coal Company has recently purchased a tract of 100,000 acres of virgin coal land known as the Elkhorn district in Kentucky, and is building a railroad of its own from Shelby to the mine. The Louisville & Nashville railroad is also building a branch to this district, and when these two are completed there will be adequate facilities for working the mines to their limit; which, it is estimated, will occur in less than two years.

Extensive borings have been made throughout the entire region, and the coal has been found to run in almost continuous veins of about 9 feet in thickness. It is a high-grade bituminous coal with about 37 per cent. volatile and possesses excellent coking qualities, making the byproduct gas available for gas-engine purposes.

Bill for Ventilation of New York Factories

A bill has been introduced into the assembly of the New York legislature by Mr. Boylan to regulate the ventilation of factories and workrooms in the State of New York. This is a measure for which a committee of the American Society of Heating and Ventilating Engineers, D. D. Kimball, chairman, has been working on for over a year.

The bill provides that a workroom must be ventilated so that the air within does not contain more than nine parts of carbon dioxide in 10,000 volumes of the air in excess of the number of parts of carbon dioxide in 10,000 volumes of the outside air, or so that there is constantly supplied throughout the interior of the room at least 1200 cubic feet of air per hour per person and in addition 1000 cubic feet of air for each cubic foot of gas burned per hour, the air to be taken from an uncontaminated source. The temperature must never be less than 55 degrees and, except in boiler rooms, never more than 72 degrees wet-bulb temperature, unless the wet-bulb temperature outside exceeds 70 degrees, when the wet-bulb temperature inside must not exceed the wet-bulb temperature outside by more than 5 degrees.

The means for ventilation must be provided for by the owner unless a written agreement can be shown that the occupier is to furnish the means.

Illinois N. A. S. E. State Convention

The seventh annual convention of the Illinois State association of the National Association of Stationary Engineers was held at Ottawa, Ill., May 19 and 20. After opening with prayer by Rev. W. G. Irish, Mayor Bradford spoke briefly to the delegates and W. H. Miller, also of Ottawa, delivered a cordial address of welcome. Response was made by F. W. Raven, national secretary.

John W. Lane, in speaking of the National Association of Stationary Engineers, made the suggestion that the State educational committee make an effort to get into closer touch with the University of Illinois at Urbana, and possibly hold, during the coming fall and winter, a session at the university, devoted to the practical problems which the operating engineer is meeting in his everyday practice.

E. P. Gould, secretary of the Central States Exhibitors Association, read a paper at the opening exercises in which he outlined methods by which the exhibitors and engineers could cooperate to the benefit of all.

At the Friday afternoon session Prof. K. G. Smith, of the University of Wisconsin, gave a talk on "Smoke and Smoke Prevention," in which he explained the fundamental laws of combustion and illustrated, by means of a kerosene lamp, how such laws must be observed to get good results. The proportions of oxygen and nitrogen in the air were taken up with reference to their effect on the carbon, hydrogen and sulphur in the fuel, the chemical problem involved being treated in an unusually clear and simple manner.

In speaking of developments in the burning of coal under boilers, Professor Smith told of a new practice in Europe, where a chain-grate stoker is being used under a marine-type Babcock & Wilcox boiler, with a stationary hand-fired grate located at the back end of the boiler in such a manner that on heavy loads the unburned fuel from the stoker will fall onto the stationary grate and burn; meanwhile the auxiliary grate can be stoked by hand if it becomes necessary, to carry the load.

Another subject of interest touched on by the speaker, was the problem of burning low-grade fuel in pulverized form. In an improved form, as introduced in Europe, the process consists of blowing the fuel upward into the furnace from the center of the grate, under a brick arch. It is claimed that by this method better combustion has been obtained and that boiler and furnace efficiencies from 76 to 82 per cent. are being realized.

W. F. Mozler, principal of the Ottawa high school, addressed the convention at the Saturday afternoon meeting, his subject being "A Practical Education." The professor spoke from experience in educating the young in the practical things of life and offered many suggestions as to how they could be guided in making a proper choice of their life work. Following Professor Mozler, W. A. Converse, of the Dearborn Drug and Chemical Company, gave an interesting talk on "The Purification of Boiler Feed Water," illustrating the important points with actual demonstrations, using chemical apparatus specially set up for the occasion.

Ex-Mayor J. T. Farrell wound up the exercises with a spirited talk entitled "What I Know about Engineering," which was well received.

One of the pleasing events of the program was the presentation to No. 6, of Peoria, of a handsome blackboard, for the highest honors in the State educational contest, the winning grade being 94.3 per cent. The convention indorsed John F. McGrath, of Chicago, for national vice-president.

Officers for the following year were elected as follows:

John F. Alt, of Ottawa No. 10, president; John R. Moore, of Chicago No. 1, vice-president, and W. E. Hill, of Moline No. 17, reëlected secretary-treasurer. Place and date of the next convention were left subject to the call of the incoming officers.

The following firms exhibited: American Steam Pump Company, Battle Creek, Mich.; V. D. Anderson Company, Cleveland, O.; George B. Carpenter Company, Chicago, Ill.; Centralene Oil Company, Chicago Heights, Ill.; Crandall Packing Company, Palmyra, N. Y.; G. M. Davis Regulator Company, Chicago, Ill.; Dearborn Drug and Chemical Company, Chicago, Ill.; Garlock Packing Company, Palmyra, N. Y.; General Specialty Company, Buffalo, N. Y.; Greene, Tweed & Co., New York; Harrisburg Foundry and Machine Works, Harrisburg, Penn.; Hawkeye Boiler Compound Company, Chicago, Ill.; Hills-McCanna Pump Company, Chicago, Ill.; Jenkins Brothers, New York; H. W. Johns-Manville Company, New York; Keystone Lubricating Company, Philadelphia, Penn.; George W. Lord Boiler Compound Company, Philadelphia, Penn.; Lunkenheimer Company, Cincinnati, O.; Lyons Boiler Works, De Pere, Wis.; McMaster-Carr Supply Company, Chicago, Ill.; *National Engineer*, Chicago, Ill.; Osborne High Pressure Joint and Valve Company, Chicago, Ill.; Peerless Rubber Manufacturing Company, New York; POWER, New York; *Practical Engineer*, Chicago, Ill.; John Roebling Sons' Company, New York and Sullivan Oil Company, Chicago, Ill.

Have you ever noticed that in the famous Greek statue of the Discus Thrower the athlete stands with his right foot forward, ready to hurl the discus?

For centuries the Greeks had thrown it this way—it was a custom, a tradition of their favorite national sport.

No one had ever stopped to think whether or not there was a better way of doing it.

But, in the 20th century—when discus throwing was more than 2000 years old—Martin Sheridan, the American athlete, went to Greece for the Olympian Games and entered the discus event for about the first time in his life.

He grasped the missile and threw it in the *natural* way, with his *left* foot forward, and in one throw smashed not only the ancient Greek custom but also the world's record.

In this little tale there are several morals.

The men who have accomplished things and gotten ahead of their fellows are nearly always the ones who have had the nerve and the brains to break with old traditions and customs.

In these modern times there have arisen newer, better methods of doing things—in the power plant as elsewhere.

And the man who puts his *best* foot forward, no matter what *custom* has decreed, is the man who will make new records and get farther ahead in his profession.

That most engineers realize this is proved by the fact that most engineers nowadays read the ads. in their technical paper.

They know that the *newer*, *better* ways to do the old things are *advertised* —and they follow those ads. conscientiously, and profit thereby.

The engineer who reads the Selling Section of POWER these days is the man who is putting his best foot forward in the double-quick march of Progress.

Are you one of them?

POWER

NEW YORK, JUNE 6, 1911

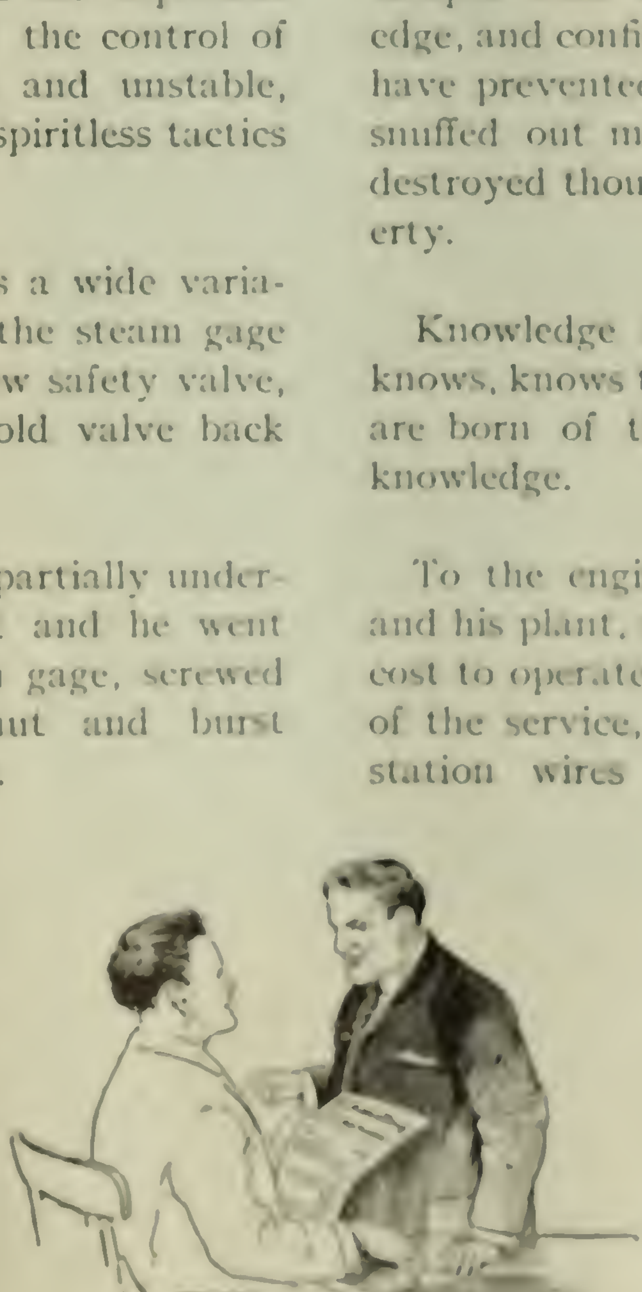
PROBABLY few engineers realize the influence that the mental attitude has upon their conditions and surroundings. It is said that shortly before Jeffries met Johnson in the ring he remarked that he wished it was over.

He went into the contest with a fear in his heart that dimmed his eye and depressed his spirit. His body, under the control of an unsound mind, was infirm and unstable, and his ineffective blows and spiritless tactics brought on certain defeat.

After seeing that there was a wide variation between the reading of the steam gage and the blowing point of a new safety valve, an engineer wished for the old valve back on the boiler.

Fear of something he only partially understood impaired his judgment and he went wrong. He trusted the steam gage, screwed down on the valve-spring nut and burst the boiler with over pressure.

While it matters little which of two pugilists has the heavier punch or can stand the more severe punishment, the lesson, by the result of the mental attitude of men at critical moments, is rich in the possibilities of its teachings.



Johnson knew and had the confidence that knowledge begets. Jeffries did not know. To him the result was a matter of doubt and he failed; not because of inferior physique and agility, but because doubt and fear lodged where only knowledge and confidence should rest.

Doubt and ignorance led the engineer to tamper with the safety valve when knowledge, and confidence in that knowledge, would have prevented a disastrous explosion which snuffed out more than a score of lives and destroyed thousands of dollars worth of property.

Knowledge is power, and the man who knows, knows that he knows, and his decisions are born of the confidence based on that knowledge.

To the engineer who knows his vocation and his plant, what it will do and what it will cost to operate it under the varying demands of the service, has no fear that the central-station wires will furnish the energy that makes the wheels go around in his plant.

It is the man who does not know who fears this competition and the one who will get the "wallop" in the first round, while he who knows and shows that he knows, will win "hands down" both as an engineer and as a man.

A Really Low-Pressure Turbine

By Henry F. Schmidt

A turbine designed to operate between an admission pressure of 2 1-2 pounds absolute and an exhaust pressure of 1 pound absolute. On a test this machine showed a Rankine efficiency of 52 per cent.

Much has been written about low-pressure turbines, that is, turbines taking steam at a pressure equal to or lower than that of the atmosphere, and also of the great increase in economy gained by the use of a high vacuum on high-pressure condensing turbines. Attempts have been made to show by diagrams that the amount of energy available in a pound of steam expanded from atmospheric pressure to a 29-inch vacuum is approximately equal to the energy available by expanding from a pressure

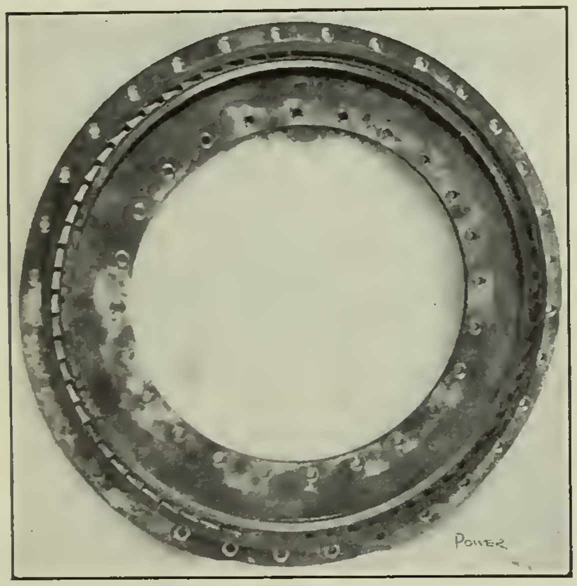


Fig. 1. Nozzle Block

of 150 pounds absolute to atmospheric pressure. Likewise, the statement has been made repeatedly that a large proportion of this available energy is lost in the low-pressure cylinder of a reciprocating engine because release occurs before complete expansion has taken place.

So far, however, it has been necessary to trust almost wholly to theory, and for the benefit of those who are not yet convinced of the soundness of the theory, some tests and details are presented of a turbine designed to develop 20 brake horsepower when supplied with steam at 2½ pounds absolute pressure and exhausting into a condenser maintaining a pressure of one pound absolute.

This turbine is of the impulse type, having all the energy available in the steam converted into kinetic form in the nozzles. There are two "velocity drops"; that is, the steam first traverses one row of moving blades and then enters reversing chambers where it is redirected into a second row of moving blades without a drop of pressure.

As shown in the view of the nozzle block, Fig. 1, the turbine is of the total-admission type; that is, it takes steam around the entire circumference. The steam after leaving the nozzles enters the inner row of blades of the rotating wheel, shown in Fig. 2, and after having passed through the inner row enters the inner row of passages of the reversing chamber shown in Fig. 3. The steam passes through the reversing chamber and leaves it at the outer openings, reëntering the rotor and passing through the outer row

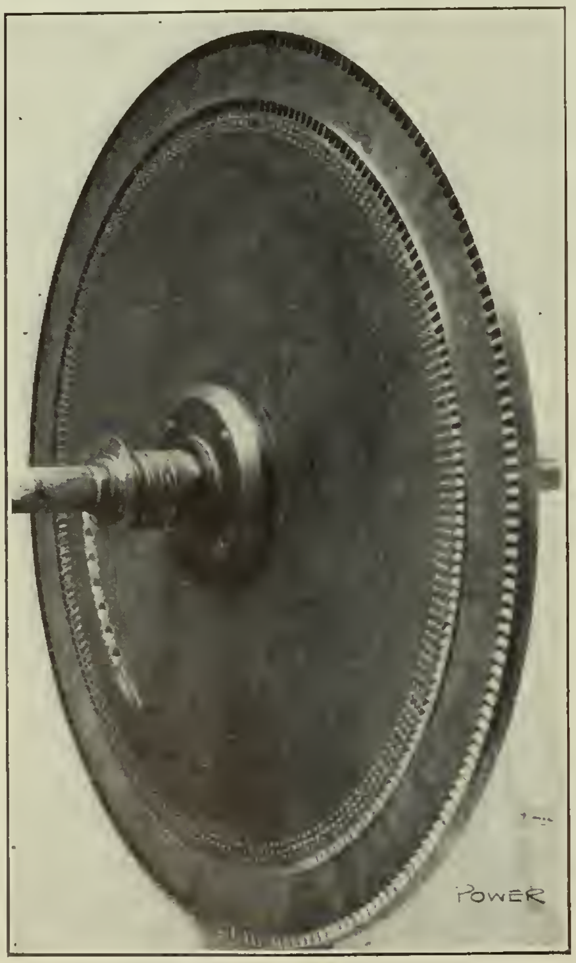

Fig. 2. Wheel Disk

of blades, after which it passes to the condenser. This path of the steam can be understood better by reference to the cross-section in Fig. 4, in which *A* is the steam inlet; *B* is the steam chest extending completely around the turbine; *C* is one of the nozzles; *D* the inner row of blades; *E* the reversing passage; *F* the outer row of blades and *G* the exhaust ports. Two exhaust ports were provided, as this was an experimental machine, and it was desired to note the effect of taking steam away at different points. The nozzle block, shown in Fig. 1, is represented by *H* in Fig. 4, and *I* is the reversing chamber, shown in Fig. 3.

Construction

The bearings are of the standard babbitted type with ring oilers, and the glands, to prevent the leakage of air into the cylinder, are of the snap-ring type and water sealed. Water guards *J J* are fitted to prevent any water escaping from the glands and getting into the oil.

Fig. 2 shows clearly the way in which the blades are attached to the disk. A groove is turned in the disk and the shank of the blades inserted, the latter being secured in place by three Stubb's steel pins driven in and riveted over. This has proved a very satisfactory fastening, and is easily made and very strong, as is shown by the fact that this turbine was run at blade speeds in excess of 600 feet per second without any ill effects, in spite of the fact that the blades are unusually heavy. Furthermore, the construction readily permits the replacement of blades which may become damaged, only a few minutes being required to replace a blade.

A point in design which may be criticized is the fact that the turbine is not split horizontally, which fact makes assembling difficult, as it requires uncoupling and drawing off the turbine half of the coupling before the rotor can be removed. The reason for employing this rather undesirable type of construction was because splitting the turbine along the horizontal joint would have involved a rather complicated construction to in-

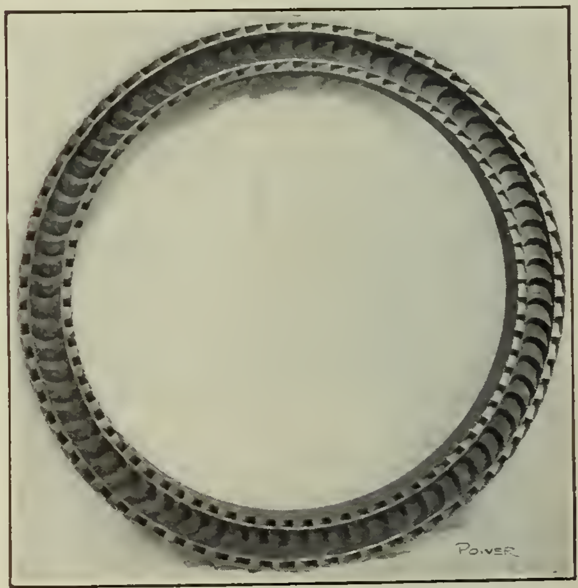

Fig. 3. Reversing Chamber

sure steam and air tightness—which, in this case, is of the utmost importance. It will be noted that there is but one joint which can leak air into the exhaust chamber, and as these surfaces are bored and turned, a tight joint was easily obtained.

The side clearances are approximately 1/16 inch and the radial clearances are very large. As a matter of fact, the longitudinal clearances are far greater than they should have been, as 10/1000 is ample clearance in a turbine of this capacity, and smaller clearances would have shown better economies than were obtained.

As there was no governor designed for this turbine, an automatic stop valve was fitted, which consisted of the usual overspeed tripping device and a 2-inch vacuum breaker, which, as the inlet pressure to the turbine was always below atmospheric pressure, would shut down the turbine before it could reach a dangerous speed.

The turbine glands were supplied with water from a barrel by the pump *G*, which delivered it to the pipe *E*. In order to maintain a constant water pressure in the glands, an overflow pipe *I* was fitted and drained any excess water back into the supply barrel.

As the glands were not perfectly tight, all the leakage to the outside was caught and returned to the barrel by the pipe *F*. By this arrangement no gland water was lost outside of the turbine, as all the water which was necessary to maintain the original level in the supply barrel must have passed into the condenser where it was weighed with the condensed steam and was, therefore, subtracted from the condensation. The supply barrel was fed from another barrel above it mounted on platform scales.

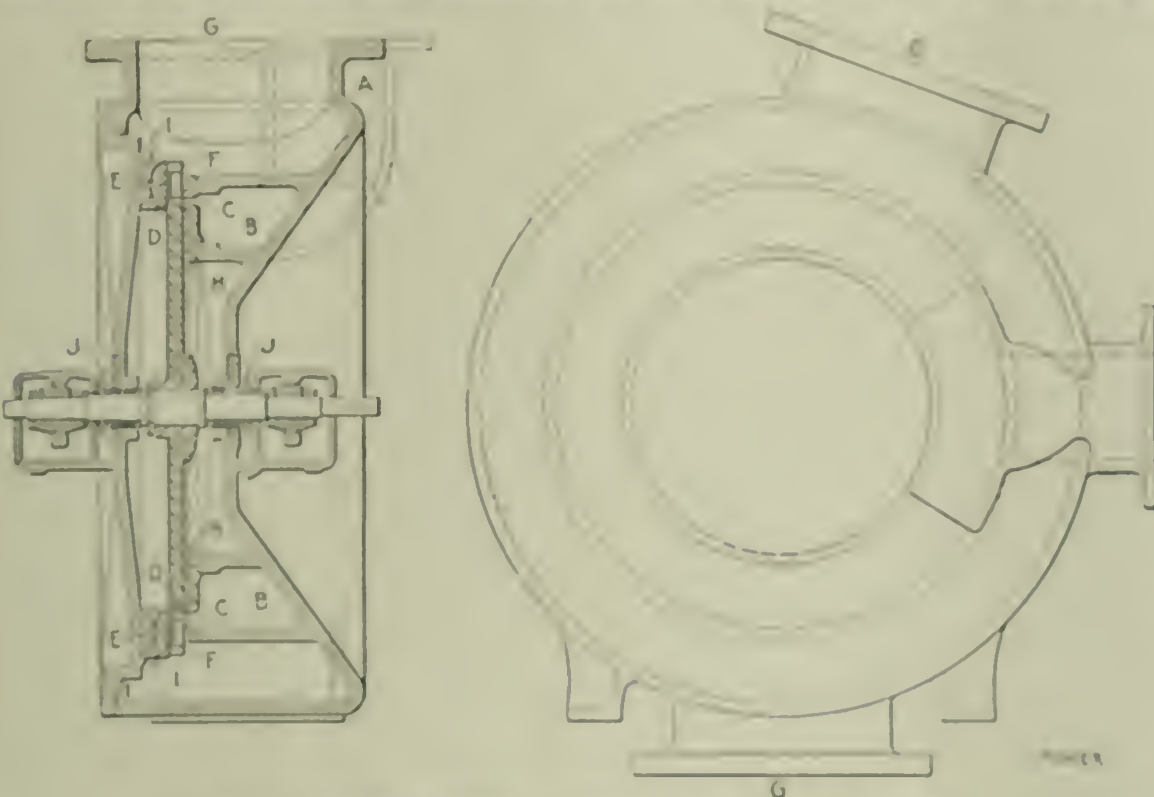

Fig. 4. Section through Turbine and End Elevation

Test Arrangements

As shown in Fig. 5, which represents the turbine ready for testing, the power developed was absorbed by a small water brake *D*. The load on the brake was measured on calibrated platform scales and water was supplied through the pipes *H H*, fitted with valves to control the brake resistance.

The inlet pressure was measured by the mercury column *B* and the steam temperature by means of the thermometer *C*, which was graduated to read to one-half a degree. The vacuum in the turbine exhaust was measured by the mercury column *A*, and the variation of speed between observations with a speed counter was observed by means of a tachometer. As it was necessary to throttle the steam supply from 150 pounds to a 25-inch vacuum, a water jet was fed into the steam line in front of the throttle to keep the steam saturated and prevent the superheating which the wiredrawing would otherwise have caused.

The steam was condensed in a surface condenser and the water weighed in tanks on platform scales, the weight being checked every five minutes.

Fig. 5. Turbine Ready for Testing

Results of Test

Although the turbine was designed to operate between 2½ pounds absolute and one pound absolute, the tests were carried over a considerable range, and the power developed varied from friction load to nearly 500 horsepower. One of the most astonishing results was the operation at friction load, 2250 revolutions per minute being attained with a pressure difference of ½ inch of mercury between the steam inlet and the exhaust, and 1400 revolutions per minute with a difference in pressure less than 1/10 inch of mercury, measured by a U-tube connected between the inlet and exhaust chambers. The latter was with nearly a 29-inch vacuum in the exhaust, but even at that low pressure 1/10 inch of mercury pressure difference theoretically gives up only about 4 B.t.u. per pound of steam, corresponding to a steam velocity of about 448 feet per second.

In Figs. 6 and 7 the horsepower, total water per hour and water rates have been plotted against the absolute inlet pressure. If all the test observations are correct, the curves of horsepower and total water per hour should be straight lines, as each varies as a straight-line function of the absolute inlet pressure. The closeness with which the actual test points fall upon a straight line shows the accuracy of these tests, as all the points shown are taken from the actual tests without any corrections of any sort whatever.

In Fig. 8 are shown the results with various inlet pressures up to 13 pounds absolute and with a vacuum of approximately 28½ inches referred to a 30-inch barometer. As will be noted from the water-rate curve, at 2½ pounds absolute the turbine consumed but 69 pounds of steam per brake horsepower, or 56 pounds less than the guarantee of 125 pounds per brake horsepower.

The curve marked "efficiency" is for the Rankine cycle, or the ratio of the brake horsepower developed to that theoretically available for the given inlet and exhaust pressures. Also the B.t.u. theoretically available has been plotted against the absolute inlet pressures.

The efficiency curve first rises and reaches a maximum at about the inlet pressure for which the turbine was designed, and then gradually decreases. The reason for the increase in efficiency at first is due to the friction load becoming a smaller proportion of the total power developed, and the decrease in efficiency beyond 3 pounds absolute is due to the fact that the nozzles were designed only for the pressure range of 2½ to 1 pound absolute, and have not sufficient divergence to efficiently handle the higher pressure ranges. This will be further observed from the tests shown in Fig. 7 with 26- and 27-inch vacuums. In these tests the point of maximum efficiency has shifted to higher inlet pressures, but occurs at approximately the same B.t.u. range as during the tests at 28¼-inch vacuum.

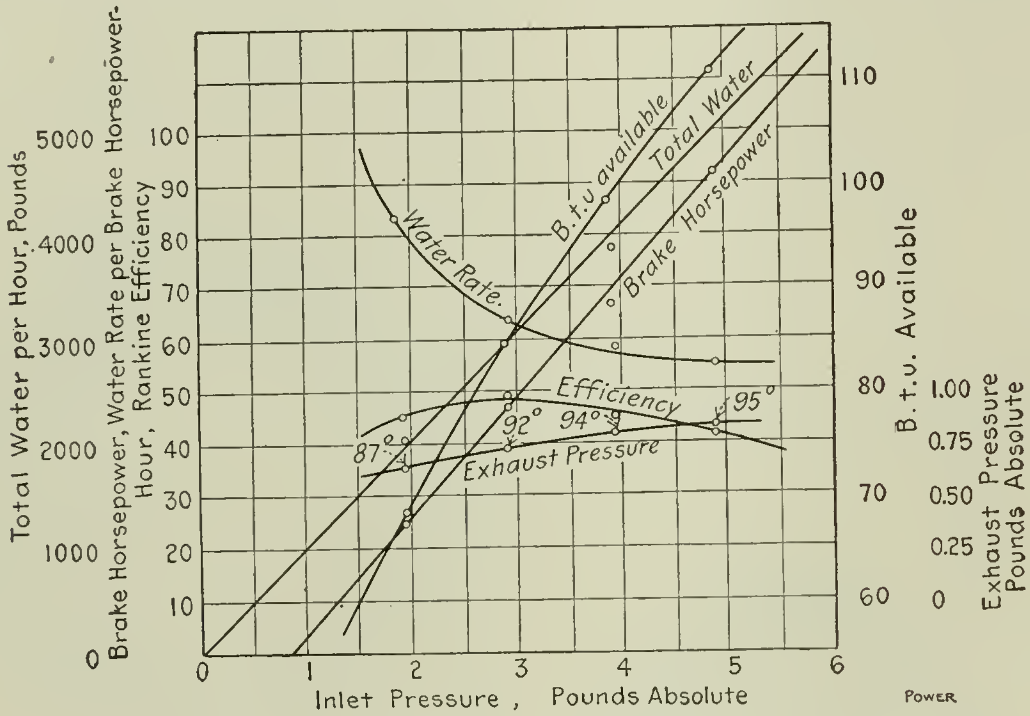

Fig. 6. Performance with High Vacuum

Conclusions

There are several points of interest shown by these tests which, though they have been known in a general way, have never before, to the writer's knowledge, been proved in the same conclusive manner as by the tests on this small turbine.

Looking at the test results the reader should not confine himself to the water rates per brake horsepower-hour, but should observe rather the Rankine efficiency, which, after all, is the only true criterion. Low water rates can easily be obtained even with a poor machine, if the operating conditions are made favorable. The actual measure of the value of a machine, however, is not its output but the proportion of the output to the maximum obtainable.

The maximum Rankine efficiency obtained was 52 per cent., and varied from this figure down to as low as 42 per cent. under extreme operating conditions. In tests on a number of high-pressure noncondensing turbines of exactly similar design and under varying conditions, the highest Rankine cycle efficiency ever obtained was 48 per cent. This shows that steam expanded at even the lowest pressures can be utilized in a steam turbine not only as efficiently but more efficiently than high-pressure steam.

However, the writer does not wish to be understood to have made the statement that in every case low-pressure steam is as efficient or nearly as efficient as steam at a moderate pressure, for there are conditions which arise where for practical purposes it is impossible to establish those necessary points in design to accomplish the best results. The tests do prove, however, that any degree of efficiency which can be obtained with high-pressure steam cannot only be duplicated with low-pressure steam but can be exceeded. Hence, it is only fair to say that while the turbine tested was not of a high efficiency, turbines of the Parsons or reaction type can be built, which over the same range would develop a Rankine efficiency of 75 per cent., or better.

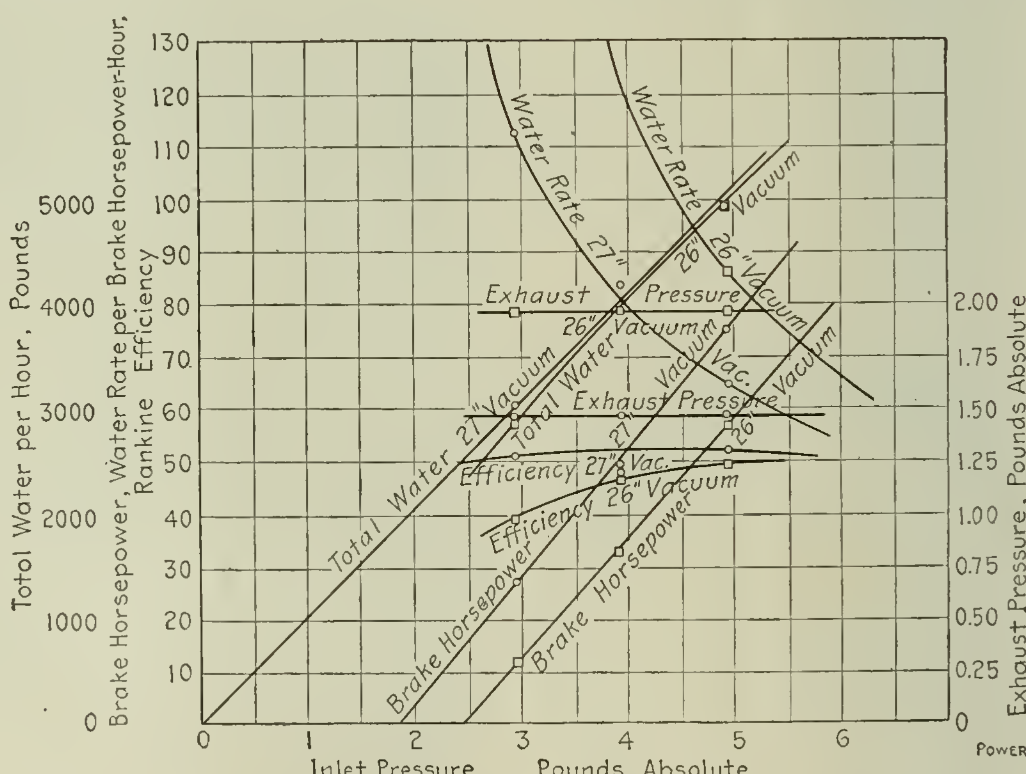

Fig. 7. Performance with 26- and 27-inch Vacuum

A Lentz Engine on the Pacific Coast

Due to the construction of an annex for the Hotel Alexandria, the leading hotel of Los Angeles, Cal., extensive additions are being made to the power plant thereof. The plant will contain six Stirling boilers of 1100 horsepower total rated capacity. Provision will be made for 700 additional boiler horsepower.

The present electrical generating equipment consists of one 150- and one 250-kilowatt Bullock dynamos, each driven by a Skinner compound automatic engine. To this will be added one 300-kilowatt Fort Wayne dynamo to be driven by a Lentz type poppet-valve engine built by the Erie City Iron Works. This is the first engine of its type to be installed in this country west of Chicago.

The refrigerating plant will remain unaltered. There are a Stevens compressor of 20 tons capacity, driven by an electric motor, and a Vulcan Iron Works compressor of 55 tons capacity, driven by a steam engine.

The hotel is equipped with hydraulic elevators which are operated by a 5,000,000-gallon Monarch pumping engine built by the H. N. Strait Company.

A complete description of this interesting plant will be published as soon as possible after the finishing touches have been made.

The Value of Flue Gas Analysis*

By Joseph W. Hays

How the fireman can be interested in the subject of combustion and flue-gas analysis without resorting to any chemical terms, whatever. The disadvantage of too much air is shown and hints are given as to taking samples.

Fuel is the largest single item of expense in almost every steam-power plant. The fuel is often purchased without reference to or a check upon its potential heat value, and is burned, almost invariably, with an utter disregard for economy. The fireman is provided with a shovel and allowed to have his own way with the coal pile. If he can throw coal straight enough for it to pass through the door and keep up steam, he is a good fellow. No attempt is made to instruct him. No check is kept upon him. He shovels coal in the same way that he is permitted to worship in this country, "according to the dictates of his conscience," and as a result wastes from 20 to 60 cents every time he puts a dollar's worth of coal in the furnace.

In order to insure the highest possible furnace efficiency it is necessary that the engineer or some other responsible person should first ascertain the correct method of furnace operation. No rules can be laid down that will apply to all plants except in a general way. Every plant and, to a certain extent, every boiler, is a problem in itself. The engineer, before he undertakes to instruct the fireman, must see to it that the boiler settings are tight and the dampers in order. He must learn what draft should be employed for the best results, how thick the fires should be carried and various other things of importance.

When the engineer knows his boiler furnaces and exactly how they should be managed to secure the best economy, the next step is to make sure that the fireman will follow instructions. This is where the real difficulty comes in, but the problem is an easy one if it is approached from the right direction.

The fireman should have explained to him what the engineer is striving to accomplish; he must be shown how the furnaces should be operated and what arrangements have been made to keep a check upon him. Say to him: "Do this and do that and you will get all of the steam possible out of every pound of fuel. If you do not operate the furnaces according to these instructions, we shall know it, and we intend to find out who the best firemen are in this boiler house."

The fireman will exert himself to secure results when he knows there is a continuous and reliable check upon him. His efforts will be redoubled when he discovers that he is in competition with every other operative in the furnace room; that it is a free-for-all race to discover who is the best man. This is only natural, and the man who says that he cannot handle firemen admits that he does not understand human nature. Place the thing upon the basis of a sporting proposition and the firemen will do the rest.

*From a paper read before the Ohio Society of Mechanical, Electrical and Steam Engineers, at Youngstown, Ohio, May 18, 1911.

The average engineer is frightened when the subject of engineering chemistry is suggested. He has never studied the science. He is too old and perhaps lacks the education necessary to tackle it. Chemistry is impossible so far as he is concerned; therefore, how can he expect to apply the science in his boiler house and reap some of the economics he has been reading about? The chemistry that the engineer ought to know, however, involves very little special knowledge. The most ordinary fireman can understand all that any practical man need know about it.

Suppose "Mike" is just an ordinary, everyday fireman; CO_2 could not be beaten into him in a thousand years, but he can be filled with chemistry without reference to a chemical formula. He is discovered in the act of throwing coal into the boiler furnace, and it will be noticed that he is careful to close the furnace door when he is through firing. Say to him: "'Mike,' why do you close the door when you are through throwing in the fuel? Why not leave it open? Why not take the door off and throw it on the scrap pile? Every time you close the door you have to open it again. This takes time and means work and might burn your fingers."

"Mike" is astonished and proceeds to deliver a lecture on economical furnace operation. He says: "Do you see that steam gage up there? Well, it is my business to keep the arrow pointing at 100 pounds. How long do you think I could hold steam if I left the fire door open? The cold air would rush in and cool off the boiler." Thus he gives, offhand, the greatest of all causes of fuel waste—excess air. When asked if it makes any difference where the excess air enters, he cannot see that it does, and his attention is called to a bare spot a foot and a half square over in the southwest corner. He is shown cracks in the fuel bed where the coal has coked and broken open in fissures. These bare places and cracks are letting fully as much air into the furnace as could possibly pass through the open fire door. Then the engineer in charge is called. He is asked if the boiler settings are tight and free from leaks. He is quite sure that they are. A candle is procured and it is found that the setting is leaking like a sieve; that there are a hundred openings big and little where the flame is drawn in. The suction at some of these holes is strong enough to snuff out the candle. The plates about the blowholes and clean-out doors are loose. In many places it is possible to insert the fingers. If it be a return-tubular boiler, a hole of several inches area may be found around the blowoff pipe, if it be a water-tube boiler, air leaks about the headers.

How much attention do the dampers get in the average plant? Is there any pretense whatever to any kind of damper regulation? There are steam boilers that are not equipped with dampers at all. Not one steam plant in five will shift its dampers a hair's breadth during the entire day's run. Not one steam plant in fifty is supplied with a proper draft gage. Not one plant in a hundred that has such a gage makes a proper use of it. Managers and owners are always complaining about the coal consumption. It is too high. They wonder where the trouble is located.

The boiler damper stands in the same relation to the furnace that the cutoff valve occupies to the engine. The one is intended to adjust the rate of coal consumption to the steam demands upon the boiler, the other to suit the rate of steam consumption to the power demands upon the engine. If steam is wasted at the engine, the money loss is not measured by the wasted steam but by the coal that was burned to generate this steam. It is a question of fuel loss, first, last and always.

In every properly designed power plant an excess of draft is provided for, in order that there may be sufficient coal-burning capacity to take care of all future loads and all probable increase in the power demands.

Excess air will do more to lower efficiency than any other known agent. Such excess should not exceed 40 per cent., but as the average plant is operated it is found in the neighborhood of 200 per cent. Enough air flows through the furnace of the average boiler to keep nearly three such boilers going under the conditions of good furnace practice. The preventable waste occasioned by such excess air is about 15 per cent. of the fuel.

When the air supply is insufficient, combustion will be incomplete and the waste due to this cause may run as high as 15 per cent. of the fuel. Most steam plants suffer from both excess air and incomplete combustion. The losses due to the first mentioned cause, however, are usually about 10 times those due to the latter.

When the draft pressure is increased the time allowed the air to work its way through the fuel bed and act upon the coal is decreased. Excess air accordingly finds its way into the furnace chamber. If the fuel bed is thin, the volume of such air excess is multiplied, and if there are cracks or "rat holes" in the fire there is another multiplication. When the draft is increased the suction is multiplied at every crack and fissure leading into the furnace and the gas passages of the boiler.

Increased draft usually means an increase in the temperature of the escaping gases. It also means an increase in the volume of the gases flowing up the chimney in a unit interval of time. When the gases are diluted and the dilution is followed by raising the temperature of the escaping mixture, there is employed the most effective method that has ever been discovered to increase the coal bills.

If coal is to be burned economically, the draft must be maintained in proper relation to the load and to the fuel in the furnace. If the dampers are manually operated, only an approximation can be expected of correct draft conditions, because, to have correct draft continuously, the damper must be kept continuously on the move in order to compensate for the several variables referred to.

There are a number of good damper regulators on the market, but there are also a great many poor ones, and a poor regulator may be worse than no machine at all. Automatic damper regulators may be divided into two classes for the purposes of this discussion: First, the machines that swing the damper from the wide-open position to the closed one when the pressure rises, and back again from the closed position to the wide-open one when the pressure falls; second, the machines that maintain the damper in such intermediate positions as the varying conditions of load may call for.

Machines of the first class may produce a perfect steam line on the gage chart, but they may and often do obtain uniform pressure at the expense of economy; whereas, machines of the second class will secure economy, and uniform pressure will follow in the wake of economy.

Regulators of the first class operate the dampers as follows: Assume the machine to be adjusted to hold the pressure at an even 100 pounds. The pressure rises slightly above this point and the machine immediately closes the damper and shuts off the draft. Combustion is interfered with because the furnace is now receiving insufficient air, and the pressure falls. This would be well enough were it not for the fact that insufficient air means incomplete combustion and a loss of 10,000 B.t.u. for every pound of carbon converted to CO. If, on the other hand, the pressure should fall below 100 pounds, the damper is thrown wide open. The furnace gets practically no air at all when the damper is closed and all the air that the chimney can pull through it when the damper is open. The machine provides the furnace one minute with a feast of air and the next minute with a famine.

Regulators of the second class keep the damper continuously on the move, shifting its position in one direction or the other with every little variation of steam pressure.

There is one particular in which practically all damper regulators fail, by reason of the fact that the machines, whether they come under the first or the second classification, are governed by the steam pressure. When the fireman opens the fire door, cold air enters, chilling the furnace and the boiler, and causing the pressure to fall. This blast of cold air reduces the furnace temperature, and the temperature drops all along the line between the furnace door and the top of the chimney. When the door is closed the temperature rises again rapidly. This means expansion and contraction, which is bad for both the boiler and the setting, causing cracks in the brickwork and leaks in the boiler. It also means a loss of fuel, because coal must be burned to restore the furnace again to its normal temperature.

When the furnace doors are opened the damper should be closed. Damper regulators usually do the wrong thing under such circumstances; they throw the damper wide open. They do this because they are governed by the steam pressure.

There are four ways in which the furnace and the fireman can waste coal:

1. A large portion of the heat energy generated may be nullified by excess air. Combustion may be complete to the last atom of the combustible, and yet, if the gases are cooled off as fast as manufactured they will be of little use to the boiler.

2. Combustion may be incomplete. In such cases a portion of the fuel passes up the furnace in an unconverted condition. Smoke usually accompanies incomplete combustion, but not necessarily and not always. There may be a great deal of smoke and very little combustible matter in the gases or there may be no smoke at all and a great deal of combustible.

3. Much fuel may be, and some fuel always is, lost with the ash and clinker. These losses are often the fault of the grate.

4. More or less heat will be radiated from the furnace and some loss of this kind is unavoidable. The only remedy is insulation so far as it can be applied to the furnace and boiler setting.

No one can look at a furnace and say exactly how near to or how far from the highest attainable economy it may be performing. With a flue-gas analysis instrument the efficiency of the furnace can at once be determined, and if coal is being wasted the cause of the loss is ascertained and steps may be taken to correct it. No other apparatus can be substituted for the gas-analysis instrument in this sort of an investigation, because nothing can be said about furnace efficiency until all is known about the quality of the escaping gases; it is these gases alone that can tell the percentage of excess air being heated and the proportion of combustible matter discarded to the chimney.

The gas-analysis instrument tells exactly what is taking place in the boiler furnace and with all of the certainty that the steam-engine indicator reports upon conditions inside the engine cylinder.

Anybody can understand and operate an engineer's gas-analysis instrument. Ordinary firemen can work it. No knowledge of chemistry, whatever, is required. Any man with sense enough to read a scale can make a perfectly correct analysis of the flue gases.

It may be explained to the fireman that the matter of cold air should be further investigated, and that here is a machine that tells all about it. It has a tube with a scale etched on it like a thermometer glass. The tube is filled with chimney gas until the water goes down to the zero mark. Then the gas is passed over into this other compartment which is filled with lye. The lye soaks up all of the coal gas and leaves nothing but air. When the soaking operation has been accomplished, the scale is read. It ought to register 14 or 15 per cent. coal gas and about 85 per cent. air. The more gas found, the less air heated, and *vice versa*. The fireman is interested; this is something he can understand, and in 15 minutes he is actually working the gas-analysis instrument like an expert. If any permanent and substantial benefit is to be derived from flue-gas analysis it is necessary that all of the firemen in the plant should be interested. Place a bonus on efficiency. This will bring the men into line if nothing else will. The results are most gratifying when the men know what the work means. It is important that the business of checking up the furnaces and the firemen should be made a part of the daily routine.

If the flue gases show around 14 per cent. CO_2 and no CO, the furnace and the firemen are doing all that can be expected of them. The percentage of CO_2 can be determined in one minute and the percentage of CO in five minutes. The percentage of CO_2 is a recognized measure of the volume of excess air.

The difference in economy between 14 and 10 per cent. CO_2 is around 5 per cent. of the fuel; between 14 and 5 per cent. CO_2, 23 per cent. of the fuel; and between 14 and 2 per cent. CO_2, 75 per cent. of the fuel. Furnaces have been worked with less than 2 per cent. CO_2.

The benefits that come from the use of gas-analysis apparatus in the boiler room are twofold:

1. The apparatus, as already stated, diagnoses the case of the boiler furnace for the engineer.

2. The apparatus keeps a check on the firemen and turns in a report at the end of the day on each one of them. If the CO_2 results are posted daily where the men can see them and a summary of the results at the end of the month, the firemen will do the rest and the fuel bills will go down as the percentages of CO_2 come up. The bonus system has been tried with good results in a number of large power plants. Pay the firemen a premium for high CO_2 averages. The company can afford to give the fireman an extra dollar when he is saving ten. It is in the nature of every man to be more attentive to business when he is under inspection.

There are hundreds of CO_2 recorders standing unused in the dark corners of power plants. The trouble was not with the machines but with the people who bought them and the others who sold them. It is one thing to possess a recorder; it is another thing to make proper use of the apparatus after its purchase.

In a large power plant equipped with four CO_2 recorders, the machines were registering from 4 to 6 per cent. of CO_2. The manager complained that there was nothing to be gained from using flue-gas analyzers; that his coal bills were just as heavy as they were before the recorders were installed. He produced a pile of charts and there was not a decent one among them. It was then pointed out to him that the business of a CO_2 recorder is to report conditions as they are and not as they ought to be. Every one of the charts was a protest against a preventable waste of nearly 25 per cent. of the fuel. Upon investigating the conditions it was discovered that the hoppers of some of the chain-grate stokers were running half empty. The fires were running short under all of the boilers. The settings were all in need of repairs. The cracks were so large in some places that the flames could be seen playing in the first passes of the boilers. The load could have easily been carried on two-thirds of the boilers and two-thirds of the coal.

It is one thing to attain high efficiency; it is another thing to maintain it. There is no apparatus that can compete with a good hand analysis set in searching out trouble and building up furnace efficiency. There is no instrument more efficient than a CO_2 recorder in maintaining efficiency after it has been attained.

In order to measure air leakage, gas must be simultaneously sampled from two places, the first pass of the boiler and the breeching. The leakage may be computed from the difference of the CO_2 content of the gases at these two places. The recording apparatus can only work at one place at a time. It is not practical, furthermore, to connect the recorder at any place but the uptake or breeching. Questions of temperature and mixture enter the problem when a permanent sampling tube is inserted into the gas passages of the boiler.

In checking up a boiler furnace it is necessary to identify each gas sample analyzed with observed furnace conditions. If the CO_2 is low there is a reason for it and the cause must be found. For example, a crack or a "rat hole" is noted in the fuel. To what extent is the air leak responsible? The engineer wants to know, and he wishes to give the fireman an object lesson. It takes one minute to get a sample of gas into the hand instrument and determine the percentage of CO_2. The volume of excess air flowing through this leak is measured. It is surprising to note the quantity of nullifying cold air for which the leak is responsible. The effect of covering the air leak is shown by the analysis. The fireman will be impressed and he will watch for these leaks in the future.

A patent has just been issued to Rosendo Ladron de Guevara, of Vera Cruz, Mex., for a boiler disincrustating compound consisting of 100 parts calcium oxide, 20 parts of pulverized baked clay, 15 parts of refined petroleum, 35 parts of the juice of agave leaves, one part of carbolic acid, two parts hydrochloric acid.

A Pair of Old Engines

By A. Heaton

The installation of a central power plant with electric transmission of power to the different buildings of the old plant of the Wheeler & Wilson Manufacturing Company at Bridgeport, Conn. (now the Singer Manufacturing Company's plant No. 10), has put a number of engines out of commission which have done good service in the past. The illustration shows the pair which drove the main machine shop, and which have just completed a run of 44 years and 3 months without being shut down during working hours to exceed a total of one and a half hours during the whole period.

They were built by the Pacific Iron Works, and had a fixed cutoff and throttling governor, but in 1882 the right-hand one was fitted with the Heaton automatic cutoff, which was illustrated in the September, 1880, issue of Power.

Engines after 44 Years of Service

The series of comparative cards shown in Houghtaling's book on "The Indicator and Its Appliances," which illustrates the difference in water consumption between automatic and throttling engines at the same load, was taken from this pair.

Both the speed of the engines and the boiler pressure have been increased twice during their term of service in order to meet the increasing demands for power, and, although laid off for the summer, they are still rated A 1 and are ready to be put into service in an emergency.

It is estimated that 250,000 electric flat irons were sold in the United States and Canada last year. There are more than 10,000,000 homes within central-station territory, of which fewer than 2,000,000 have electric service; consequently the estimated sales last year approximated one iron to every eight houses.

Flow of Water in Clean Iron Pipes

By Albert E. Guy

Concluding article of a series upon the development and use of the "alinement chart" as applied to the flow of water in pipes. The present chart gives the horsepowers equivalent to various quantities of water at different heads.

In the preceding articles of this series an attempt was made to show the resemblance between operations on a slide rule and those performed on a three-line diagram. The problems used as examples were rather crudely worked out, and the reader may conclude, after perusing the present article, that the order has been unduly reversed; that is, the theory should have been expounded first and followed by the examples. However, as the practical man is inclined to make light of "so called theory," it was deemed best to adopt the method used. With this as a basis the formulas may now be put into a more concise form, and their derivations explained.

In its simplest form the slide rule consists of two duplicate scales capable of being slid past one another. On each a given number is represented by its logarithmic length measured from the origin of the scale, marked "1," to the division representing the number. To multiply a number A by a number B, to the length $1 - A$ on one scale is added the length $1 - B$ on the other scale; the sum is read directly on the first scale, but the graduation of this scale is such that the reading recorded is exactly $A \times B$. Division is accomplished by subtracting one length from another.

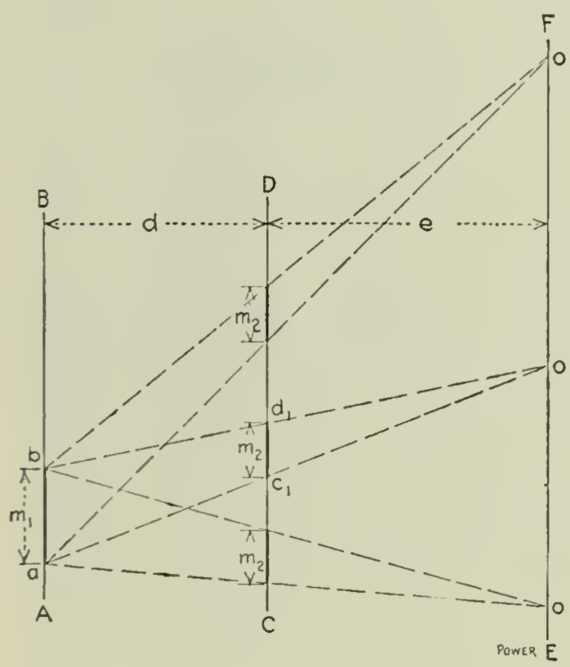

Fig. 7

Likewise, with three-line diagrams, multiplication or division is effected by the addition or subtraction of logarithmic lengths of numbers, but with these differences:

The number A is read on one scale, B on another, and the result C on a third scale. On the slide rule the logarithmic length of one number is the same on each scale, whereas on the diagram this length may be different on each of the scales. In short, a three-line diagram may be considered as composed of three specially constructed "slide-rule scales" properly spaced and set so that, by means of a straight-line index, an equation of the form

$$A x B y = C^z$$

may be solved at one reading.

In addition and subtraction, the quantities added or subtracted must be of the same kind. To satisfy this requirement, the scales of the diagram must be so located that the index, placed in any given position, will automatically reduce the large scale and increase the smaller, so that, as measured on the third scale, the logarithmic length spaced off on each will be that of the same number.

The scales $A B$, $C D$ and $E F$, Fig. 7, are parallel and fixed, and no matter how the triangle $a b o$ is placed, provided its base ($a b = m_1$) remains on the scale $A B$, and its vertex o on $E F$, the intercept ($c_1 d_1 = m_2$) will always be on scale $C D$ and its length will remain constant. The ratio $\frac{m_1}{m_2}$ is a constant and

$$\frac{m_1}{m_2} = \frac{d + e}{e}$$

In Fig. 8, the logarithmic length of the number 10 is m_1 for scale $A B$, m_2 for $C D$, and m_3 for $E F$. This length is called the *modulus*. It takes one modulus for the number 10, two moduli for 100, three for 1000, four for 10,000, and so on.

By joining point A to the point representing 10 on $E F$, and E to that representing 10 on $A B$, the two lines intersect precisely on the point representing 10 on $C D$. From this the relation between the three moduli can be obtained.

As in Fig. 7,

$$\frac{m_1}{m_2} = \frac{d + e}{e}, \text{ and } \frac{m_3}{m_2} = \frac{d + e}{d}, \frac{m_1}{m_3} = \frac{d}{e}$$

Whence,

$$d = e \frac{m_1}{m_3}$$

and

$$e = (d + e) \frac{m_2}{m_1} = \left(e \frac{m_1}{m_3} + e\right) \frac{m_2}{m_1} = e\, m_2 \left(\frac{1}{m_3} + \frac{1}{m_1}\right)$$

and

$$\frac{1}{m_1} + \frac{1}{m_3} = \frac{1}{m_2} \qquad (16)$$

From this

$$m_1 = \frac{m_2 m_3}{m_3 - m_2}$$

$$m_2 = \frac{m_1 m_3}{m_1 + m_3} \qquad (17)$$

$$m_3 = \frac{m_1 m_2}{m_1 - m_2}$$

The position of the scale is determined by equation

$$\frac{d}{e} = \frac{m_1}{m_3}$$

With these formulas the problem is entirely solved.

To test the correctness of the diagram thus established, join point 100 on $A B$ to point 10 on $E F$; also, 10 on $A B$ to 1000 on $E F$; the corresponding readings on $C D$ will be respectively

$1000 = 100 \times 10$ and $10{,}000 = 10 \times 1000$

From this it may be inferred that the product of any number on $A B$ by any number on $E F$ will be read on $C D$ with the degree of accuracy aimed at when the diagram was established.

As explained in the preceding articles, the products just obtained are the logarithmic sums as read on $C D$ of the parts spaced off on the other scales. Thus,

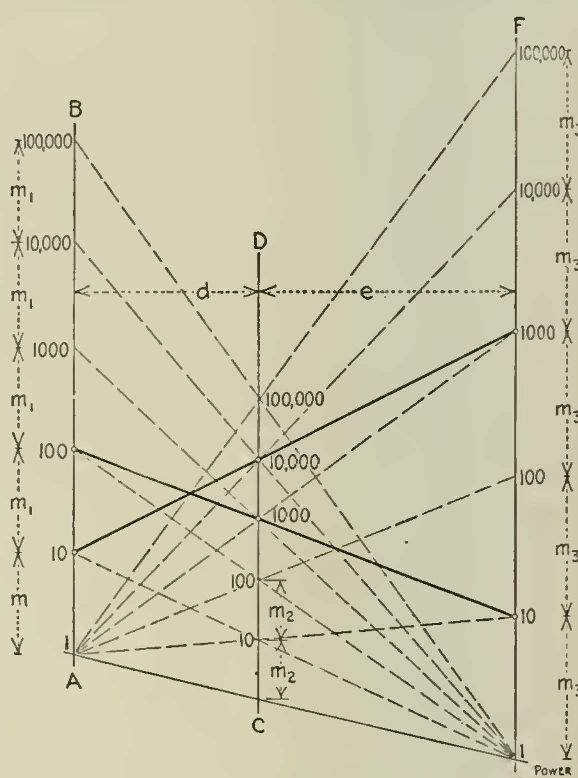

Fig. 8

$1000 = 2\, m_1$ (on $A B$) $+ m_3$ (on $E F$) $= 2\, m_2 + m_2$ (on $C D$)

and

$10{,}000 = m_1$ (on $A B$) $+ 3\, m_3$ (on $E F$) $= m_2 + 3\, m_2$ (on $C D$)

Usually the datum line $A E$ does not appear in a finished diagram.

The graduations of the scales will depend upon the equation represented and may be different from those of Fig. 8; for example, let the equation be

$$G = P^2 R^3$$

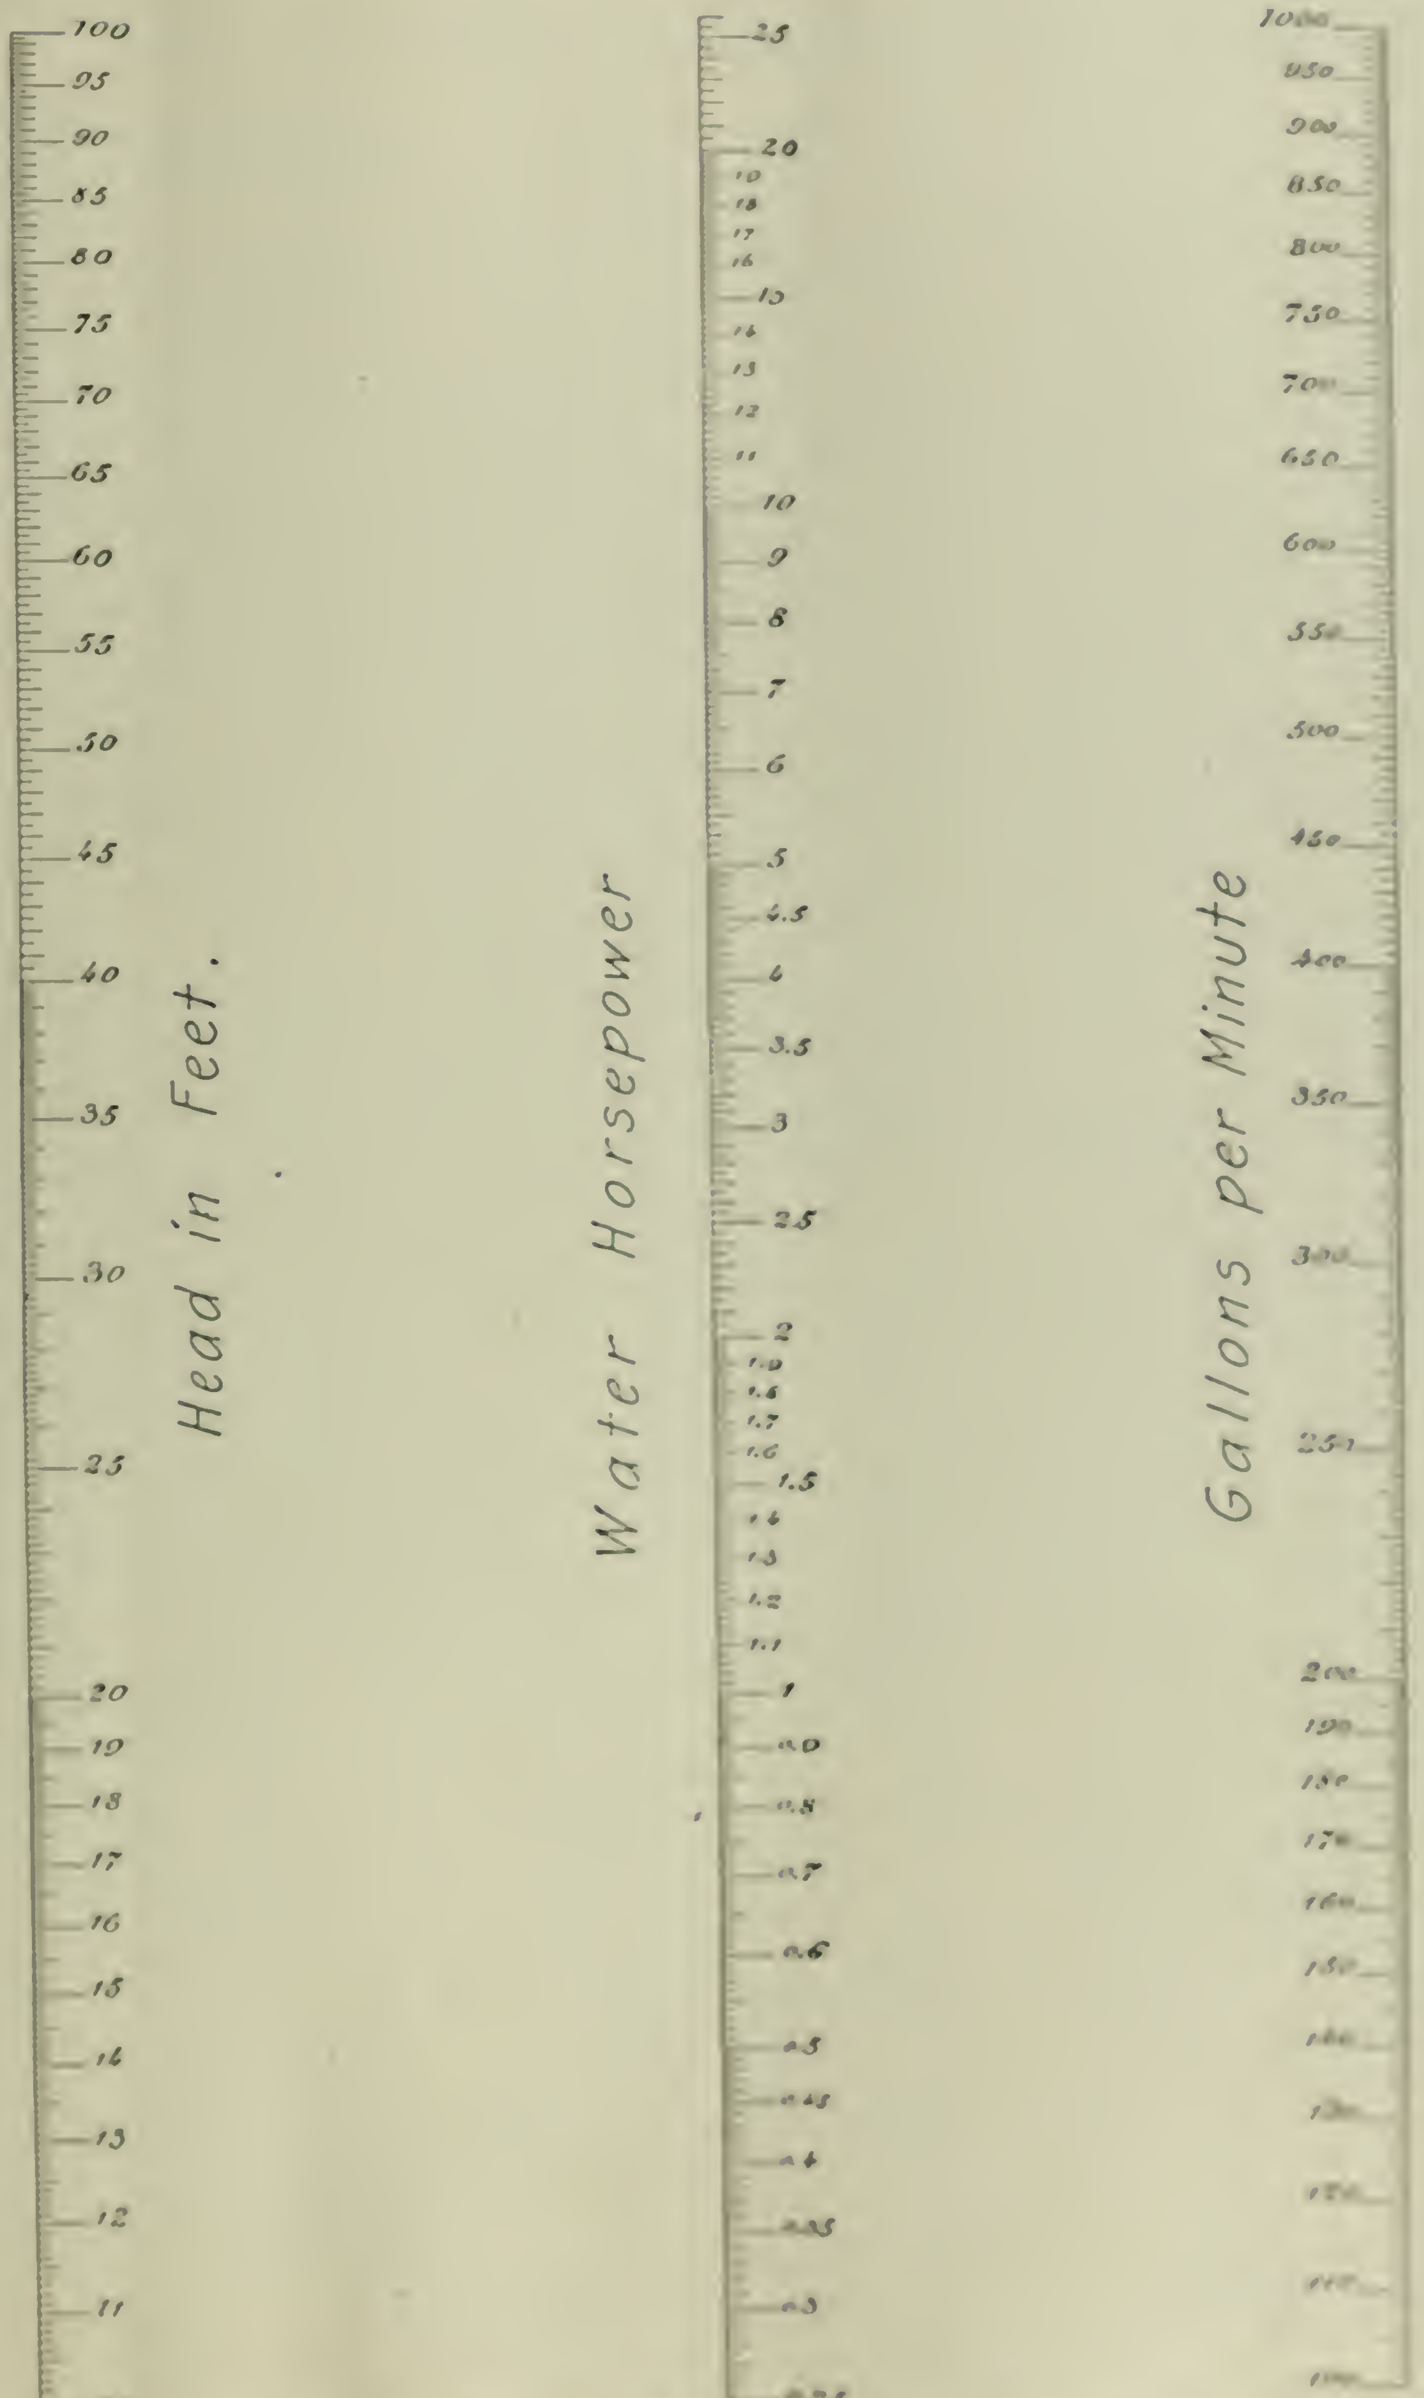

CHART NO. 3

If any two of the factors represented by the scales are known, the third may be found by drawing a straight line through their positions on their respective scales. The line will intersect the third scale at the number representing the desired factor.

the value P being read on $A B$, R on $E F$ and G on $C D$. Selecting, for example, a value of the equation where P equals 12 and R equals 8,

$$G = \overline{12}^2 \times \overline{8}^3 = 144 \times 512$$

In order to find the value of G it would be necessary to join point 144 on $A B$ to point 512 on $E F$ by a straight line cutting $C D$ precisely at G. But these numbers, 144 and 512, are not at hand, and it is precisely for the purpose of saving the trouble of figuring them and the more difficult task of reading them accurately on the scale that the whole diagram is established. Hence, the scale of R should be made with a modulus M_3, such that when a number as R (= 10) is used, although this point on the scale would read only 10, it would correspond to a value of $\overline{10}^3$ or 1000. And, although it might be stated that the modulus of R is M_3, this being equivalent to the logarithmic length of the number 10, at the same time it would be well understood to equal three times the length of m_3, because on scale $E F$, 1000 equals $3\,m_3$. Likewise, the modulus of P, on $A B$, would be M_1 (equal to $2\,m_1$) because on $A B$ when P equals 10 or M_1; in reality it represents

$$P^2 = \overline{10}^2 = 2\,m_1$$

The general form of the equation solved with a three-line diagram being

$$A^x \quad B^y \quad = \quad C^z$$

and adopting m as the modulus or logarithmic length of the number 10, this equation, treated by logarithms, becomes:

$$x \text{ log. } A + y \text{ log. } B = z \text{ log. } C$$

and

$$x\,A\,m_1 + y\,B\,m_3 = z\,C\,m_2$$

If the scales are to express the true value of each function, such as A^x, although simply marked A, the moduli adopted for the three functions may be M_1 for A^x, M_2 for C^z, M_3 for B^y, and the general equation will be:

$$[A^x B^y = C^z] = [x A\,m_1 + y B\,m_3 = z C\,m_2] = [A\,M_1 + B\,M_3 = C\,M_2]$$

If this reasoning be applied to the calculation of Chart No. 2, shown in the preceding article, the ease with which the necessary elements can be established, as compared with the somewhat laborious process followed before, will be at once apparent.

Neglecting the constant, the equation in connection with this chart was

$$Q = D^2\,V$$

Q being on the first scale, V on the third, and D^2 on the second. The equation may be written

$$Q\,M_1 = D\,M_2 + V\,M_3$$

It was found convenient to use the moduli $M_1 = 83\frac{1}{3}$ millimeters, and $M_3 = 125$ millimeters, with $d + e = 170$ millimeters.

Applying equation (17)

$$\left(m_2 = \frac{m_1\,m_3}{m_1 + m_3}\right)$$

$$\frac{M_2}{2} = m_2 = \frac{M_1\,M_3}{M_1 + M_3} = \frac{83\frac{1}{3} \times 125}{83\frac{1}{3} + 125} = 50$$

whence,

$$M_2 = 50 \times 2 = 100 \textit{ millimeters}$$

Then,

$$\frac{d}{e} = \frac{M_1}{M_3} = \frac{83\frac{1}{3}}{125} = \frac{2}{3}$$

$$d = \tfrac{2}{3}\,e,\quad d + e = \tfrac{2}{3}\,e + e = \tfrac{5}{3}\,e = 170$$

$$e = \frac{170 \times 3}{5} = 102 \textit{ millimeters}$$

$$d = 170 - 102 = 68 \textit{ millimeters}$$

The location of the constant depends upon the conditions of the problem, and also upon the most preferred arrangement of the scales on the diagram. When, as in Chart No. 2, the constant is introduced on the second scale, either of two ways may be followed. At the intersection D^2 on $C D$ of a straight line joining two points Q and V, selected on $A B$ and $E F$, the value of the constant, expressed with a logarithmic length of modulus m_2, is spaced off on $C D$, either above or below D^2, as the case may be, and the scale is then laid out with D^2 located at the point just found. Or, the equation may be solved with the constant, as has been done, for a given value of Q and D^2, thus obtaining the corresponding true value of V. A straight line joining these Q and V intersects $C D$ at the exact location of D^2, and the scale of the diameters (D) is laid out as in the first instance.

Horsepower Chart

When a quantity of water Q weighing W pounds is raised through a hight H feet, the power expended, independent of frictional losses, is

$$W \times H \textit{ foot-pounds}$$

The quantity is expressed in cubic feet or in gallons. In matters concerning waterworks or pumping installations, Q is expressed in gallons per minute (g.p.m.), in million gallons per 24 hours or in cubic feet per second. The engineer usually deals with gallons per minute; hence, when estimating, the other values are transposed into gallons per minute.

One United States gallon is equal to 231 cubic inches or 7.4805 cubic feet. One cubic foot per second equals

$$7.48 \times 60 = 448.8 \textit{ g.p.m.}$$

or, with sufficiently close approximation, 450 gallons per minute may be used. One million gallons per 24 hours equals

$$\frac{1{,}000{,}000}{24 \times 60} = 694.445$$

approximately 700 gallons per minute.

It is usual in calculations to assume the weight of one cubic foot of clear water at 62 degrees Fahrenheit to be 62.355 pounds.

The water horsepower (w.hp.) corresponding to $Q \times H$ foot-pounds of work done is:

$$\frac{G.p.m. \times H \times 231 \times 62.355}{1728 \times 33{,}000} = \frac{G.p.m. \times H}{3958.9}$$

With the constant in round figures, this becomes:

$$\textit{Water horsepower} = \frac{G.p.m. \times head}{3960} \qquad (18)$$

The hight H is usually termed the head. When the water is discharged against a pressure of P pounds per square inch, the corresponding head is

$$P \times 2.309$$

Equation (18) transformed, becomes:

$$\text{log. } (w.hp.) = \text{log. } (G.p.m.) + \text{log. } (Head) - \text{log. } 3960$$

After a few trials it is found most convenient to put the head on scale $A B$ with M_1 equal to 250 millimeters, $G.p.m.$ on $E F$ with the modulus M_3 equal to 250 millimeters, and the $w.h.p.$ on $C D$ with a modulus M_2.

Equation (17) gives

$$M_2 = \frac{M_1\,M_3}{M_1 + M_3} = \frac{250 \times 250}{250 + 250} = 125 \textit{ millimeters}$$

$d + e$ is selected equal to 143 millimeters; hence, since

$$\frac{d}{e} = \frac{M_1}{M_3} = 1$$

$$d = e = \frac{143}{2} = 71.5 \textit{ millimeters}$$

The first and third scales are each laid out with a 10-inch slide-rule scale 250 millimeters long; then, after solving equation (18) for one set of values of $G.p.m.$ and of H, a line is drawn joining these two points on the $A B$ and $E F$ scales, and intersecting $C D$ at the precise corresponding value of the horsepower. The $w.hp.$ scale is then drawn with a 10-inch slide-rule scale of squares, 125 millimeters long, the number on the scale coinciding exactly with the number at the point just determined on $C D$.

This chart is made to read directly on $C D$ the water horsepower corresponding to a head ranging from 10 to 100 feet, with a quantity varying from 100 to 1000 gallons per minute. Should the head dealt with be greater than 100 feet, say 265 feet, for example, while the gallons per minute are between 100 and 1000, then the water horsepower corresponding to 26.5 feet should be read on the middle scale, and this reading multiplied by 10 would be the required horsepower.

For a quantity greater than 1000 gallons per minute, say 7550, the water horsepower corresponding to 755 gallons per minute would be read on the middle scale, and the reading multiplied by 10 would again give the water horsepower required.

The process would be the same for heads and quantities simultaneously greater than the scale limits; thus for 265 feet and 7550 gallons per minute, the reading obtained would be that corresponding to

$$\frac{26.5 \times 755}{3960}$$

and that, multiplied by

$$(10 \times 10) = 100$$

would be the required water horsepower.

How Mat Made Good and Then Lost

By Luke Marier

By hard work and diligent application to his studies Mat worked himself up from fireman to chief engineer with a first-class license. With his ambition satisfied Mat became careless and drifted back to a miserable failure more rapidly than he had risen.

Let me assert that if I ever read an interesting bit of literature it certainly was the editorial which appeared on the first page of POWER for March 28. It is real, true and practical—and the admonitions it contains should unquestionably actuate the average engineer who, through long years of trudging in the same old habits, has forgotten himself and laid his studies aside long ago; that is, if he studied at all.

It would be well for all of us to read that same editorial again and thoroughly absorb its wholesome advice.

Health is quoted as being a valuable asset, for an engineer. The following is the story of two engineers; it illustrates what an important part health plays in a man's career.

Matthew Ella was the son of a very poor couple, totally ignorant of the English language and just emigrated from Canada. He was full of ambition and energy; and possessed a bulldog determination to succeed.

Shortly after he arrived in a certain New England city, he secured a small job as carpenter's helper. Soon after this he made the acquaintance of the night fireman of the F. R. B. Company, and came regularly to spend his evenings in the plant with his friend, cleaning out furnaces, etc.

The steam-engineering field seemed alluring to this young man, and he got all the pointers he could on boilers and auxiliaries from his new friend. He also got well posted on questions which might be encountered during an examination. Invariably he would remain and work strenuously until midnight, in spite of the fact that his regular work during the day was most tiring.

After a couple of months—worn and pale as a ghost—he applied for a first-class fireman's license and got it. Immediately he took charge of a fireroom in a large cotton mill where there were 10 horizontal tubular boilers. But after a week he was compelled to descend to coal wheeling because of his inability to "make good." This did not discourage him, but instead, made him realize he needed experience.

Three months elapsed before he made any headway. This time, he accepted the "dignified" position of oiler in the L—— L—— mills, and "made good." He remained in this position for about 18 months. During this time he got somewhat entangled in things matrimonial and presently "tied the fatal knot."

About this time he was offered another position for more money and he accepted without a question. All the while, Mat studied incessantly on a well known correspondence-school course and acquired an ever-increasing degree of proficiency in the English tongue. He also studied with a private instructor who gave him many "good pointers" or "jewels" as they were called. These "jewels" played a mighty important part when at length he was examined for a first-class engineer's license, which he secured.

Next, Mat became assistant engineer in the M—— mills, where he made himself valuable in many ways. He operated one plant while the chief made his headquarters at the other plant across the road, perhaps five minutes' walk away.

It was on a Thursday morning that the chief came to see Mat's "big license." Mat, anxious to show the chief his beloved "ticket," pulled it from his pocket with alacrity and handed it over with a smile. The chief examined it with a frown and a look of displeasure. "What is this good for anyway?" demanded the chief. "Will this help to run the plant any better or any more economically?"

"Well, this surely will mean, at the very least, $2 more in my pay envelop," replied Mat, whose smile had instantly changed into a frown like the chief's. "And if I can't get the increase here I can get it somewhere else," he added.

This sort of talk naturally aroused the chief and enmity was created. Mat began to keep an eye open for a vacancy somewhere.

Presently the job at the L—— L—— mills was open and as Mat was familiar with the plant there, he immediately applied for the position and was fortunate enough to get it. He was placed in full charge at a salary of $22 a week, the largest sum he had ever seen in his envelop up to this time.

This plant was located some two miles from his home, which distance he cheerfully plodded morning and night. This was indeed healthful for him, he was pale no longer, but instead, had the color in his cheeks which he had totally lost during the five years of hardship. He steadily increased in weight and eventually this plodding got to be commonplace. He began to feel considerable dignity and soon required a larger-sized hat and perhaps the removal of a few buttons from the upper part of his vest to allow for chest expansion.

All this led him to the purchase of a horse and buggy. He had reached the goal of his ambition and was in a mood now "to take things easy." He grew indifferent from doing so little and let things about run themselves.

His mind became centered on "money making." Most every night would see him make the rounds of his acquaintances in an endeavor to sell them jewelry, in which there was a handsome profit, some 50 per cent. to be realized on every sale. This formed a sort of side business, which proved to be quite remunerative. He once told me that he never sent less than $30 to the bank every week. Shrewd and saving he certainly was.

However, this business did not adjust his engines nor repair his boilers, which soon got in need a general overhauling. The fires of ambition and interest were dying out. He said to me one day that he was not paid for what he did but, rather, for what he knew. This was simply idiotic!

Everything had been very well adjusted and as "clean as a whistle" when the plant was turned over to him and this had enabled him to "take it easy." And, so he did—but his stomach did not, especially from the time he purchased the horse and buggy. It became mighty difficult to digest, say, a good heavy bit of fried steak or a generous portion of clam chowder, especially if it was half cooked and prepared in a hackneyed fashion. After a feast on such things he would doze for the rest of the afternoon in his arm chair. Imagine what beautiful unprintable language his stomach would have uttered had it been able to speak!

Johnny B—— often advised him to exercise but such advice was simply futile—he was too arrogant ever to take heed. He often told me that he had worked and studied so extremely hard to obtain his license that now he intended to rest, as he did. He was [illegible] since he took charge of this plant studying was simply repugnant to him, and he read but one steam technical magazine.

Months slipped away, and so did the pink in poor Mat's cheeks. He got to be indifferent from doing so little and repairs were utterly neglected. A deplorable condition of affairs must come to exist.

One afternoon while visiting his plant, my attention was attracted by the unusual thudding of the eccentric on the tandem-compound Corliss engine. I observed that the eccentric strap held by merely the top bolts, the bottom bolts had fallen into the oil tray below. Further observation showed that cylinders were cutting; boilers were in need of resetting; the other engines needed as thorough an overhauling as did the Corliss; the condensing system was in very poor condition; in a word, everything was on the verge of complete dilapidation.

Finally, after being in charge for 22 months, Mat took sick and two weeks after died. Poor fellow, but perhaps this was as fortunate for him as to be suddenly destroyed by a bursting cylinder head. His headquarters were directly abreast of the high-pressure cylinder of the tandem-compound Corliss engine, one of the eccentric straps of which held only by the top bolts.

Mat had often boasted that it would be quite a difficult matter for the company to find a stranger to run his plant successfully should he ever leave, since this plant was so differently constructed than any other he had seen.

"My dear friend," I said, smilingly, "should you leave this job this very minute, there would be a dozen capable applicants ready to fill it in half an hour."

He smiled and could not believe it.

At any rate, this is just the condition of affairs which existed when he died. Some ten or fifteen good, capable men applied. The one who was selected was a brilliant sort of fellow, level-headed, well read—a gentleman, one you may meet in every hundred engineers, one who attends strictly to business. This man was an engineer worthy of the name; always on the alert, always attending to even the most trivial things with care and precision; he was a master. He remained in charge for some 18 months, during which time he overhauled everything from sump pit to chimney top. The finest thing about this *gentleman* was that his head always remained at its normal size.

When finally he moved up another rung, he accepted a job as chief engineer in New Bedford, Mass., for some $15 a week more than he was receiving at this place.

Vapor Heating Systems*

By Thomas G. Mouat

About twenty-six years ago a journeyman steamfitter remarked to the writer that vapor was the coming heat. Upon being asked what he meant by the term "vapor," he replied that it was steam slightly above atmospheric pressure. In those days it was deemed necessary to carry from 1 to 10 pounds of steam pressure in order to heat a building successfully with the ordinary gravity low-pressure system without the means of producing a partial vacuum; and most boiler manufacturers still set the pop valves to blow at 15 pounds.

This steamfitter's prophesy has been realized, and, although it is a long step from 10 pounds to 2 ounces pressure, it has been practically demonstrated that a building can be heated in the coldest weather with from 2 to 3 ounces pressure, and the term "vapor heat" is now applied to a steam-heating system which operates under this very low pressure.

The main object of vapor heating is to provide for a system that will operate with just a little heat turned on each radiator, enough heat to be comfortable without overheating in moderate weather and plenty of heat for the coldest days, by simply opening the supply valves a little further. Several attempts were made from time to time to perfect a system, which would permit the partial heating of the radiators, but in each case they met with failure, due to the inability to control the pressure with the ordinary diaphragm damper regulator and devices of this character, where the steam pressure was directly applied to do the work. It was not until the direct application of steam in connection with a diaphragm was dropped, and the agency of water plus the steam pressure was employed that a system permitting positive and practical graduation was perfected. The graduated admission of steam to each radiator may now be accomplished in a properly constructed vapor system by the use of a sensitive pressure and damper regulator attached to the boiler with fractional valves and special return fittings on the radiators, and an opening in the return pipe near the boiler to permit the escape of air. No air vents are used on the radiators.

The regulator must be so constructed that it will open or close with the variation of an ounce of pressure. This result has been obtained by a regulator operated according to the principle of a hydraulic balance, water being forced out of a stationary tank into a movable tank placed at the end of a lever which causes the movable tank to tilt downward and close the dampers. When the pressure has dropped an ounce, part of the water leaves the movable tank and returns to the stationary tank; the former is then tilted upward by the aid of a counterweight and the reverse operation occurs.

There is also a regulator on the market operated by a float in a tank placed alongside of the boiler. When the water is forced out of the boiler the float is raised and the drafts are closed. When the water in the tank drops back into the boiler again, the float descends and the dampers are opened.

The graduating valves are constructed so as to permit a small amount of steam to enter the radiator, so little that it will be condensed in heating a small portion of the radiator; or, on the other hand, they may be opened still farther and heat the entire radiator. The valves are furnished with stop screws so that they may be set to heat the entire radiator without permitting any steam to pass through the radiator into the return pipe.

Water radiators are used, which heat horizontally along the top first and thence downward according to the amount of steam turned on. The return fitting is placed at the opposite end and is connected to the bottom connection of the radiator. This return fitting is constructed with a small water seal which presents a full opening for the flow of condensation into the return pipe, and a restricted opening for the escape of air into the same pipe. This restricted opening and water seal retard the flow of steam into the return pipe. The air and water travel together to a point near the boiler where an opening for the escape of the air is provided in the top of the return pipe. From this a pipe leads to the chimney flue, where a slight reduction in pressure is produced, tending to help the removal of the air. The water separated from the air falls to the boiler.

The ordinary steam-heating system with its variable pressure, uncertain regulation and the tendency toward a vacuum will not permit of any graduation A sufficient reduction of pressure in the radiator would immediately fill the radiator with water through the return pipe; or in a one-pipe system the radiator would gradually fill with water if the supply-valve area was materially decreased. No vacuum can be produced in a vapor-heating system of this type because, as has been already stated, it is open to the atmosphere. With the ordinary steam-heating system the supply valves must be either turned on full or shut off tight, which frequently makes the rooms either too hot or too cold, causing waste of fuel and discomfort.

With the vapor-heating system, however, the pressure is generally much higher in the supply pipes than in the radiators. It may be 2 ounces in the pipes and only a small fraction of an ounce in the radiators, due to graduation and condensation. The water of condensation returns to the boiler at a very low temperature, averaging about 85 degrees Fahrenheit, and with some vapor systems the return water may be reheated by means of the waste gases.

There are many other reasons which recommend the vapor system to the public. The very low pressure at which the system operates reduces the cost of maintenance to a minimum. It is noiseless in operation, and is economical due to the sensitive regulation, the very low pressure and the graduation. Furthermore, it is capable of keeping up a steady heat from 10 to 12 hours

*From a paper delivered before the Ohio Society of Mechanical, Electrical and Steam Engineers, at Youngstown, Ohio, May 18, 1911.

with hard coal without attention. There are no air vents to leak, sputter, or emit odors into the rooms, and it is much quicker to act than hot-water heat, and the danger from leakage or freezing is reduced to the minimum. The radiators are smaller than those used for hot water, and about 15 per cent. larger than those required for the ordinary steam systems. When natural gas is used for fuel, the regulator is attached to a butterfly valve on the gas-supply pipe, which prevents overpressure and makes the system almost automatic, with the exception of turning the valves on and off at the radiators.

Boiler and Flywheel Explosions in America

It may be of interest to read what our British contemporary, the *Mechanical Engineer*, has to say in regard to boiler and flywheel explosions in the United States, and incidentally a few side remarks on American recklessness.

The United States maintains its unenviable position as record breaker in respect to accidents from the working of power plants. According to *The Locomotive*, a little publication issued by the Hartford Boiler Inspection and Insurance Company, there occurred last year no less than 533 explosions of boilers, killing 280 persons and injuring 506 others. As compared with the rate of fatality in this country the figures are astounding, and, moreover, are in no ways exceptional. There were 550 explosions in 1909, while the average for the previous four years was 455, with a similar proportion of killed and injured. It is difficult to compare these figures exactly with similar ones in this country, because the exact number of boilers in the States is not known, while the above figures only refer to the results of explosions of boiler shells and do not include the multitude of minor fatalities and scalding cases arising from the failure of steam pipes and subordinate details of steam apparatus, which, however minute, and whether on land or afloat in any vessel flying the British flag, come under the purview of the Boiler Explosions Act, and hence are included in the annual returns. Taking this sweeping inclusion, the average number of failures for the past ten years only works out at 69 per annum, with a fatality of 23 and a list of injured of 52. Were such minor failures as are embodied in these returns included in the statistics given by our contemporary, they would, of course, be greatly increased. But if we neglect them, it will be seen that, roughly speaking, the comparison is about ten to one. There are, no doubt, a larger number of boilers in the States than here; exactly how many it is impossible to say, though if we assume twice as many, a very liberal estimate, the figures imply a recklessness and absence of supervision in the States which is serious.

Similar recklessness appears to characterize the working of engines as of boilers, judging from a list of flywheel bursts recorded by our contemporary during 1910, which is admittedly incomplete since it rests mainly on the reports of such accidents as were sufficiently important to secure notice in the press. The list gives details of 67 accidents of this kind, causing the deaths of 16 persons, and more or less serious injury to 28 others. A perusal of the details, where these could be obtained, show that in a great many cases the accidents were due to the failure of the governing mechanism, though we cannot help feeling that the structural weakness of flywheels usually fitted to prime movers in the States, and the correspondingly small margin between safe and bursting speed, is responsible in considerable measure for the frequency of failure.

Duffy Wants a "Picture"

By Danny Hogan

"An' how's the laundry?" asked Doolin.

"Fine," replied Duffy, "the boss wants me to take out a license an' be the engineer as Cogan is drinkin' again."

"An why not?" asked Doolin, "you've been there seven years doin' this and that an' by rights you should know enough to get a picture for the frame."

"I know," says Duffy, "but I dunno if I could answer the questions about bilers. I'm told one must know all about riveting an' I'm no biler maker at all."

"True for ye," said Doolin, "an' biler makin' is one of the grandest studies we have. There ain't, Duffy, within reason, annything made by man that equals for profound interest an' deep research, a steam biler. An' the older it is, the more interesting it becomes. Ye would need years to learn the line. But there's no call, Duffy, for you to learn biler makin' to be an engineer. The City Hall gang ain't biler makers either. They will ask you some questions from a book and look at the answers an' find out if you are right.

"They will ask you, no doubt, to lay out a lap-joint seam for 5/16-inch plate at 60,000 pounds tensile strength and how to find the thickness of plate for a 60-inch biler, 100 pounds pressure, with a double-riveted seam."

"I couldn't do it," said Duffy.

"In two hours," replied Doolin, "ye can learn it all an' can get a job as a layer out."

Mr. Doolin filled his pipe and on some manila paper proceeded to lay out as follows:

P = Pitch of rivets;
WP = Working pressure allowed;
F = Factor of safety, 5;
R = Radius or ½ diameter;
T = Thickness of plate;
TS = Tensile strength of plate;
D = Diameter of rivet hole;
A = Area of rivet hole;
N = Number of rivets in a pitch;
S = Shearing strength in single shear;
RE = Rivet efficiency;
PE = Plate efficiency;
E = Lowest efficiency.

$$WP = \frac{TS \times T \times E}{R \times F} \quad (1)$$

$$RE = \frac{A \times N \times S}{T \times TS \times P} \quad (2)$$

$$PE = \frac{P - D}{P} \quad (3)$$

$$T = \frac{WP \times R \times F}{TS \times E} \quad (4)$$

$$E = \text{Lowest of } (2) - (3) \quad (5)$$

$$P = \frac{A \times N \times S}{T \times TS} + D \quad (6)$$

$$F = \frac{TS \times T \times E}{R \times WP} \quad (7)$$

$$R = \frac{TS \times TE}{F \times WP} \quad (8)$$

"There, Duffy, ye have," said Doolin, "the data, so as to speak, of lap seams either single, double or triple riveted. An' with that ye can use some short cuts. For instance, firebox steel may be taken at 56,000 TS and the shearing strength of steel rivets is 42,000 pounds. Now, 56,000 is to 42,000 as 3 is to 4.

"In finding P you can drop the large figures and with 5/16-inch plate and ¾-inch rivet hole make it

$$P = \frac{0.4417 \times 2 \times 3}{0.3125 \times 4} + 0.75$$

an' P will be 2.87 inches, or 2⅞ inches. Now, what is the efficiency of this, ye will ask. Well,

$$PE = \frac{2.875 - 0.75}{2.875} \text{ or } 73 + \text{ per cent.}$$

$$RE = \frac{0.4417 \times 2 \times 3}{0.3125 \times 4 \times 2.875} \text{ or } 0.73 + \text{ per cent.}$$

Ye will note, Duffy, that PE and RE are equal. Some prefer to favor the plate over the rivet, having in view that with the "bull" the rivet will surely fill the hole an' the plate may be hurt in the bending rolls. But, if you increase the pitch by as much you reduce the calculated E of the joint. Now, ye can work over these matters until your head is full and ye will get the picture in frame."

"But," says Duffy, "how will I know what size rivet to use for a given thickness of plate?"

"That's right," replied Doolin. "Well, 'tis this way. With plate of from ¼ to 5/8 inch ye can use

Thickness × 2

to find the diameter of rivet hole. From this [illegible]. Some use

$T \times 2 - \frac{1}{16}$ inch

and some

$T \times \frac{3}{2} + \frac{1}{16}$ inch

but $T \times 2$ gives [illegible] practice an' [illegible] a light job. Another thing, Duffy, is important. Suppose we lay out a straight line to be the pitch line, we must now find the distance from this line to the edge of the plate for the joint might fail by crushing out in front of the rivet. Ye should allow $1\frac{1}{2}$ diameters of rivet for this distance an' if you use $T \times 2$ for the diameter the matter of the plate crushing out will be properly taken care of."

"What is the allowance for steel plate crushing in this way?" inquired Duffy.

"The rule to find this," said Doolin, "is

$$D \times T \times 95{,}000$$

With the 5/16-inch plate and ¾-inch rivet hole, this equals 22,266 pounds, showing it is stronger than the shear of the rivet. In designing one must look after this crushing detail the same as the rivet shear and the net plate efficiency; so bear that in mind. The City Hall bunch may spring this on ye so it's well ye go over it and absorb it in your system."

"I will," says Duffy, "but there is one thing else I never understood. How do you find the distance between pitch lines on double and triple rows? Tell me that."

"Well," said Doolin, "the authorities vary on this point also. For instance, many rules ignore the matter, important as it is. In this country we use zigzag riveting exclusively and each shop is a law to itself on this subject. A safe rule to use for common plates is,

$$Pitch \times 0.7$$

for double and

$$P \times 0.65$$

for triple riveted. In the joint we have discussed this would give the distance as 2 inches and it represents good practice.

"The lap of these joints, ye will remember, will equal the distance from center of rivet hole to edge of plate times 2 plus the distance between the rows. Here is a table of rivet values that covers all sizes an' will save your pencil an' temper. Ye will need to work out various sizes, etc., to be able to answer anny question they may spring on ye."

"I know," replied Duffy; "I'll do it, too, for I want the picture in the frame and the extra money the job will pay. But what does this double shear mean in the rivet table?"

"When ye understand," said Doolin, "the lap joints which are the single shear I'll put ye wise to the butt-strap joints. It will be another story."

RIVET VALUES IN POUNDS PER SQUARE INCH

42,000 LB. SINGLE—78,000 DOUBLE SHEAR

Diameter of Rivet Hole	Area	Shear

Air Required per Pound of Coal

By Charles M. Rogers

Some reasons tending to show that, as a rule, a high percentage of CO_2 indicates a good furnace efficiency. From the results of actual observations the amount of air per pound of coal is calculated in detail.

Some experts are of the opinion that a high percentage of CO_2 is always accompanied by a correspondingly high loss due to incomplete combustion, that is, the formation of CO. In the writer's opinion this is usually not the case, although in some instances while forcing the fires for the purpose of obtaining a high percentage of CO_2, this holds true. Under ordinary conditions, however, with the stokers running normal, a high percentage of CO_2 is indicative of a high furnace efficiency.

With the usual boiler setting it is difficult to obtain an average CO_2 above 12 or 13 per cent., without considerable loss, due to the formation of CO, unconsumed carbon in the ash, increased weight and temperature of the escaping gases, and the potential energy contained in the unconsumed combustible constituents in the smoke.

Recently, in a certain plant, while the CO_2 recorder was showing good results and the stokers were running normal, a complete analysis of the gases was made and the pounds of air per pound of coal and the loss due to the formation of CO, were calculated. Observations of the flue-gas temperatures in the breeching showed them to be 10.43 per cent. lower with an average of 14 per cent. CO_2 than with an average of 12 per cent., which represents a saving. Further observations showed that the gain due to the reduced weight of the flue gases and likewise increased percentage of CO_2 was balanced by the loss due to incomplete combustion. The accompanying chart shows an autographic record of the percentage of CO_2, and the corresponding draft.

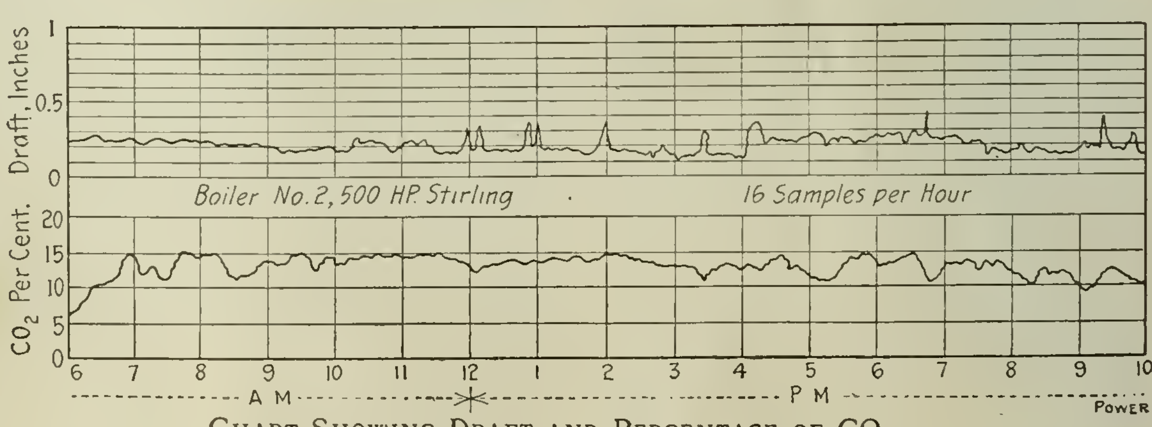

CHART SHOWING DRAFT AND PERCENTAGE OF CO_2

In order to determine the number of cubic feet of air supplied per pound of carbon, it is necessary to determine the total weight of oxygen from the following analysis, and knowing that air contains 23.1 per cent. by weight of oxygen, the air supplied per pound of coal can be readily calculated. In the particular case referred to, an analysis of the gases for four hours showed 14 per cent. of CO_2, 0.68 per cent. of CO and 6.02 per cent. of O. For convenience in figuring, 100 cubic feet of flue gas will be assumed. The respective weights per cubic foot of the component gases are: 0.1234, 0.0781 and 0.0893 pound. Then the total weight of each gas in 100 cubic feet of flue gas are:

CO_2.... 14 $\times$ 0.1234 = 1.7276 pounds

CO..... 0.68 $\times$ 0.0781 = 0.0531 pound

O..... 6.02 $\times$ 0.0893 = 0.5376 pound

The atomic weight of carbon is 12 and of oxygen 16; then a unit of CO_2 contains $\frac{32}{44}$ $\left(\text{equal to } \frac{2 \times 16}{12 + (2 \times 16)}\right)$ part by weight of oxygen and $\frac{12}{44}$ of carbon. Then in 1.7276 pounds of CO_2 there are

$$1.7276 \times \frac{32}{44} = 1.2564 \textit{ pounds}$$

of oxygen and

$$1.7276 - 1.2564 = 0.4712 \textit{ pound}$$

of carbon.

In one unit of CO there are $\frac{16}{28}$ $\left(\text{equal to } \frac{16}{12 + 16}\right)$ part by weight of oxygen and $\frac{12}{28}$ of carbon. Then in 0.0531 pound of CO there are

$$0.0531 \times \frac{16}{28} = 0.0303 \textit{ pound}$$

of oxygen and

$$0.0531 - 0.0303 = 0.0228 \textit{ pound}$$

of carbon. In 100 cubic feet of the flue gases there are

$$1.2654 + 0.0303 + 0.5376 = 1.8243 \textit{ pounds}$$

of oxygen and

$$0.4712 + 0.0228 = 0.4940 \textit{ pound}$$

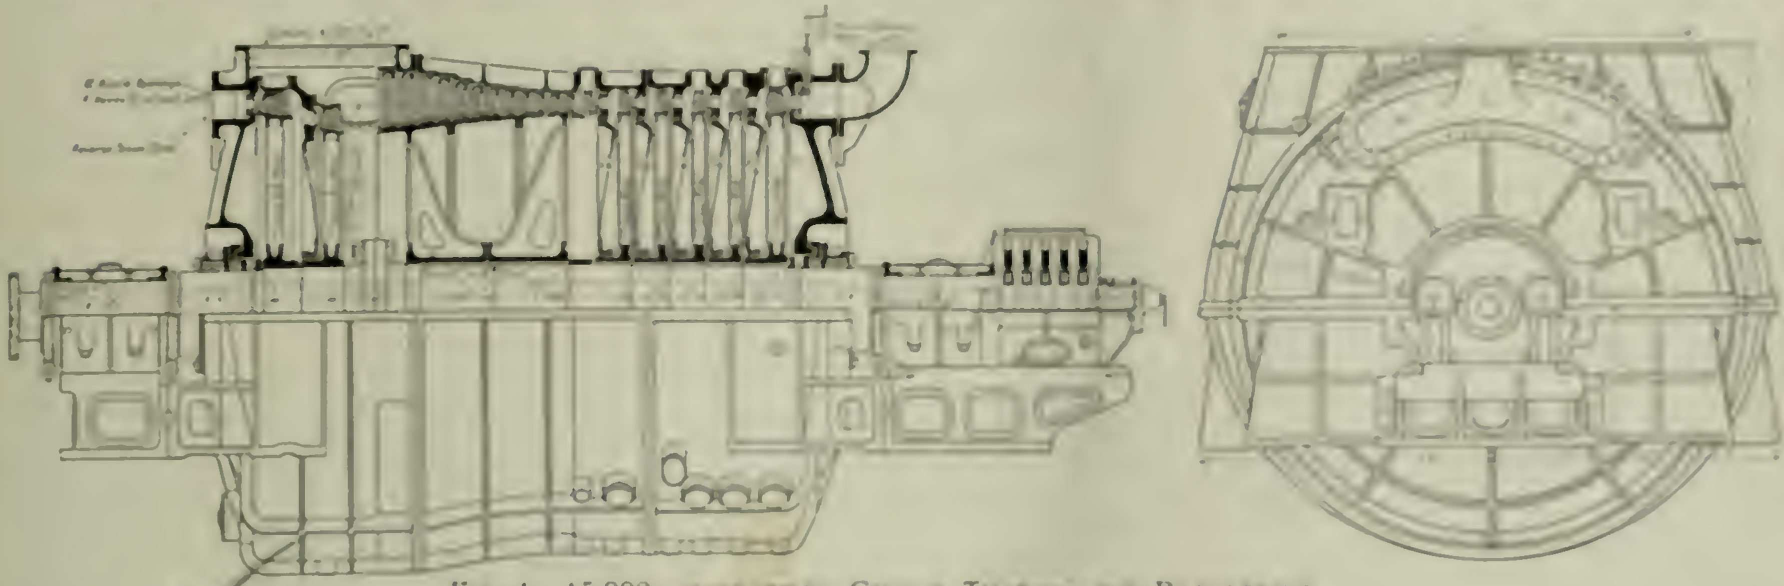

FIG. 1. 15,000-HORSEPOWER CURTIS TURBINE FOR BATTLESHIP

of carbon. There are then 0.4940 pound of carbon for every 1.8243 pounds of oxygen or, for every pound of carbon, there are 3.693 pounds of oxygen. As air contains by weight 23.1 parts of oxygen, this analysis would show that

$$3.693 : 23.1 = X : 100$$

where X represents the weight of air supplied per pound of carbon. This is found to be 15.98 pounds. As the coal contained only 70 per cent. carbon, the

mula 36 $(H - O/8)$. This, however, would amount to less than one, and is negligible for practical work. Without knowing the ultimate analysis of the coal it would be somewhat difficult to calculate the heat lost in the escaping gases.

When carbon burns to CO_2 there are 14,650 B.t.u. produced; consequently, when it burns to CO, producing only 4460 B.t.u., there is a loss of 10,190 B.t.u. Then the loss due to the formation of CO is found by multiplying the number of pounds of carbon burned to CO by 10,190 and dividing the product by the calorific value of the coal; that is,

$$\frac{10,190 \times 0.0228 \times 100}{12,450} = 1.87 \textit{ per cent.}$$

loss, due to the formation of CO.

Then about 16 pounds of air were supplied per pound of carbon, which is an excess of 40 per cent. over the theoretical requirement of 11.54 pounds; and as 40 per cent. excess air is considered good practice, no mistake should be made by

Curtis Marine Turbines

In this country great progress has been made in the impulse turbine, especially by the Fore River Shipbuilding Company, of Quincy, Mass., which has devoted itself very largely to the manufacture of the Curtis turbine for war vessels. *The Engineer* in a supplement illustrated two of the latest turbines built by this firm, the smaller turbine being the type employed for a scout cruiser, and the larger that for two new battleships. The accompanying illustrations are reproductions, and the following data are particulars of these vessels:

	Scout Cruiser	Battleship
Number of shafts	2	2
Number of turbines	2	2
Brake horsepower of each turbine	7500	[illegible]
Revolutions per minute	[illegible]	[illegible]
Steam pressure, pounds per square inch	[illegible]	[illegible]

weight of air per pound of coal used would be

$$15.98 \times 0.70 = 11.19 \textit{ pounds}$$

The hydrogen and oxygen contents in the coal were not known; hence, a slight error is introduced as the oxygen combines with $\frac{1}{8}$ its own weight of hydrogen and forms water. Each remaining pound of hydrogen requires 36 pounds of air for combustion, and is calculated by the for-

firing so as to obtain a CO_2 reading of about 11 per cent., providing the coal is somewhat near the same grade and the furnace equipment is similar to the particular installation considered.

In Munich, peat sells for 280 marks (about $66) for a carload of ten metric tonnes (about eleven short tons).

able degree. In both turbines there are five moving wheels, the total number of stages being sixteen and eighteen, and the diameters 85 inches and 120 inches respectively, while in each case there are two reverse stages with twelve nozzle openings and four valves. For the ahead turbines there are twenty nozzles, each provided with a valve, these being of the usual sliding type.

Types and Connections of Alternating Current Generators

By Norman G. Meade

Classification of Generators

Alternating-current generators may be divided mechanically into three classes:

Belt-driven machines, entirely self-contained, with two or three bearings, a shaft and a pulley; direct-driven machines, having one or two bearings and a shaft arranged for direct coupling to the prime mover; engine-type alternators, consisting of the field magnet and armature without bearings or shaft, the field magnet being the revolving member and arranged to be mounted on the extended shaft of the steam engine or other prime mover. These three types are illustrated in Figs. 1, 2 and 3, respectively.

Alternators of small capacity are built in two forms, one with a revolving armature and a stationary field magnet and the other with a revolving field magnet and stationary armature. The latter has come into general favor with manufacturers because of its more simple mechanical construction and the greater facility with which the extra insulation necessary for a high-tension armature winding may be provided when the armature is stationary.

Fig. 4 shows the elementary connections of a single-phase revolving-armature alternator and its exciter. The connections of a revolving-field alternator are exactly the same in all essentials, the only distinction being that the low-tension current for the field winding passes through collector rings and brushes, because the magnet revolves, and the high-tension armature current does not, because the armature is stationary. The exciting current for the field winding of any standard alternator may be supplied from any constant-potential direct-current circuit of about 125 volts.

Electrically, alternators may be also divided into three types: Single-phase,

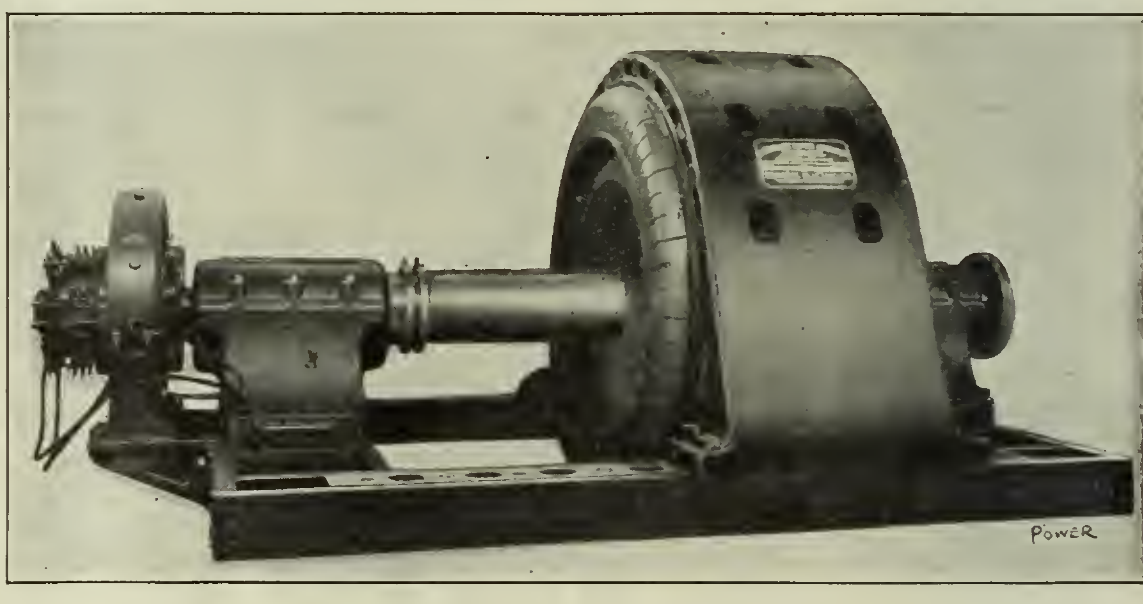

Fig. 2. Alternator for Direct Coupling

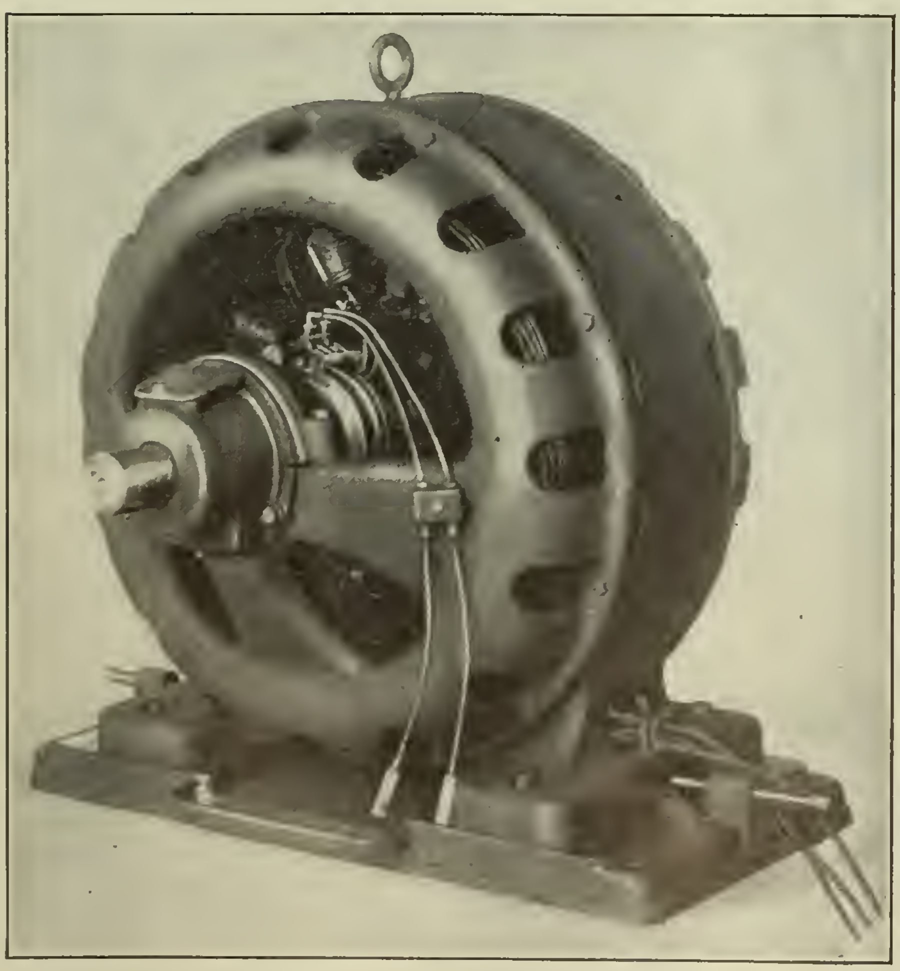

Fig. 1. Alternator for Belt Drive

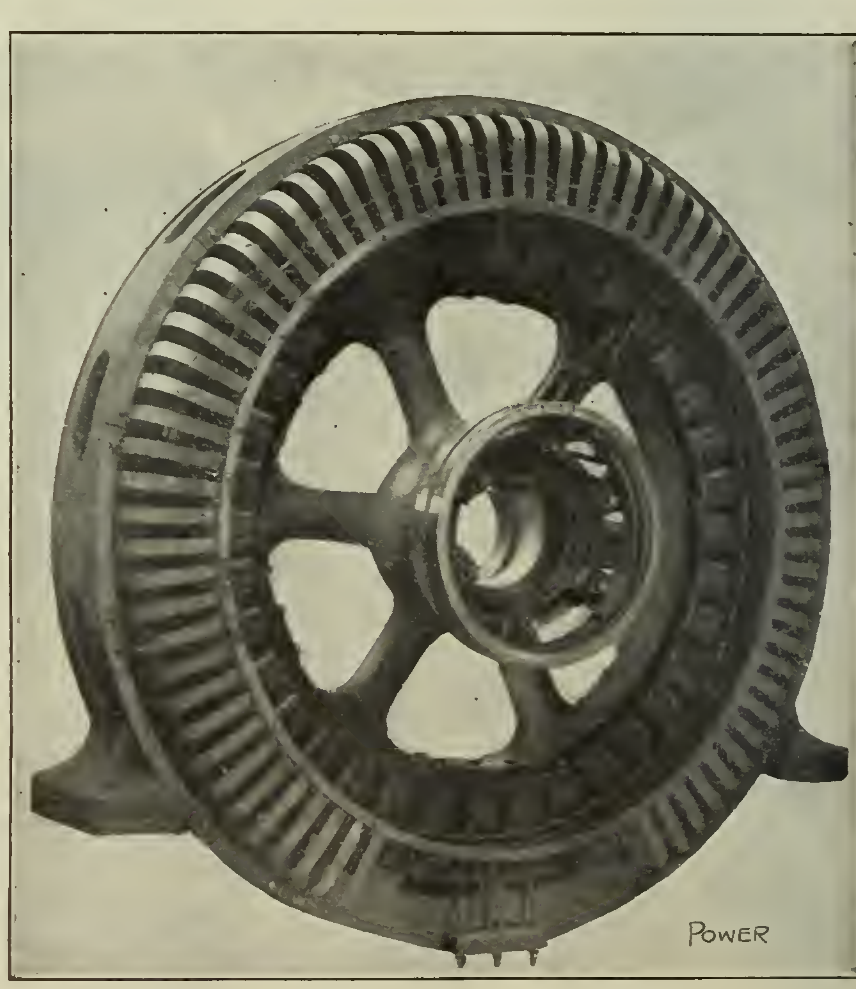

Fig. 3. Alternator for Direct Mounting

two-phase and three-phase. There was formerly a fourth type designated the "monocyclic," but that is no longer manufactured. Fig. 5 is a schematic diagram of a single-phase armature winding for

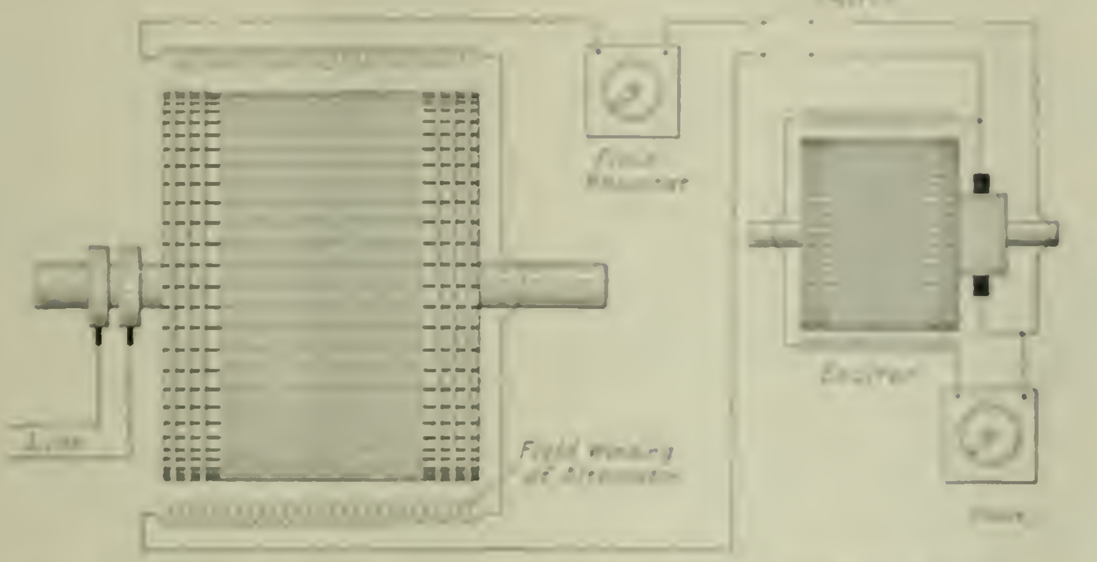

Fig. 4 Connections of Single-phase Alternator and Its Exciter

an alternator having six field-magnet poles. As alternators are generally designed to deliver a high voltage the coils are connected all in series and the two ends are connected to two collector rings

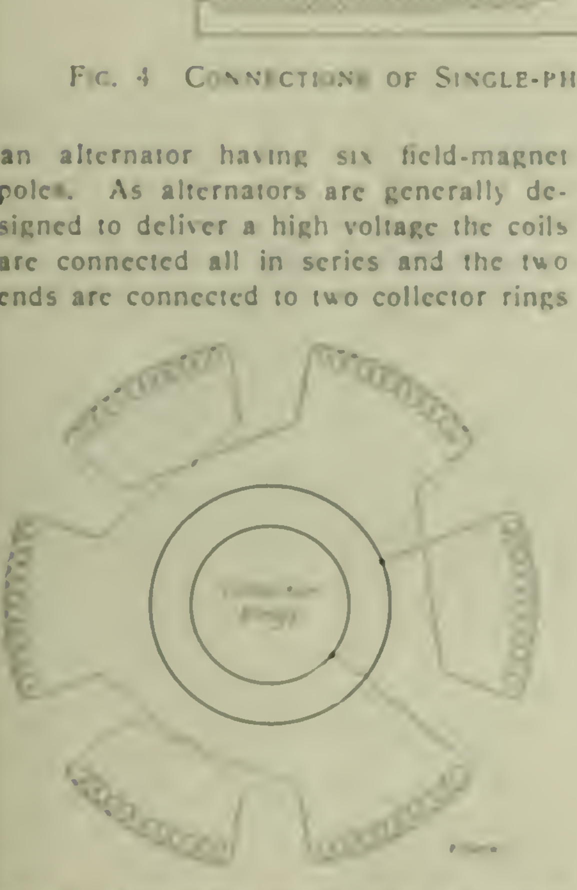

Fig. 5. Single-phase Six-coil Armature Winding

on the revolving-armature type of machine, as here shown, or to terminal blocks or leads on the revolving-field type of machine.

Fig. 6 is a diagram of the most common type of two-phase winding, which com-

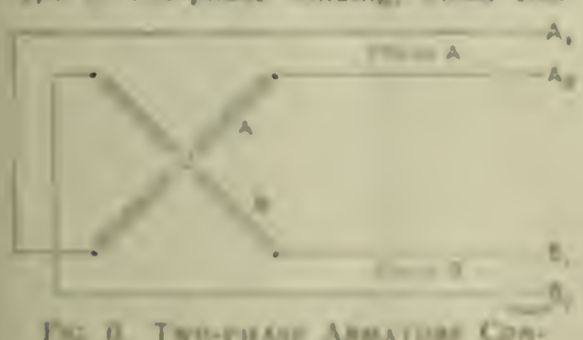

Fig. 6. Two-phase Armature Connections

prises two distinct circuits. The windings, indicated by A and B, are connected respectively to the external circuit-wires A_1, A_2 and B_1, B_2. The windings have no electrical connection with each other and the circuits are also distinct. The circuit A_1, A_2 constitutes one "phase" or division of the general system and the circuit B_1, B_2 the other. In some instances, instead of using two separate circuits with four terminal connections, as shown in Fig. 6, a common return wire is employed as shown at C in Fig. 7. This arrangement is seldom used in modern plants.

The three-phase alternator furnishes three electromotive forces differing in phase by 120 degrees or one-third of a complete cycle. This is accomplished by providing the armature with three

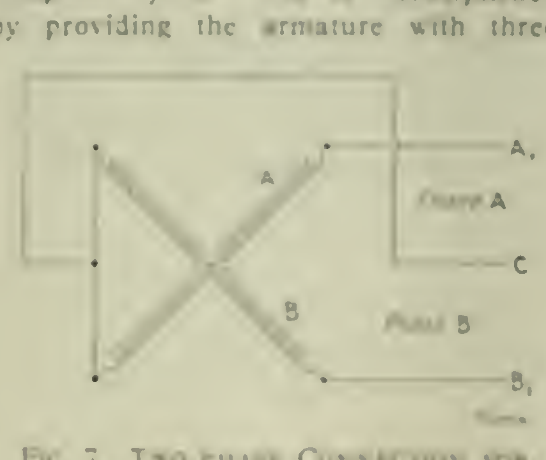

Fig. 7. Two-phase Connection for Common Return

windings displaced 120 degrees from each other. There are two general types of windings, designated as the "star" or "Y" and the "mesh" or "delta", these are represented diagrammatically in Figs.

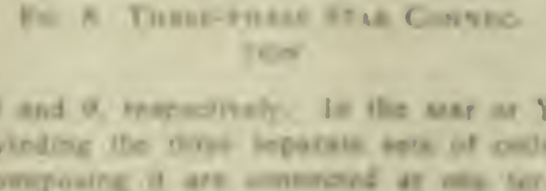

Fig. 8. Three-phase Star Connection

8 and 9, respectively. In the star or Y winding the three separate sets of coils composing it are connected at one terminal each to a common junction which forms the neutral point of the winding and the three free ends are connected to the line wires. The connections of the delta winding are evident in Fig. 9.

The monocyclic alternator was built for use in stations where the greater part of the load consists of electric lights but where it is desired to supply current also to a number of induction motors. It is really a single-phase machine with an auxiliary armature winding which is used only to supply current for starting motors.

Fig. 10 shows the connections of a

Fig. 9. Three-phase Delta Connection

monocyclic generator and Fig. 11 shows the arrangement of the coils on the armature core. The larger coil indicates the main winding and the smaller one the auxiliary winding, which is commonly called the "teaser" winding. In the diagram, Fig. 10, the electromotive force of

Fig. 10. Monocyclic Generator Connections

the generator has been put at 2080 volts and the various voltages indicated correspond to this potential. If the machine were wound for the more modern voltage of 2300, the teaser winding would give 575 volts.

As there are two main terminals and the teaser terminal, three collector rings

Fig. 11. Monocyclic Armature Winding

are provided, as shown. Between each end of the main winding and the end of the teaser winding there is a resultant electromotive force which is nearly 12 per cent. larger than one-half of the main electromotive force, as indicated by the voltage figures. This e.m.f. also differs in phase from the main e.m.f. and it is this feature which enables an induction motor to start automatically when supplied from a monocyclic alternator.

Small single-phase generators are usually provided with compensating field windings by means of which the field excitation is made to vary automatically in proportion to the load and thereby compensate for the voltage drop in the armature winding. The field magnet is equipped with two windings similar to those used on compound-wound direct-current generators. The main winding is supplied with direct current from the exciter and the other winding is supplied with rectified current from the armature of the alternator, causing the excitation of the field magnet to increase when the load increases. The current flowing through the compensating winding is rectified by a commutator and is reduced to the proper voltage by means of a series transformer.

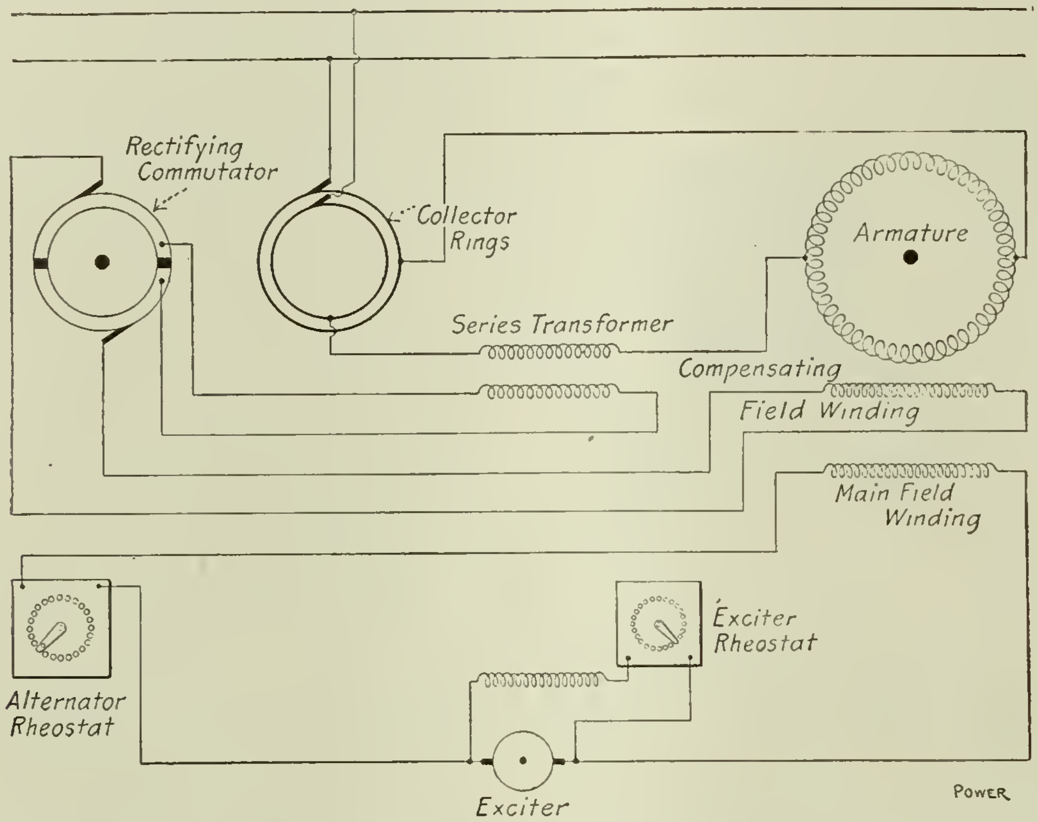

Fig. 12. Complete Circuits of Single-phase Compensated Alternator and Its Exciter

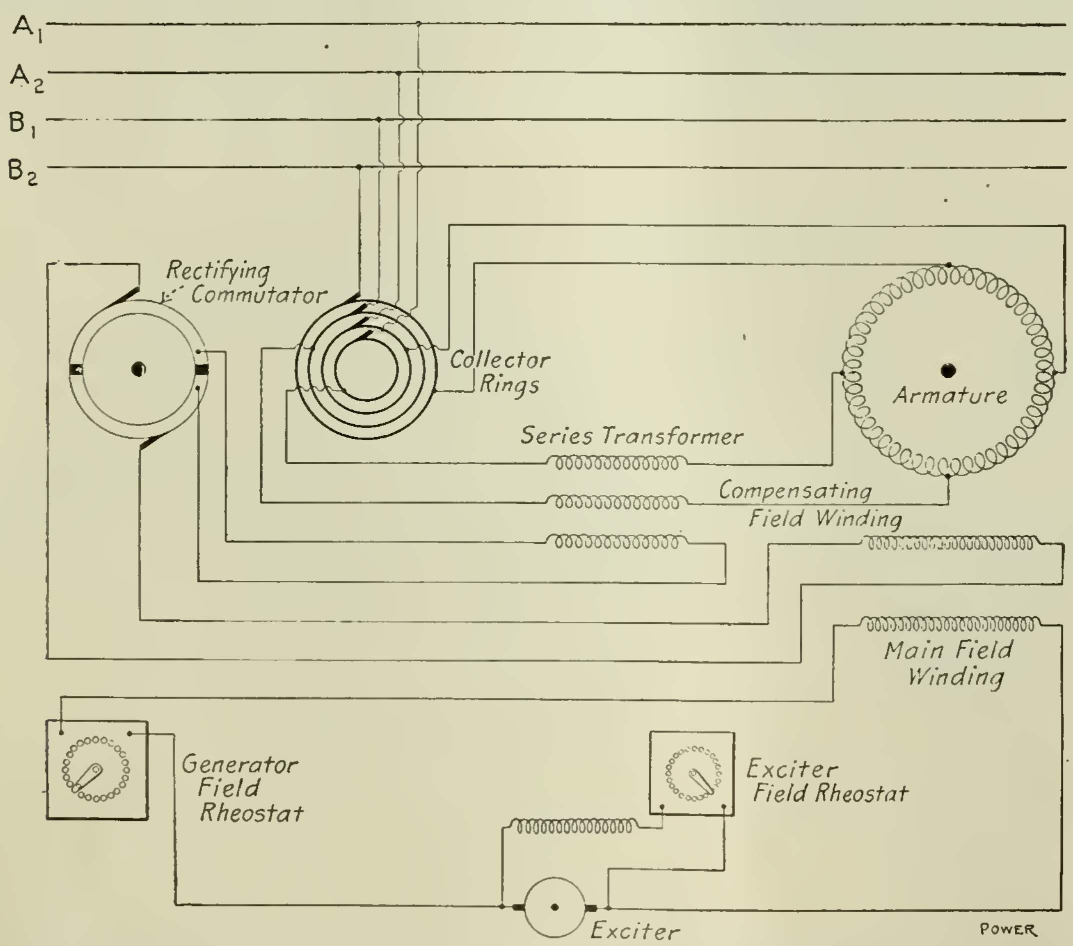

Fig. 13. Complete Circuits of Two-phase Compensated Alternator and Its Exciter

Fig. 12 shows the connections of a single-phase alternator with a compensating winding, and Figs. 13 and 14 show respectively the corresponding connections of a two-phase and a three-phase alternator.

Switchboard Connections of a Single Generator

Figs. 15, 16 and 17 are diagrams of the connections of single-phase, two-phase and three-phase alternators, respectively. The usual switchboard accessories of a single-phase machine, as indicated in Fig. 15, consist of a pair of fuses or a circuit-breaker, an ammeter, a voltmeter, a ground detector and its plug receptacle, a field rheostat and field-connecting plugs and sockets; the exciter is connected to the generator field winding by means of these plugs and sockets.

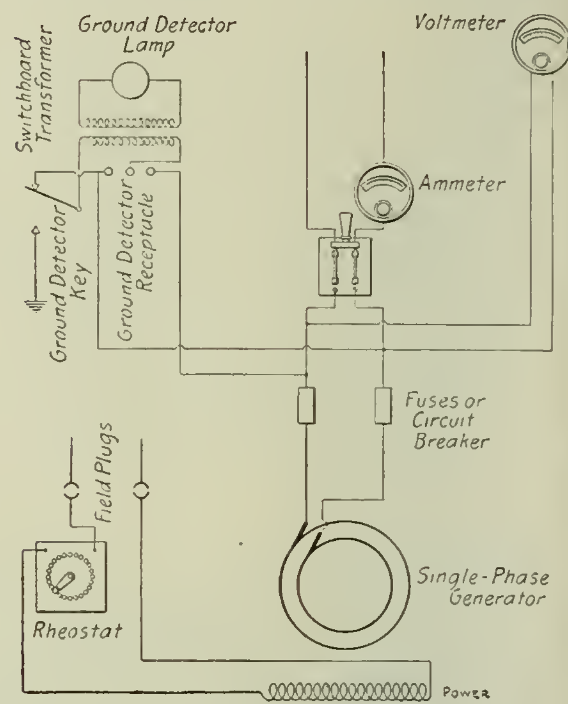

Fig. 15. Circuits and Switchboard Connections of Single-phase Alternator

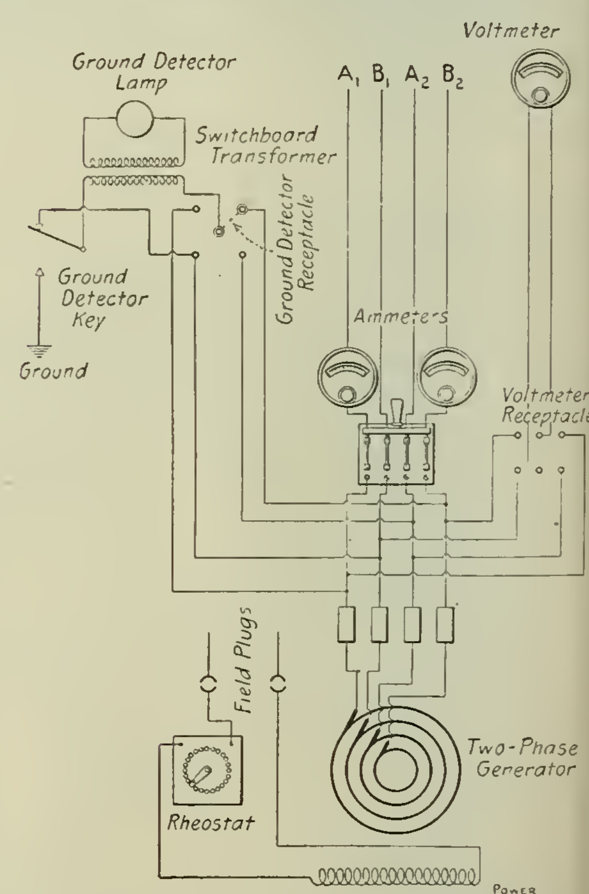

Fig. 16. Circuits and Switchboard Connections of Two-phase Alternator

For low-tension generators of about 600 volts and under, a lamp supplied through a transformer is used to indicate grounds. The ground-detector receptacle is provided with three holes and by means of

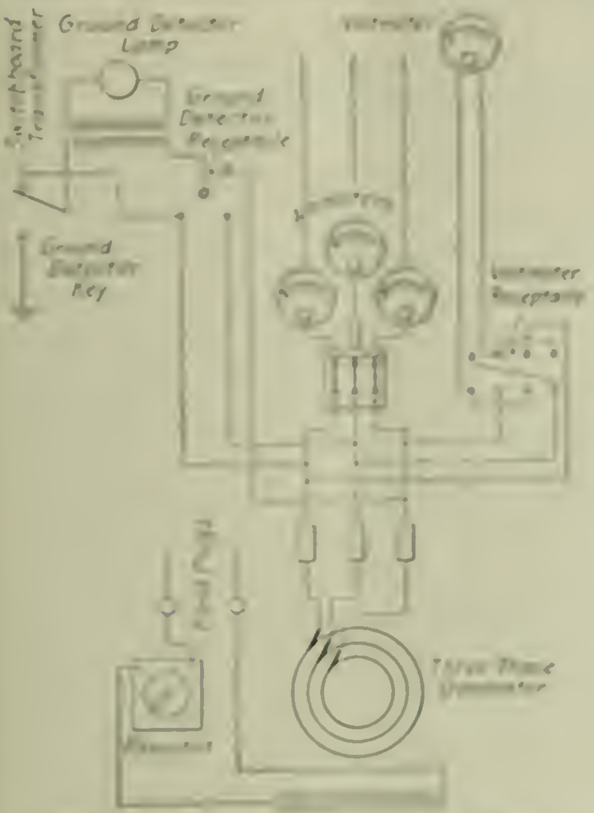

FIG. 17. CIRCUITS AND SWITCHBOARD CONNECTIONS OF THREE-PHASE ALTERNATOR

a double plug the lamp can be connected to either side of the circuit by inserting it in the left-hand and center holes or in the right-hand and center holes. The detector key is depressed when the plug is in one of the two positions and if there be a ground it is then indicated by the burning of the lamp.

Fig. 10 shows the switchboard connections of a two-phase low-voltage alternator. With this type of machine two ammeters are necessary, one for each phase. By means of the voltmeter receptacle a single voltmeter may be connected to either phase; with the plug in the center and right-hand holes it is con-

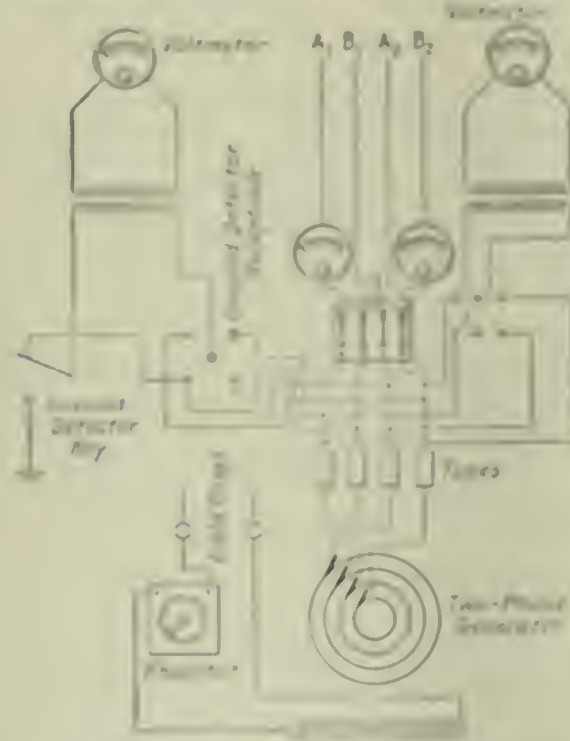

FIG. 18. CIRCUITS AND CONNECTIONS OF HIGH-TENSION TWO-PHASE ALTERNATOR

nected to phase A. The ground-detector receptacle is constructed so that the ground-detector lamp can be connected to either wire of either phase.

The connections of a low-voltage three-phase alternator are shown in Fig. 17. The connections are similar to those of the two-phase generator with the exception that three ammeters are necessary, one for each phase, and the voltmeter and ground-detector receptacles are arranged a little differently to allow connection to either one of three phases instead of either one of two only.

Fig. 18 shows the switchboard connections of a high-voltage two-phase alternator, which differ from those in Fig. 10 only in that a voltmeter is used instead of a lamp for indicating grounds and the main voltmeter is connected to the alternator leads through a transformer instead of by a direct metallic circuit.

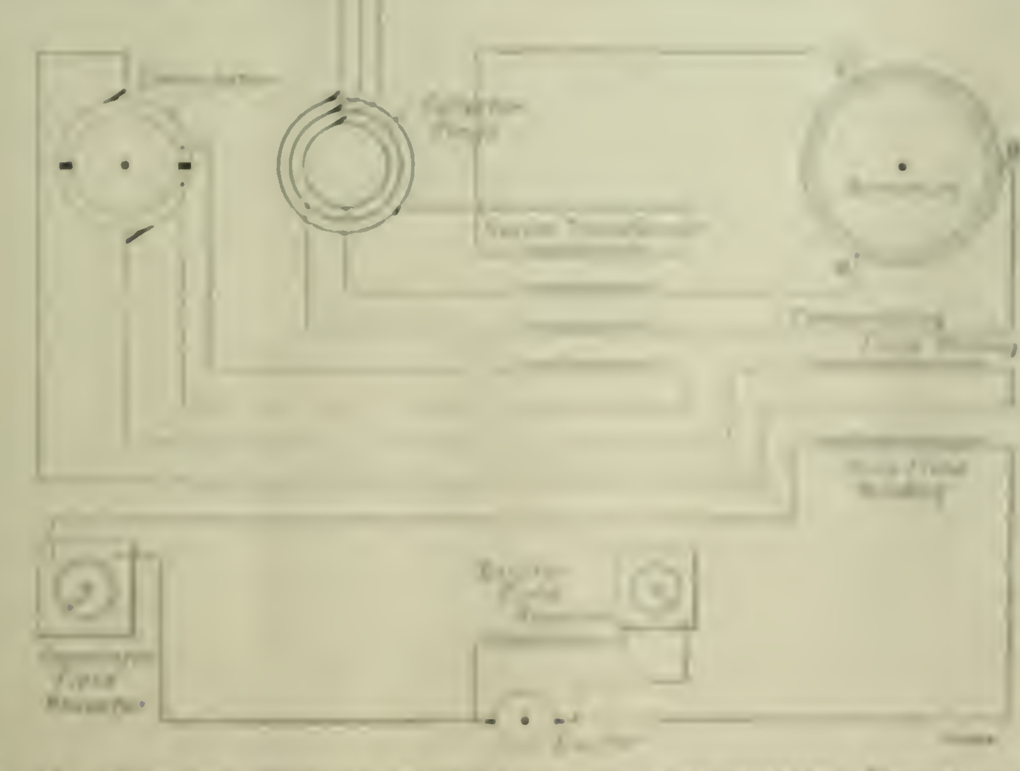

FIG. 14. COMPLETE CIRCUITS OF THREE-PHASE COMPENSATED ALTERNATOR AND ITS EXCITER

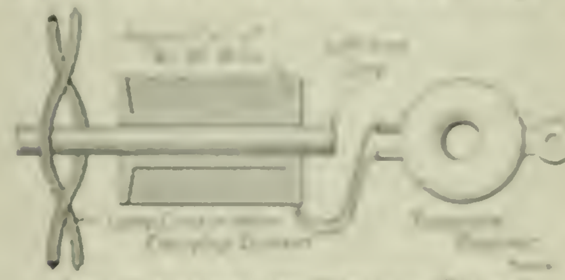
Identification of Alternating and Direct Current

The device shown in the accompanying drawing is of much convenience, not only in testing house wiring but in conduit and line work. One of the many uses to



ARRANGEMENT OF TESTING DEVICE

which it can be put is the distinction of alternating and direct currents, which has been the subject of considerable discussion in this department. If the soft-iron core be brought near a wire in which an alternating current is flowing, a loud hum will be heard in the telephone receiver; in the case of a direct-current circuit, the only indication will be a click when the circuit is closed or broken.

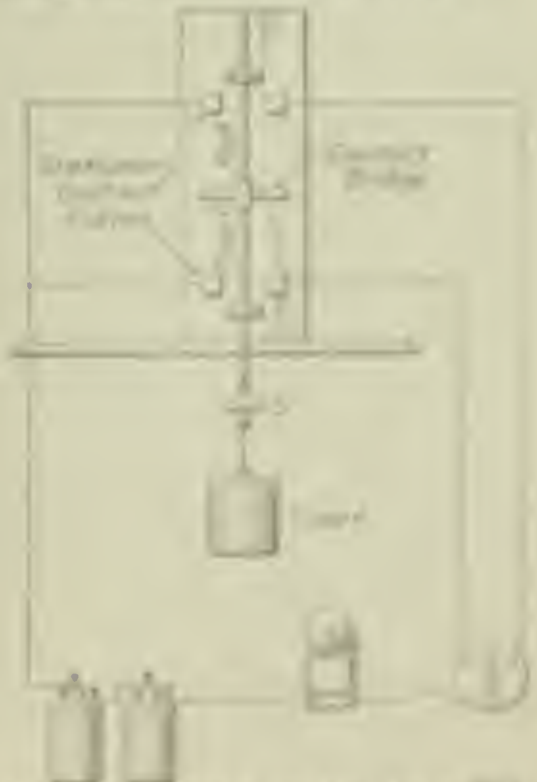
Mr. Dolphin's Signal System

In Mr. Dolphin's description of a water-tank signal system, which appeared on page 733 of the May 9 issue, the diagram of connections contained an error. The two wires leading up from the two-way switch to the float contacts were shown connected by a "jumper." The correct diagram is shown herewith.



CORRECT DIAGRAM OF MR. DOLPHIN'S CIRCUIT

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Peat Gas Power in Germany

By F. E. Junge

Scarcity of resources and density of population force the German engineer to reduce to the utmost the cost of power in industrial production. In most German industries the power cost is an important item in the total cost of manufacture and, unlike wages and interest rates, it can be lowered by scientific endeavor without harming the income of either capitalists or workmen.

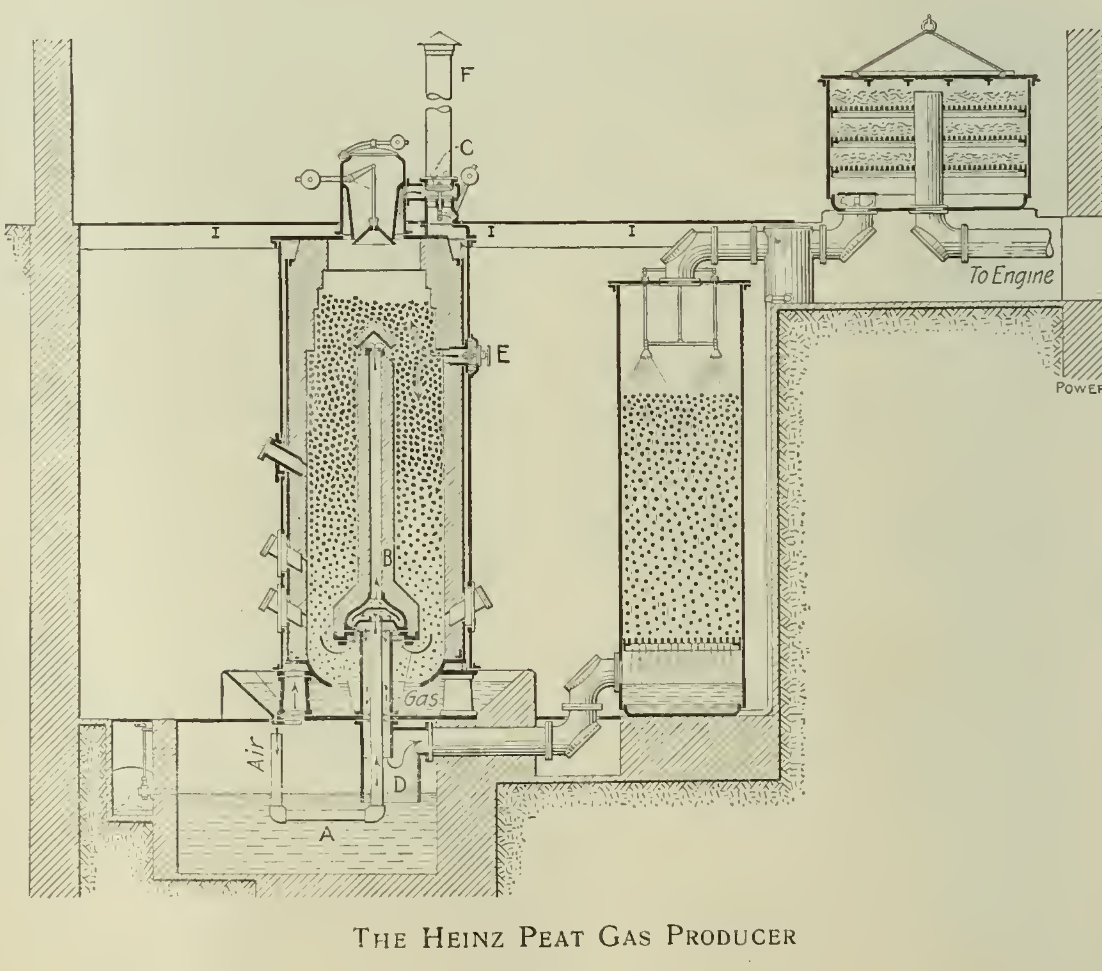
Fuel Supply

While there is a sufficiency of high-grade coals, like anthracite, bituminous and lignite, in the country, it has been found more profitable to use these fuels wherever possible at the mouth of the pit than to transport them by rail or canal to the power houses. In combined iron- and steel-smelting plants and coal mines, for instance, gasification in coke ovens and producers is most practicable, the coke and gas produced being utilized in the furnaces of the plant, the valuable byproducts, tar, benzol and ammonium, being marketed while the surplus available energy is distributed by high-tension electrical systems to neighboring industries, cities and agricultural districts.

Unfortunately, the German coalfields are not distributed symmetrically over the whole country; they are located partly in the extreme east and partly in the extreme west. Consequently, industries which are located in the middle or northern regions suffer from the natural discrimination by lack of cheap sources of power. This disadvantage is being gradually overcome, at least in some sections of the country, by utilizing the peat bogs, which are abundant, for the generation of power.

These bogs have an average depth of 3 meters (9.8 feet). Assuming that one cubic meter of raw peat yields about 150 kilograms (330 pounds) of dry peat, the quantity of dry peat available in Prussia for purposes of power production can be estimated at some eleven billion tons. In Germany, labor is comparatively cheap and reliable. Hence, when installing a power plant we can figure on fetching the raw peat by hand from the field and transporting it by rail or cableway to the power house, which is built in the immediate vicinity of the bog and located below the surface level so that the peat can be dumped from the cart or bucket right into the producer.

One laborer with an average pay of 75 cents a day supplies about 1800 kilograms (3960 pounds) of dry peat per day, 1 kilogram (2.2 pounds) costing about one-twenty-fifth of one cent. For purposes of large-scale power generation, automatic dredges are employed. Such a machine weighs about 3000 kilograms (6600 pounds), is run by one attendant and produces 6 tons of dry peat per hour. The detail cost of operation is 3.5 cents for fuel (benzol), 0.25 of a cent for lubricant, 1 cent for wages, making the total 5 cents per ton of peat turned out. This obviously does not include interest, amortization and repairs to the dredging machine. The capital invested in peat bogs need not be amortized because in most cases good fertile soil is laid open to the plow, whereby the value of the land increases.



The Heinz Peat Gas Producer

Utilization of Peat

There are various processes which enable one to utilize not only the peat gas but a number of valuable byproducts besides. Thus the Woltereck process provides for the utilization of ammonium, which is produced in considerable quantities when a mixture of air and steam is passed above a stratum of carbon. Frank and Caro, having adopted an improved Mond process, utilize not only the byproducts but also part (15.5 per cent.) of the potential heat energy of the peat. Ziegler makes coke, gas and byproducts in special peat-coke ovens. But it is obvious that all these processes, interesting though they are, are rather complicated, requiring both mechanical and chemical skill and making the enterprise often unprofitable, especially when markets for the disposal of byproducts are not at hand. The direct combustion of peat on special grates under steam boilers has also not proved a complete success, because, in most cases, ordinary steam coal must be mixed with the peat in order to evolve the necessary heat.

By far the greatest practical success has been attained with the direct gasification of raw, air-dried peat in producers, the gas being used for the development of power in gas engines and no utilization of byproducts being attempted. Being both porous and light, peat is by nature well suited for gasification in producers. These qualities permit a deep bed of fuel to be used which, in turn, offers a large surface to the air, whereby the oxygen finds ample opportunity to unite with the carbon of the peat. The chief difficulty is, of course, to dispose of the tar-forming constituents and of the high moisture contained in the peat and the only practical way so far developed is to eliminate both within the generator itself. To attain this some producer designers employ two zones of combustion, the same as when using lignite, the gas produced being usually withdrawn from the middle, between the two zones. Some of them draw the gas which is produced in the upper zone through a bypass into the lower zone, the gas being cooled on its way down and the water vapor condensed. Naturally there is some heat lost by this cooling and, furthermore, it is difficult to maintain combustion in the upper zone when the fuel is very wet, because the heat liberated by the combustion below does not materially assist the combustion above.

Peat, being a very poor conductor of heat, does not yield its moisture contents easily by mere warming up. It has been observed in practice that frozen lumps of peat after being for three hours in the combustion zone of the generator, where they were subject to a temperature of some 3000 degrees Centigrade, when taken out were incandescent on the outside but still frozen within, there being a zone of moisture between the outer layers and the kernel.

Another mistake which was made in the construction of peat producers consisted in arranging so that the gas was taken out from the side of the generator wall. There the fuel is generally looser than in the center of the bed; hence, the resistance offered by the fuel to the passage of air is less and combustion livelier, whereby hollow spaces burn out near the wall, through which the air entering below may escape into the delivery pipe without doing any useful service. This leads to operative difficulties.

Finally, there is the difficulty with double-zone peat gas generators that the amount of air admitted to the two zones at various loads cannot be balanced. It is obvious that there must be a fixed ratio between the air entering above and the air entering below, if the composition of the gas during operation is to remain the same. But the flow of air depends on the resistance offered to its passage by the fuel column, and this resistance changes constantly and not proportionally in the two zones; consequently, at one time relatively more air enters from above than below and at another time more from below. If the load on the engine should drop from full to quarter load, the suction effect of the engine in the gas generator will be very low and the air will enter through the path of least resistance, which may be either above or below, depending on the momentary composition of the fuel beds. There is no certainty of operation and the output of the producer remains in practice often far below its rated capacity.

The Heinz Producer

All of the difficulties mentioned appear to have been overcome in a peat producer designed by Carl Heinz for the Görlitzer Maschinenfabrik in Görlitz, Silesia, which seems to afford the most satisfactory method of utilizing peat for the purpose of power development. Unlike the double-zone type, the air enters above and the gas is withdrawn from the center of the combustion chamber below. Gasification of the fuel takes place in one direction only, and the air, instead of traveling along the walls of the generator, is forced to enter the inner strata of the fuel bed. The heavy gases produced in the upper layers of the fuel bed are forced to pass through the incandescent zone below, where they are split up and converted into light and permanent gases.

Another feature of the Heinz producer consists in the complete utilization of the heat generated in the processes of gasification. The accompanying illustration is a vertical section of the complete producer. All of the air for the generator is taken from the pit beneath it, which also contains the scrubber water and the gas-delivery pipe *D*. Part of the air is drawn through the pipe *A* and the superheater *B* into the upper part of the fuel column, whence it must travel down through the fuel bed in order to reach the gas outlet below. The remainder of the air ascends through the space between the outer and the inner shells of the generator, absorbing radiant heat, and under normal conditions it enters, through the valve *C* at the base of the purge pipe *F*, the combustion chamber above the fuel bed. The outer shell usually does not become warmer than the surrounding atmosphere, and the delivery pipe entering the scrubber is only moderately heated, indicating unmistakably that almost all of the heat which is usually lost through convection and radiation is utilized in the generating process.

If the water content of the peat exceeds certain limits, somewhere around 60 per cent., an auxiliary process is employed temporarily by starting a second combustion zone near the top of the fuel bed. This is done by opening the pipe *F* and the auxiliary air-inlet valve *E*, as soon as the attendant notes that the fire on top of the fuel column is disappearing. The valve *C* then closes automatically and the air which is preheated in the space between the shells enters the fuel bed directly through the valve *E*. Thus combustion is started at the level of *E* both ways, the up-draft being provided by the pipe *F* serving as a chimney and the down-draft by the suction of the engine. As soon as incandescence is reestablished on top of the fuel bed the purge pipe *F* is closed off and the valve *E* also, the normal process is thereby resumed. By the temporary employment of this expedient, fuels of very high water content can be gasified. Of course, there is a moisture limit, for in peat containing 80 per cent. of water the 20 per cent. of combustible would be only sufficient to vaporize the water and no combustible gas could be produced. With the auxiliary process the consumption of fuel per horsepower-hour becomes somewhat greater than normal, but the operation is very simple and free from troubles.

In this producer all the gases emanating from the scrubber water are drawn up with the air into the combustion chamber and destroyed. The gas produced is very clean. With continuous day and night operation cleaning of the engine is necessary only once every three months, there being only a slight coating of sediment on the interior surfaces. The removal of slag and ashes can be done at any time during operation.

Air-dried peat, under conditions as they are in Germany, can be had for an average price of 25 cents on the bog. The consumption of peat containing 40 per cent. of moisture varies between 1.9 and 2.7 pounds and that of air-dried peat between 1.20 and 1.62 pounds per brake horsepower-hour, according to the composition of the fuel and the load on the engine. The efficiency of the generator alone is about 92 per cent. and that of the complete plant about 80.5 per cent.

CORRESPONDENCE

Make and Break Ignition Troubles

Under this heading in the April 18 issue of Power, Mr. Kiehn refers to igniter troubles and gives particulars of tests for locating them. Operating engineers will find scant need for these tests if they will remove their make-and-break igniters, say, twice a week, not necessarily for filing up or adjustment but just to see that conditions are all right, that the points are not badly worn and pitted and that serious corrosion has not taken place. Waiting until trouble comes and then applying Mr. Kiehn's tests would savor rather of laziness. It is no great trouble to occasionally remove the two nuts which usually hold the igniter in place; the wiring need not be disconnected at all if the igniter is all right. The foregoing applies to high-tension jump-spark plugs as well as to make-and-break igniters.

Prevention is better than cure in the engine room just as truly as in the conservation of personal health.

Readers with Something to Say

Practical information from the man on the job. A letter good enough to print here will be paid for. Ideas, not mere words wanted

Filing Clippings

Although most of the articles appearing in POWER will be found to be interesting, few will be of such a nature that the average man will want to keep them, for what interests one man, another already knows.

If the card index of the articles kept for reference is used, a good plan is to give not only the title of the article but also information regarding the text.

I have been clipping articles and filing them for the last ten years and, after trying out all other ways, I believe this to be the best.

In order to keep the articles upon different subjects separate from each other they should be placed in heavy manila-paper folders, which should not be folded exactly in the middle, but so that one side will project ½ inch above the other side. This will furnish space upon which to write the title or number of the file. The best way is to use numbers and to have one number placed in each corner of the folder. By means of an alphabetical index written on a sheet or sheets of paper and kept in the file it will be easy to find the proper folder at any time, as this index will give the number of the folder as well as the type of the articles to be found in it.

Instead of filing the folders alphabetically a better plan is to place all of those referring to closely related subjects together. As an example, all of the articles referring to engines, although they might be in several folders, would be so placed that the folders containing them would follow each other. Then there should be several numbers left vacant so that if other folders containing matter on engines, but not contained in any of the first folders, are added later there will be space for them at the proper place. After the space left for added folders there should be several folders covering boilers and their various parts. The file should be made up in this way until all of the subjects have been covered.

In order to be able to turn quickly to the right folder without having to turn over a number of them before reaching the right one it is well to have what are known as guide cards. These are made of stiff paper and are placed between each ten folders. They should project about ⅜ inch above the folders and this ⅜ inch should be cut away for four-fifths of the distance across the tops. The projecting tabs, after the rest has been cut away, should be staggered so that they will not be directly behind each other but each will be one-fifth of the distance across the top to the side of the one in front. Then the guide cards numbered 10 and 60 will be directly behind each other, as will 20 and 70, and so on.

Making Smokestacks in Manila

The accompanying photograph shows how two smokestacks were rolled on three rollers made out of old pipe. One was a 58-inch stack for a crematory and the other was an 11-inch stack for a road roller. One of the pipe rollers is not shown in the photograph. Any old pipe and timber which happens to be on hand answers. The rolls are adjusted by turning the nuts on the bolts that pass up through the four corners of the frame with monkey wrenches in the hands of the two natives.

HOW SMOKE STACKS ARE MADE IN MANILA

A part of the 58-inch stack is shown, but the 11-inch stack was sent out before the photograph was taken. The rollers are easily turned by means of a chain pipe wrench. A piece of strap iron is placed between the pipe and timbers.

Air Compressor Lubrication

Having noted that considerable interest is being taken in the subject of lubrication by readers of POWER, I am giving the accompanying data which may be of interest. It is a report of the use of lubricating oils in the three air-compressor plants of the Isthmian Canal Commission for the month of February, 1911. It shows the number of revolutions, square feet covered per pint of oil, output in cubic feet of air and the cost per million square feet covered.

Oils Used:	Empire Air Compressor	Las Cascadas Air Compressor	Rio Grande Air Compressor
Valve oil . . .	87¾ gal.	22 gal.	38 gal.
Stationary-engine oil .	157¾ gal.	35 gal.	60 gal.
Air-compressor cylinder oil. . . .	87¾ gal.	23 gal.	45 gal.
Revolutions per gallon of valve oil:			
	236,458	295,655	217,650
Revolutions per gallon of stationary-engine oil:			
	131,532	185,840	137,845
Revolutions per gallon of air-compressor cylinder oil:			
	236,458	282,800	183,682
Square feet covered per pint of valve oil:			
	1,041,107	1,392,597	1,025,122
Square feet covered per pint of air-compressor cylinder oil:			
	1,354,971	1,837,513	1,028,152
Cost per million square feet covered (surface):			
Valve oil. . .	$0.0234	$0.0175	$0.0237
Air-compressor cylinder.	$0.0134	$0.0098	$0.0176
Output of free air, cubic feet:			
	378,879,661	118,770,526	151,205,582

In the air-compressor plants at Empire, Las Cascadas and Rio Grande, there are 14 compressors, each of 425 horsepower and all operating at a steam pressure of 125 pounds. The engines are simple twin cylinder. The compressors are of the double-cylinder cross-compound type. The area of the two steam cylinders is 9.42 square feet; the area of the low-pressure air cylinders is 15.17; the area of the high-pressure cylinders is 9.42 square feet. The speed of these compressors is from 127 to 137 revolutions per minute.

Empire, Panama.

Adjusting Cutoff of Corliss Engine

When about to adjust the cutoff of a Corliss engine, of the short-range cutoff gear, start the engine running very slowly and loosen the check nuts on the reach rod, and see that the governor is down on the stops. Then lengthen the rod until the knockoff cam starts to disengage the valve stem; screw the rod out until the knockoff cam will not disengage the hook; or, in other words, until the engine carries the valve. After setting the first cutoff cam set the head-end cam in the same way.

In the case of a long-range cutoff gear, shorten the reach rod until it carries the valve and then lengthen the rod until it will just disengage the hook. Then adjust the knockoff on the second valve or one on the head-end in the same manner.

All Corliss engines with short-range cutoff gears should carry the valves without disengaging when running slowly. A Corliss engine with a long-range cutoff should disengage the hooks at all times; if not, the steam will blow through the engine.

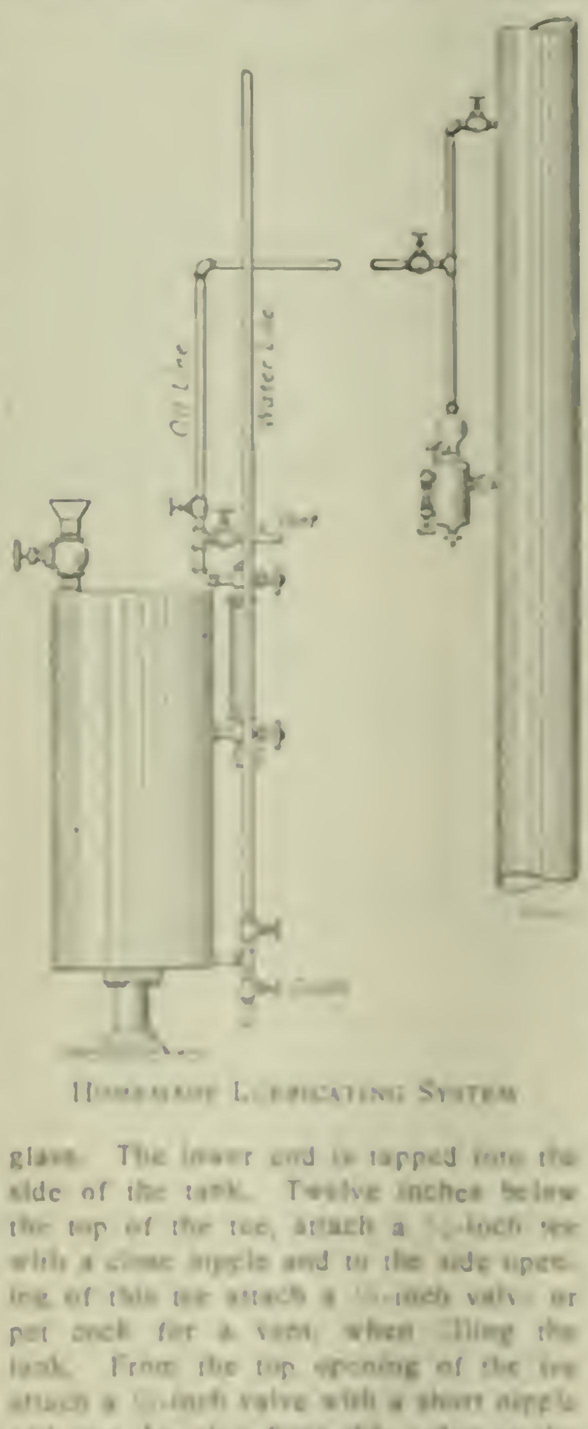
Cleveland, O.

Homemade Lubricating System

The accompanying illustration shows a gravity system for cylinder-oil distribution which works better than any system I have yet tried.

The oil tank is made of a piece of 10-inch pipe, 2 feet or more in length, with the ends capped. On the bottom there is a 2-inch pipe flange fastened by cap screws and into this is screwed a piece of 2-inch pipe about 2 feet long. The bottom flange serves for a floor stand for the tank.

At the bottom of the tank a hole is drilled and tapped for a [illegible]-inch nipple with a tee on the end. A nipple and valve is screwed into the lower end of the tee to serve as a drain. Into the upper end of the tee a short nipple with a valve is screwed and to this the water-condensing pipe is attached, which is connected to a steam pipe. This condensing pipe must not be less than 2 feet above the highest point to which oil is to be delivered. In case the boilers are below the engine level run the pipe up above the highest point of oil delivery and then down to the tank; the cap on the top of the tank should have one [illegible]-inch and one 1[illegible]-inch drilled hole. The larger hole is to be used for filling. It is better to have a short piece of pipe with a valve screwed into this hole, but a plug may be used instead. The [illegible]-inch hole should have a short nipple screwed in and a [illegible] and [illegible] by [illegible]-inch tee screwed securely to the side opening of the tee which is attached to the upper end of the gage



HOMEMADE LUBRICATING SYSTEM

glass. The lower end is tapped into the side of the tank. Twelve inches below the top of the tee, attach a [illegible]-inch tee with a close nipple and to the side opening of this tee attach a [illegible]-inch valve or pet cock for a vent, when filling the tank. From the top opening of the tee attach a [illegible]-inch valve with a short nipple and run the pipe from this valve to the engine or pump lubricators in as direct a line as possible, reducing to [illegible] inch for branch lines.

In case of single-connection lubricators, the oil line should be attached to the bottom of the lubricator where the drain comes out, by using a close nipple, tee and pet cock.

To start the system, fill the tank full of oil, close the valves in the drain, vent and oil line and open the valve in the water line, allowing it to fill with condensed water to its highest point. Have all valves in the branch lines closed and then open the valve in the oil line at the tank and loosen a union at the most distant point to allow air to escape very slowly, until oil shows. Then make the joint tight. The various lubricators are then ready to feed.

Los Angeles, Cal.

A Successful Municipal Electric Plant

It has been said by many that municipal ownership is a failure. This is true in some cases, but not in all. I believe that when a municipal electric light and water works fails to produce a revenue for the city, the cause is due to either mismanagement or graft and possibly both.

That one municipality owns and operates water and light plants successfully is shown by the figures given herewith.

After years, with an annual expenditure of $5000 for city lights, while the citizens were burdened with the rate of 50 cents a light, or 15 cents per kilowatt-hour, the council purchased the plant from the private corporation for the sum of $14,500 and ran it under municipal rule for about a year, when it was found that the equipment and capacity were entirely inadequate for the needs of the city—the electrical units consisting of one 75-kilowatt direct-current generator and one 30-light arc machine.

Therefore a new plant was built which consists of two high-pressure boilers and two 16x15-inch four-valve engines which run at 225 revolutions per minute. Ten dollars covers the cost of the repairs on both engines since they were put in operation three years ago. Two 150-kilovolt-ampere alternators with two 9-kilowatt exciters and a switchboard were also installed. Current is produced for 2 cents per kilowatt-hour. This includes the salaries of two engineers, two firemen and the cost of unloading the coal.

Current is furnished for the waterworks plant two miles distant. The waterworks plant consists of one 125-horsepower motor direct connected to a three-stage centrifugal pump.

A close record is kept at the electric plant of the coal, oil, grease, waste and packing and other supplies used. The amounts used are put down on the daily station report. All meters are read daily and the readings are kept on the daily station report. The total outlay, including the erection of the building, was approximately $[illegible].

As soon as the new plant was put into operation a continuous service was established which has given the people the advantages of both the day and night service, while formerly, under the old plan, only night service was available.

All rates were put on the meter basis of 12 cents per kilowatt-hour, but after the erection of the new plant, this cost was further reduced by the establishment of a sliding scale which ran from 12 cents per kilowatt-hour down to 8 cents, according to the amount consumed.

Under municipal rule, and in spite of the reduced rates for power, the plant has netted the city a good profit. Besides taking care of the indebtedness of a few thousand dollars, incurred at the time the new plant was erected, keeping up the necessary repairs to the machinery, paying salaries of the employees and other necessary incidental expenses, the commission now has on deposit the sum of $10,000, which, although a portion came from the water works, was largely made up from the revenues of the electric-light plant.

I believe this plant is doing as well as most of the privately owned plants and better than most of the municipally owned plants.

Newnan, Ga.

No Water—Burnt Sheet

The following paragraphs tell about what might have been a disastrous boiler explosion had the boiler in question been cut in on the header at the time of the accident. The boiler is one of seven, all of which were connected into one common header.

This boiler was washed out on a Sunday and was filled with water to the second gage cock and left for the night fireman to steam up and cut in on the header for work Monday morning.

The boiler was fired about ? o'clock a.m. When the day crew came on duty at 6 o'clock a.m., one of the firemen noticed that the boiler had only 75 pounds pressure and opening the fire door to put in a fire discovered that the sheet over the fire was red hot. He closed the door and had gotten about 10 feet away when the rupture occurred.

The boiler exhausted itself of what steam and water there was in it in about four minutes. It was then noticed that there was still two gages of water in the glass, and upon investigation it was found that the bottom water-column connection was closed. The ruptured sheet was down 8 inches and the diameter of the bag was about 10 inches. The opening in the sheet was 6 inches long and the metal was drawn until the thickness at this point was but 1/16 inch thick.

The fact that this boiler was not cut in is perhaps all that prevented a disastrous explosion. The safety column was a hindrance as the water in the column sustained the float and kept the pressure on the controller-valve diaphragm which prevented the cold water being pumped in on the hot sheet.

I write this letter merely to show how some of the so called mysterious boiler explosions occur. If this boiler had exploded violently, anyone who might have seen it five minutes before the accident could have sworn that there was but 75 pounds of pressure indicated by the gage and two gages of water at the time. In reality there was 75 pounds pressure and practically no water.

Worn Governor Links Cause Trouble

At the plant where I am employed, a new, medium-speed cross-compound engine of an uptodate make was installed. When I indicated the engine I got a card that showed an unequal distribution of the load. I made adjustments but found that when I got the cutoff equal on both ends, I had interfered with the lead. As I believe that proper lead is more important than equal cutoff I put the valves back where I found them.

The governor of this engine is fastened to the shaft by means of setscrews set into the holes in the shaft. If one wishes to move the governor it would be necessary to move the hub an inch or more in order to find a new place for the screw and this would set the eccentric too far ahead or behind to give the proper lead.

After this engine had been running about a year it would speed up when the load was thrown off. It finally got to racing so badly that I would have to cut out the condenser in order to prevent a dangerous speed.

I located the trouble in the governor-link bearings which connected the weight to the eccentric. They were badly worn. The stud pins on which the link worked are of brass, but the link is made of wrought iron. This wearing allowed the weights to move out to their farthest position without carrying the eccentric with them, thus allowing the valves to open a small amount. This, combined with a 27-inch vacuum, caused the engine to race. I put in new links and this stopped the trouble.

Faulty Piping and Carelessness Wreck Engine

The Corliss engine in a mill plant became overloaded and a new high-speed engine was set up to take care of the lighting load.

Not wishing to install an extra condenser or to exhaust to the atmosphere, it was decided to connect the exhaust as shown in the illustration. The engineer wished to connect the engine direct to the condenser, but the makers of the engine connected it as shown. The engineer also wanted an automatic relief valve put in the pipe line, but the valve *B* was used instead.

The lights were on but a few hours, morning and night, and this small engine had to be cut in to the receiver connection while the mill was running. It was the custom to open the valve *B* in the morning and leave it open until the lighting engine was started in the afternoon. Then, while one man closed the valve *B*, another would open the valve *A*, which was placed where the back-pressure gage could be watched. It was, therefore, an easy matter to open the valve and keep a nearly even pressure.

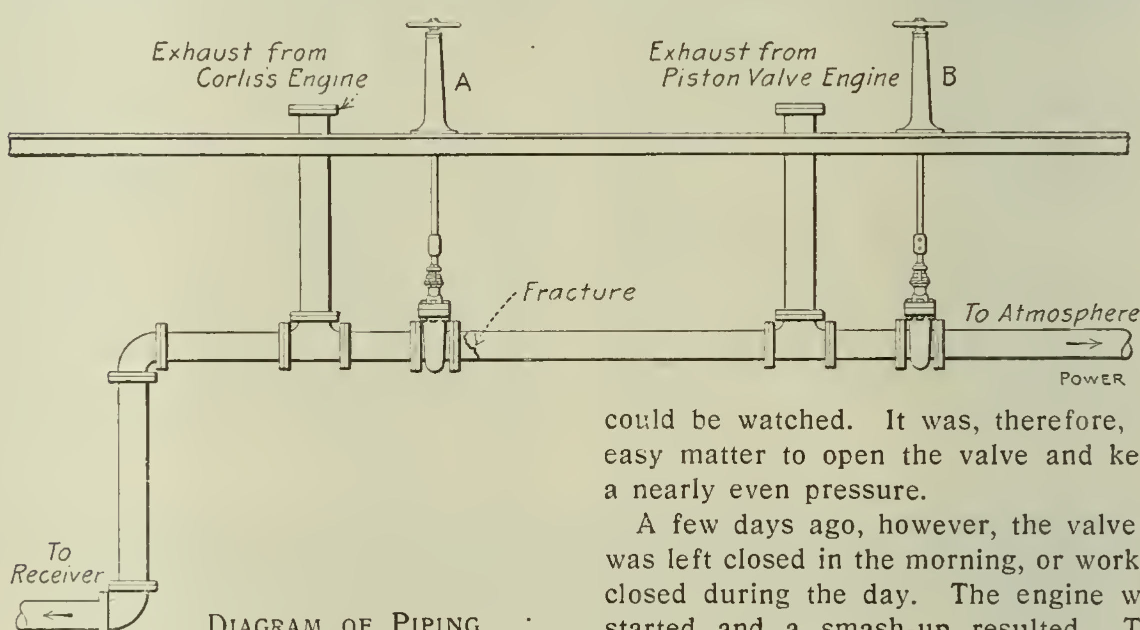

Diagram of Piping

A few days ago, however, the valve *B* was left closed in the morning, or worked closed during the day. The engine was started and a smash-up resulted. The irregular line shows where the exhaust pipe burst.

It is my opinion that the valve *A* was open just enough to allow the pipe to partly fill with water, thus causing the trouble. The engine had hardly turned over when the crash came. It is not strange that the exhaust pipe burst, but just why the engine was smashed so badly is puzzling. The engine accident indicates water in the cylinder while running at full speed, but the exhaust-pipe fracture would suggest water hammer.

Exeter, N. H. L. Johnson.

How to Condense Steam

I am working in a small steam plant where the drinking water is not fit to use.

Can some Power reader give me an idea of how to get up a cheap, convenient device to condense sufficient steam to get a couple of gallons of good drinking water a day?

E. G. Eldred.

Ellensburg, Wash.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Smoke Abatement

I agree with Henry D. Jackson, in the April 11 issue, on preventing smoke by the coking method of firing. I have used the coking method with good results, and prefer it to the spreading or alternate method for most kinds of coal. With this method we have had hardly any smoke, except when crowding the boilers beyond their rating, and then we did not have as much smoke as when other methods of firing were used. When burning run-of-mine coal we have had to resort to the spreading method for over the peak, which sometimes amounted to 50 per cent. overload; otherwise the coal burned too slowly.

Of course, no hard and fast rule can be laid down for firing, yet in the average plant the coking method can be used to advantage, although the fireman objects to it on account of the intense heat he must work in while pushing back the incandescent coal. If the bonus system were introduced and the fireman could see a few extra dollars in it, he would do it as cheerfully as going to a Sunday ball game.

I do not mean to say that firemen are of the shirking kind, but since they are paid a scant living wage for a 12-hour shift in a hot, dirty boiler room, with little or no chance for advancement, the inducement to save coal is not strong.

The coking method of firing and the bonus system of payment are certainly worth consideration.

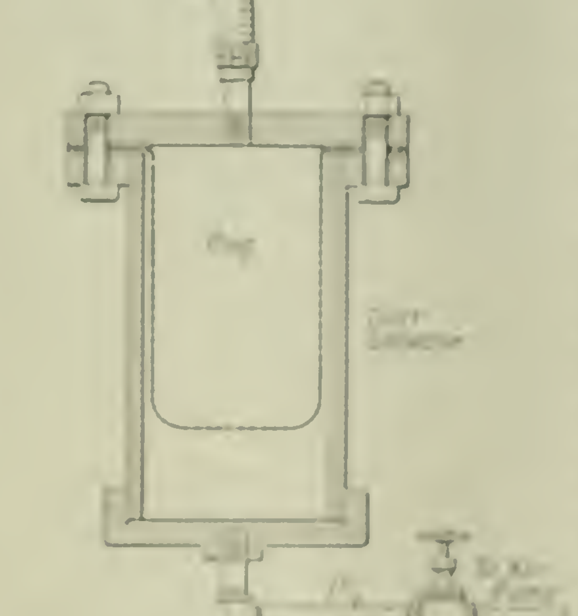
M. W. UTZ.

Minster, O.

Vacuum Cleaner

S. G. Rose, in POWER of May 2, page 688, asks for information upon how to construct a vacuum cleaner for use in his engine room. I will explain as well as I can how to construct a cleaner which will be found very useful in sweeping the floor and cleaning the walls and also will be found especially useful in the cleaning of street-car seats or steam-road coach seats. It can be used wherever there is an air pump or a condenser.

First, take a piece of pipe, preferably 12 inches in diameter, and cut it to the desired length (not less than 2 feet). Cover one end with a cap having a 1-inch pipe connection in it. Cover the opposite end as shown in the drawing. Make a bag out of good strong material like duck or canvas that will fit nicely inside the 12-inch pipe, not coming closer to the bottom than 6 or 8 inches. The top should be made flaring and will last longer if bound with a couple of sheet-iron rings the size of the flange. This sack is to catch the dirt and dust and is to be inserted inside the 12-inch pipe, the flaring top to be clamped between the halves of the flange union. To clean the bag, simply take it out and



VACUUM CLEANER

turn and brush it; it should go in either side out. The 12-inch vacuum chamber can be placed in any convenient location and connected to the suction side of the air pump or condenser with a 1-inch pipe, the connection being made in the bottom below the bag.

For the top there should be a 1-inch hose connection, taken preferably from the center of the flange union, or a pipe may be run from the flange union around the plant to any desired location and taps taken from it at different points, where a shorter length of suction hose will answer for the cleaner.

The cleaner may be made from hardwood, or a heavy brush may be used to advantage by cutting the bristles out of the center lengthwise of the brush, so as to form a slot about ½ to ¾ inch wide. The brush loosens the dirt and the air will draw it up into the hose. A slot will, of course, have to be cut through the wood of the brush and a holder for the hose may be made from a piece of pipe secured to the tin back with which it will be necessary to cover the brush.

J. G. DENNINGTON.

Oil City, Penn.

Solution to Coat Economizer Tubes

In the April 11 issue, page 573, a letter was published on economizer tubes corroding, by C. B. Smith.

The conditions he described are similar to other cases where the feed water used was remarkably pure and good. The deterioration of economizer tubes first came to my notice several years ago and seemingly nothing could be done to stop it. Then I thought it might be possible to plate or coat the inside of the tubes in some way to prevent the pure water from reaching the iron. I got prices, but the cost and expense was just double the price of the economizer.

Then it occurred to me that if I deliberately formed a lime scale on the surface of the tubes that it would accomplish the result I was after. I took the matter up with the Solvay Process Company and they recommended the use of a solution of lime to form such a scale. Some barrels of lime were bought and made up into a solution; the economizer was filled up and the gases were allowed to go through it for a day or so and thereby a nice fine glazed coating on the iron was obtained. The trouble immediately stopped and the machine remained sound and good for the following ten years without any repairs.

It is well known that lime is more soluble in cold water than in hot. Hence, I made a cold-water solution and, passing the gases through the economizer, the water precipitated the lime compound on the iron surface.

I would recommend that the next time after Mr. Smith's economizer has been bored and cleaned out, he have such surface coating applied to his machine and see if it does not stop further corrosion. This coating is as thin as tissue paper and makes no noticeable falling off in efficiency.

I do not think the coating has ever been renewed and, on account of the [illegible] pure water, no scale continues to form appreciably. Before, the scale was formed principally from the iron itself. I have applied the same treatment to one or two other machines where similar trouble showed, with success and no further complaints of corrosion.

Boston, Mass.

Cooling Hot Bearings

On the inquiry page of the April 18 issue of Power, H. C. B. asks for the best way to cool hot bearings while running and the answer is, "Use graphite and oil." I am aware that this mixture is what may be termed the standard cure for cooling hot bearings but, according to my experience, a good deal depends on other things. The best way to feed this mixture has always seemed to me to be through the oil or grease-cup hole, using a plug of wood to stir it through and having the mixture slightly warmed so that it runs through easily. Then, if the oil grooves in the bearing are cut on the small side or are shallow, this method of cooling off will not be so efficient as it will be if they are deep and of generous proportions. The same remark applies to short grooves leading "nowhere" which are not to be compared to crosscut grooves.

Another factor in the successful application of the graphite-oil mixture is the material of which the bearings are composed. Babbitt or antifriction metals are not as quickly cooled by the graphite-oil mixture as are gun-metal or bronze bearings. For antifriction metal bearings I prefer to use flake mica mixed with a good lubricating oil in the proportions (by weight) of 16 parts of oil to 1 part of mica. This mixture has indeed always seemed to me to be at least as efficient, if not more so, as the graphite-oil mixture in curing hot bearings, although I do not advocate its continuous use. I have been successful with the mica-oil mixture in cases which the graphite-oil treatment would not look at, and am acquainted with a railroad engineer in the running department of one of the largest railways in this country who advocates its use for locomotive hot boxes, although he uses more mica in his composition than I do for ordinary bearings—I think his is a 10 to 1 mixture.

Only a few weeks ago a friend of mine was having trouble with the gear box of his 25-horsepower automobile. This would run very hot in spite of all he could do and even the thickest oil he used would become thin enough to run out through the ball bearings and make a nasty mess in the undershield. The gear box has been back to the makers twice but has been returned, each time running hot again. The ball bearings are not the cause of the trouble, which appeared to originate with the gear wheels of the fourth speed, which is indirect and which my friend uses most of the time to save his engine. After he had tried oils and greases of all kinds and consistencies, including all sorts of graphite mixtures, I proposed giving the mica-oil mixture a trial. He did so with perfect success attending the experiment. The mixture was 15 parts of Vacuum Mobiloil, "C" grade, to 1 part of flake mica. I am inclined to the opinion that flake mica—more so than flake graphite—forms a more substantial cushion between the bearing surfaces, be they journal and brass or tooth against tooth, and it is not so easily squeezed out.

I have a case on hand at present of a 6-ton motor lurry, in which the steel timing wheels at the front of the engine make a loud buzzing noise in spite of their oil-tight casing being filled with lubricant of good repute and the right consistency. Encouraged by the success attained by it in the gear box above mentioned, I am going to give the flake-mica mixture a trial in this case. Were the gear-wheel case open to the engine-crank case I should hesitate before trying a mixture of more than 1 part of mica to 20 parts of oil because, the engine being provided with forced-feed lubrication with drilled crank shaft, connecting rods, etc., I am afraid that the small passages in these parts might become choked with the flake, with perhaps serious results to the engine.

John S. Leese.

Manchester, Eng.

The Position Higher Up

Mr. Miles' article on the above subject in the May 2 number contains some good points and moves me to submit a few comments on the subject of advertising for positions and answering employers' advertisements.

In writing an advertisement for a position it seems to me it should contain a brief description of ability, an offer to refer to past employers, a mention of sobriety, and, last but not least, a willingness to accept the position on trial.

I have always found it an easier matter to write an intelligent advertisement than to answer one of the ordinary kind placed by many employers. Even after corresponding with them it is a difficult matter to get them to state the full particulars of the position in question.

Several years ago I placed an advertisement for a position that would pay not less than a stated amount, and received an offer as head engineer in a 600-barrel flour mill in a small town of a few hundred inhabitants.

On asking for full particulars they informed me the mill operated day and night, I would be expected to do my own firing, and the plant consisted of two boilers and one Corliss engine.

I accepted the position and on arriving found two boilers, one Corliss engine, one high-speed engine driving a generator furnishing lights for the village and the mill, and one engine running the elevator. In addition there was a geared locomotive used for switching purposes to be kept in repair.

I refused to remain under those conditions, and was therefore out the expense of a 500-mile trip that could have been avoided had they given me the full particulars.

We often see an advertisement reading something like this: "Wanted: First-class engineer to take charge of complete steam-power plant. State experience and salary desired. References required."

There is nothing intelligent about such an advertisement. Possibly it is a 6000-horsepower plant and again it may be only a 1000-horsepower plant. If one were to make a price to fit the former and the plant was of the latter, possibly he might lose just the position that would suit him best. It might have been an uptodate plant in the locality he desired and had he known it could have made the price accordingly. The chances are the letter would never be answered.

Joseph Stewart.

Hamilton, O.

An Engineer's Views

Referring to the editorial on the first page of Power of February 21, it is only too true that a great many of us do become so absorbed in the routine work that we fail to see the advantage of adopting some new method or appliance, and at other times we realize the advantage but wait for some favorable opportunity to explain our views, and while we are waiting some specialist comes in and recommends that such and such be done. It also often happens that when the engineer does advise the purchase of some new machine or appliance, he is not prepared to show just what the advantages are or what the saving will be, while the expert is loaded with the necessary data to prove all that he claims. It would be unreasonable to expect the operating engineer to be as well posted on all subjects connected with the power plant, as half a dozen specialists would be on the different subjects.

The engineer and manager should be on friendly terms and should understand each other and the conditions under which the plant must be operated. The engineer should endeavor to prove that, while he is a necessity, he is the most valuable man on the place, not by doing all the dirty jobs that no one else wants to do, but by keeping up with the times, being posted on the latest and most improved methods, and last but not least by putting his knowledge into effect. A few years ago the engineer was the one called on to do all the odd jobs that no one else was willing to do, while today there are hundreds of plants where the engineer is highly respected and has all the authority he wants. There are hundreds of managers and owners looking for men capable of assuming the responsibility of their plants and making a success of them.

The refrigerating engineers have recently organized the Practical Refrigerating Engineers' Association, for the purpose of educating and elevating its members, and their constitution plainly states that the association shall at no time take part in any strike or anything that will in any way interfere with perfect harmony between its members and their employers. Owners and managers are eligible to associate membership and are welcome at any and all of their meetings. It is the earnest desire of the association to create a more friendly feeling between its members and their employers than generally exists.

J. B. Embrey.

Shreveport, La.

Water Coils Burn Out

On page 534 of Power, April 4 issue, is an article by R. A. Booth about water coils burning out. I would suggest that all the return bends be taken off and manifolds substituted. It is evident, with the coils burning out so rapidly, that the pipe is not always filled with water.

Suppose the boiler is being fed lightly, then the water having a slow but forced circulation would gradually increase in temperature until steam was generated. This would, of course, allow the coils to be burned.

To obtain proof of this, Mr. Booth could attach a thermometer cup to the line after it leaves the coil to enter the boiler.

If the feed pipe, after leaving the coil, does not come out of the brickwork, it would probably be an easy matter to extend the pipe and return it so that the temperature of the water could be taken. By doing this Mr. Booth might also obtain an answer to his second question, "Do these coils increase the efficiency or capacity of the boiler?"

Mr. Booth also asks what advantage the coils have over other kinds of feed-water heater? This is a question that can be best worked out individually. If Mr. Booth has plenty of exhaust steam that is going to waste, then without a doubt a good first-class exhaust-steam heater would raise the temperature of the feed water to around 212 degrees and would be a good investment. If the temperature of the feed water cannot be raised economically beyond 120 degrees, then I should think the coils would have the advantage.

Some time ago, at a plant where I worked, they decided to try coils in the furnace. The boilers were forced pretty hard and were fired with anthracite coal. Everything went along smoothly for about a month; then came the climax in the shape of a return bend bursting. Both fire doors were blown open and hot water, ashes and coal enveloped one of the coal wheelers, badly burning and scalding him. The brickwork inside the furnace had to be renewed.

G. H. Handley.

Newburgh, N. Y.

The Line Shaft Breaks

The question in reference to the breaking of line shafts in Power for May 2 comes under my observation and practice, generally with the following results: Hemp rope is continually expanding or contracting with weather conditions, and on the single-rope, or what is better known as the independent-rope, drive always gives the most trouble from breakage of the shafting. Take Fig. 1 for an example, which shows a central wheel with bearings placed a considerable distance from the hub. The shaft is sure to break sooner or later. By moving these bearings close up to the hub, the danger of breakage is greatly lessened.

The tension of the rope causes a continual springing of the shaft, and, to further sustain this statement, the shaft invariably breaks in damp weather when the rope would be the tightest. Another reason is that the rims of large rope wheels vibrate, due to the side swing of the rope. I believe this also tends to spring the shaft and compels it to yield when the bearings are placed as far apart as shown in Fig. 1. By moving the bearings A and B closer to the hub a much better support is obtained.

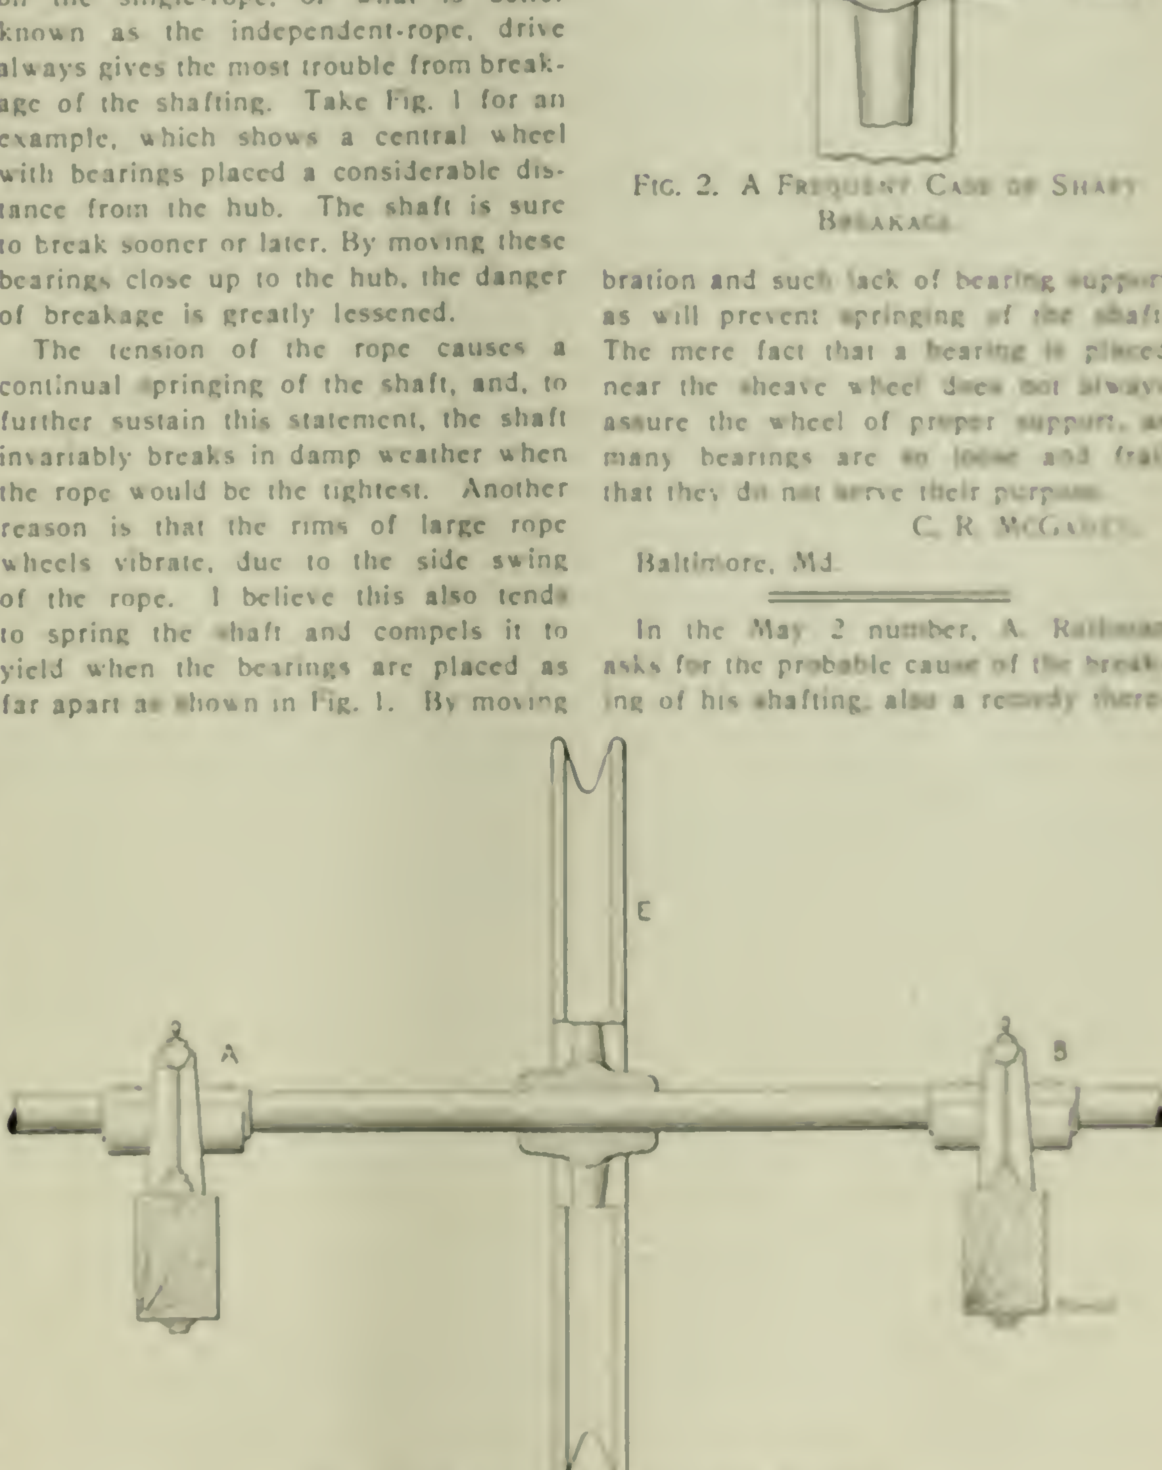

Fig. 1. Bearings Too Far from Wheel

Fig. 2 shows another example in shaft breakage. I have seen this both in belted and rope-drive wheels. The same shaft was broken several times in the same place, the break occurring in each case at the center of the hub, which was made with a long counterbore. This break would always occur at M. On one occasion the hub was bored out up to the counterbore and a sleeve inserted. No further trouble was experienced. Whether this proves the case or not it is a practical example. Possibly a piece of shafting was secured that was more homogeneous.

I believe that Mr. Rathman will find that his trouble comes from lateral vibration and such lack of bearing support as will prevent springing of the shaft. The mere fact that a bearing is placed near the sheave wheel does not always assure the wheel of proper support, as many bearings are so loose and frail that they do not serve their purpose.

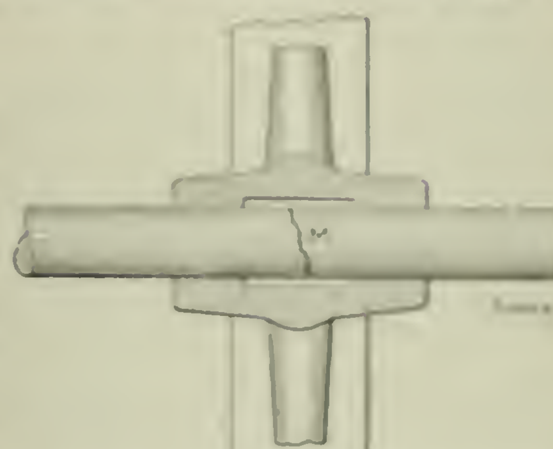

Fig. 2. A Frequent Case of Shaft Breakage

C. R. McGahey.

Baltimore, Md.

In the May 2 number, A. Rathman asks for the probable cause of the breaking of his shafting, also a remedy therefor. He has hardly given sufficient data for accurately diagnosing his case, for he might have mentioned the number of revolutions the shafts are making per minute, the distance between the hangers and the pulleys, the kind of machinery driven, etc. In the absence of such details only general suggestions can be offered.

Seeing that the shafts are carrying rope sheaves they should be proportioned for head shafts. Applying a rule used by Jones & Laughlin for cold-rolled iron shafts of this class, hangers not more than 8 feet apart, the following formula is obtained:

$$H.P. = \frac{Dia.^3 \times r.p.m.}{100}$$

It will be found that the $2\frac{15}{16}$-inch shaft, to transmit 50 horsepower, must run at a speed of not less than

$$\frac{50 H.P. \times 100}{2\frac{15}{16}^3} = 198 \textit{ revolutions per minute}$$

In the same way the $2\frac{7}{16}$-inch shaft, to transmit 20 horsepower, must run 138 revolutions per minute. If the shafts run slower they are overtaxed. When shafts are so loaded and supported that the deflection amounts to more than 0.01 inch per foot of clear length between bearings, they are apt to break. To guard against this use hangers at shorter intervals and, if possible, place a hanger close to each side of a sheave. If the full power is delivered by one sheave located in the middle of an 8-foot span, the $2\frac{15}{16}$-inch shaft ought to be increased to $3\frac{3}{16}$ inches.

It is stated that the shafting is in line; but while this may have been the case once, it should be verified periodically, especially after an accident, and the anchor bolts of the hangers tightened. Care should also be taken to allow sufficient end play, the shaft collars and couplings being set to allow full sway to expansion resulting from heating. A shaft 245 feet long will, in warming up from 60 to 110 degrees Fahrenheit, increase one inch in length.

If the shafting suffers from irregular vibrations, it might be advantageous to place a few small flywheels on it for equalizing. Keyways are known to weaken shafting and to affect its alinement. The diameter should therefore be increased, or split pulleys and couplings used, which are merely clamped to the shafting and strengthen instead of weaken it.

If the path of the ropes is not steeper than about 45 degrees from the floor up, the drive may, as a last resort, in some places at least, be changed over from the American system with its one continuous rope, to the English system with a number of independent ropes. In this way the shafts may be slightly relieved and in case one rope breaks the others will carry the load until opportunity permits making repairs.

Charles H. Herter.

New York City.

Judging from the sizes of shafting given by Mr. Rathman and supposing that they run at a moderate speed, the shafts should easily deliver the power mentioned without being strained, but the fact of their breaking is evidence of a strain beyond their power to withstand.

From the article it would appear that the shafting is suspended from the ceiling by hangers. I have seen hangers sprung out of line considerably by belt tension, thereby causing the very trouble of which Mr. Rathman complains. This can easily be tested by taking a broomstick, driving a wire nail into each end, the whole being long enough to reach from some point near and to just touch the shaft when stationary. Put the shaft in motion and the stick will show any bending or nonalinement.

I would next look at the distance from center to center of the bearings on each side of the driving wheels and would endeavor to place them as close as conditions will permit. If the bearings are as close as possible, then a new shaft should be installed with a "swell" of at least ½ inch where the driving wheels go and let the larger diameter extend some distance on each side.

I have in mind one shaft which had given a lot of trouble and had been replaced several times. Increasing the size did not overcome the trouble. When the broomstick method was tried it was at once apparent that the supports on the ceiling were not rigid enough to stand the strain when the shaft was in operation. The shaft was then placed on proper foundations on the floor, and no further trouble was experienced.

C. F. Sampson.

Philadelphia, Penn.

If Mr. Rathman's shaft is in line and is not overloaded. I would suggest that a hanger be placed near the sheave. Without much doubt the distance between the hangers is too great, and when the shaft is carrying the load the strain is at the sheave.

Albert T. Guilman.

Stafford Springs, Conn.

Installing Oil Burner

On page 694 of Power, May 2, E. W. E. asked for a little information on installing oil burners.

Having had some seven years' experience in that line of work, I would say that the answer gives him the *little* information, and very little at that, especially if he is in no way familiar with oil burning.

The proper arrangement of a furnace for the economical burning of crude oil depends on several conditions, one of which is the kind of boiler under consideration. As he does not state this, I will suppose he means a standard return-tubular boiler of the class usually employed in stationary work and 66 inches in diameter by 16 feet in length. In this case the bridgewall should be entirely removed and the grates should not be less than 24 inches or more than 36 inches from the shell of the boiler for economical results. The combustion chamber should be filled up with earth to within 16 inches of the shell at the back end of the boiler and continued on an incline toward and meeting with the back end of the grates, and may be rounded slightly up toward the side walls.

The entire surface should be covered with firebrick, including the grates, excepting a space 12x18 inches in each corner at the front of the furnace. These will admit a sufficient amount of air for most cases. Aside from this the interior of the furnace need not be changed from what it was for burning wood or coal.

The blowoff pipe should be protected by a firebrick pier built up in front of it to where it enters the shell. The burner should be set in the center of and extending into the furnace 4 inches beyond the door-jamb line. The distance from the top of the firebricks on the grates to the center of the opening in the burner should be 6 inches. Be sure to set the burner exactly level. If it is allowed to slant downward, the flame will strike the bricks and reflect against and injure the boiler shell. If it points upward, the oil will not burn steadily and the boiler, as in the other case, will be injured.

The opening in the burner tip should be of a sufficient width to just allow the flame to reach the side walls when working at its full capacity. If this plan is followed, no damage will result to the boiler under the heaviest firing. However, care should be taken not to crowd the fire until the setting has become thoroughly heated up.

Charles F. King.

Portland, Ore.

Buying Coal on B.t.u. Basis

I have followed with a great deal of interest the numerous articles in Power from the scientific writers who have been urging that a little more science is all that is required to make everything lovely in the power house, but I am afraid that these writers too often overlook the problems of human nature and established commercial conditions.

For instance, I have been greatly impressed with the arguments in favor of the purchase of coal on a B.t.u. basis, so I decided hereafter to buy heat units instead of mere carbon and ashes, and solicited bids from numerous mines for a shipment of 400 tons of pea coal for gas producers, payment to be made on a basis of B.t.u. Practically every mine on the line of the Central Railroad of New Jersey (to which we are bound hand and foot) replied in effect that they did not take any stock in heat units and I could buy the coal just as they offered it or go without, as I chose.

I agree in the abstract with everything that the scientific men have written, but, unfortunately, very few of their suggestions can be carried out under present conditions.

POWER

The Oil Engine

There is probably no field in which prophecy is more futile or less likely to be vindicated than in engineering. People are continually developing apparatus which had been solemnly declared impractical years ago by those versed in the scientific principles involved. For example, before steamships were fully developed it was asserted by authoritative students of the subject that Fulton's efforts, while laudable and practical within a very restricted range, could never result in transatlantic steamboats because a boat could not carry enough coal to keep up steam throughout such a long trip, even if the engine could be made to run continuously, which was considered highly dubious. It was also proclaimed that Professor Langley's optimism regarding the possibility of building a flying machine was without solid scientific foundation because it would be impossible to make an engine light enough to enable it to sustain its own weight and that of the machine and the operator.

The same general kind of predictions have been made concerning the future of high-compression oil engines such as the Diesel. In the first place, the supply of petroleum products could never be sufficient to meet the requirements of any very large aggregate of power output; in the second place, the nature of the operating cycle demanded the unremitting care of a corps of highly skilled technical nurses which would cost more in excess wages than the saving in fuel expense and fixed charges would cover. These predictions are apparently being refuted as effectively as the others have been. Recognizing the limited supply of crude petroleum, the Germans have resorted to the production of fuel oils from almost as many and as unsuspected sources as have been pressed into use by makers of American breakfast foods. Also realizing that men trained in high-grade manufacturing are not commonly obtainable in Siberian wastes or South American jungles, they seem to have raised the mechanical structure of the oil engine to such a degree of dependability as to encourage its use almost outside the geographical limits of civilization.

We are reliably informed that the Diesel type of oil engine is in actual use in Siberia, under mechanically low-grade supervision, to the extent of thousands of horsepower, and we sincerely take off our hat to the men who have achieved the results which make such a thing possible and express a cordial wish that American engineers may emulate their fine example.

Mathematics and the Engineer

It is, perhaps, unfortunate that comparatively few operating engineers are mathematicians and that any matter containing algebraic signs is avoided like a pestilence by the most of them. But there is this mitigating condition: Mathematical talent and practical fitness for the care and operation of moving machinery are seldom found in one individual.

It is, however, fortunate that all of the mathematical knowledge that is really needed by an engineer may be readily acquired by anyone who has the attainments expected in a schoolboy fourteen years of age. It is not so much the lack of the little skill necessary to handle algebraic formulas and elementary trigonometry that handicaps the operator as his aversion to logical thinking.

As a boy, when playing seesaw, he instinctively took such a position on the plank that his weight balanced that of the boy on the other end, but he did not then, and probably has not since, considered that his weight multiplied by his distance from the supporting trestle or the fence rail exactly equaled the product of the other boy's weight and his distance from the fulcrum. If he had, and in consequence of this consideration had calculated the weight of his playmate from the relative distance of the two from the fulcrum, no safety-valve problem would require the hours of study sometimes given to the subject.

There is no good reason why the engineer should balk at algebra or trigonometry. The formulas are merely a "shorthand" way of writing a rule and they are much simpler and more easily remembered than the long-drawn-out statement of the same operations expressed in conventional English. When the electric generator, the refrigerating system, the air compressor and the hydraulic elevator were placed in his charge, the engineer did not balk because he did not understand them. He tackled the problems man-fashion and mastered them.

If he would pursue the same course with mathematics he would be surprised at the shortness of time in which formulas that previously seemed hopelessly complicated became clear.

No investment that an engineer can make will pay such dividends as time spent in the study of the elementary branches of the science most nearly related to his work.

Practice and Theory

At the recent meeting of the American Society of Refrigeration, in Chicago, it was said that when a need arises in this country for some application of refrigeration, when something needs to be done and done quickly, we go ahead and do it and then send to Germany to find out how we did it.

The one illustrates practice, the other theory. Seemingly they do not always go together. For instance, theory says that we should always keep the fire doors closed; that air, admitted over the fire, results in cooling the gases of combustion and therefore decreases efficiency. But many firemen who never heard of a heat unit have discovered that leaving the door cracked open immediately after firing results beneficially.

Careful experiments with pyrometers in boiler settings have verified the fact that the temperatures are actually higher and more water is evaporated when the door is opened slightly immediately after firing, than when the door is kept closed.

The nontheoretical fireman who first found this out was satisfied to know what he knew without knowing why he knew it, but the man who made the pyrometer experiments was not so easily satisfied. He called on theory to explain and theory responded with an explanation.

Of course, after practice had pointed the way it was easy to show that on account of the large amount of volatile matter being distilled from a freshly replenished fire, better combustion could be obtained by allowing some air to enter directly over the fire and burn the gases, which otherwise would not get sufficient air through the grate and would pass off unburned. Theory did not lead the way in this, however; it was practice which first demonstrated it.

The moral is: Do not be hedged in too closely by the theories that you already know; by trying something that seems to be contrary to those theories you may do something better than it has ever been done before, and the theoretical law governing the case will be promptly brought to the front. But do not take this as advice to waste time and money on things that clearly violate fundamental natural laws, such as perpetual-motion schemes.

The Passing of the Piston

Eight years ago we published an editorial under the above title. With the passing of the years the tendencies which were the theme of that article have become more marked. For large electrical work nobody thinks of anything but the steam turbine which is now built in units of twenty thousand kilowatts, with no indication that the limits of capacity or of efficiency have been reached, and is developing a horsepower-hour on less than ten pounds of steam.

More than four million kilowatts capacity have been sold by the three large companies, the far greater proportion of it since the editorial in question was written. The small steam turbine is making serious inroads into the field of the high-speed automatic engine. The turbine pump is continually winning favor even for pressures as high as those required for boiler-feed service.

And now comes the centrifugal blowing engine to contest the field with the massive air tub driven by a slowly running reciprocating engine. A sixty-thousond-foot centrifugal blower turbine driven with condenser complete can be had for sixty thousand dollars. A gas-engine driven blowing engine of the same capacity would cost two hundred thousand. Is the greater efficiency of the gas engine worth this difference in cost?

Chimneys

A subject about which the average engineer knows very little is that of chimneys. He may have a somewhat hazy recollection of having been taught that the principal factor affecting natural draft is the difference between the weights of the column of gas within the chimney and that of the outside air; but if called upon to calculate the size of a chimney he would probably be all at sea.

Both Rankine and Peclet attempted to solve the problem from a theoretical standpoint, but their formulas were more or less involved and it was found hard to apply them to practice. Later authorities have formulated empirical rules, but their constants have differed widely and the results, as a whole, are far from satisfactory.

The design of a chimney is much more complex than determining the dimensions of a steam engine to produce a given power at a given steam pressure and piston speed. In the case of the steam engine most of the quantities are fixed or under complete control, whereas, with the chimney, so many variables enter into the problem as to make it indeterminate except for assumed conditions. If more coal is to be burned per square foot of grate surface it means a larger volume of gas passing up the chimney, which must be provided for by increasing either the area or the velocity, the former requiring a larger diameter of chimney and the latter a greater hight. Furthermore, different thicknesses of fuel bed require different intensities of draft, or a wind blowing over the top of the chimney may produce suction and increase the draft. The length of flue, number of bends and the path of the gases through the boiler, all have their effect upon the draft.

With such conditions, it may seem strange that so many chimneys are built which successfully meet the conditions of service. The fact is, however, that chimney designers, while employing empirical formulas to a certain extent, really depend more upon their experience and the large amount of data at their disposal than upon the formulas.

A Good Suggestion

At the Illinois State convention of the National Association of Stationary Engineers, a valuable suggestion was made regarding the possibility of the organization coöperating with the University of Illinois in educational work. The Illinois State Association has an educational committee the duty of which is to promote, in one way or another, interest in engineering subjects among the different local associations.

This has been done by issuing, periodically, a list of questions to be answered by the associations, with a prize for the highest grade during the year, and by giving lectures on various engineering topics at different points in the State.

The suggestion was to consider the possibility of arranging with the university an annual meeting extending over perhaps two days and one night, at which lectures would be given and tests run on various power-plant equipment available in the laboratories, the subjects being such as would appeal especially to men engaged in the steam-engineering field.

There is no doubt that the university would welcome any such arrangement. A great deal of the information now gathered by the university is ineffective merely because of the failure to get it into the hands of the proper persons. One of the former professors, happening to be in the engine room of a power plant and noticing some bulletins of the university on the desk, asked the engineer how he came to get them. The reply tells how a great deal of this material goes to waste: "The university sends the bulletins to the superintendent; he throws them into the waste basket and I pick them out!" Undoubtedly there is too much of this waste-basket circulation.

It is to be hoped that there will in the future be more of an organized effort on the part of engineering societies toward closer relations with the various institutions of learning, not only in Illinois, but elsewhere.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Steam Engine Regulation

I have a 16x42-inch Corliss engine which takes steam full stroke a large part of the time. If I change the length of the knockoff rods to give a longer cutoff, the engine lags and seems to have little power. What can be done to improve the regulation?

W. H. M.

It appears that your engine is either overloaded or the valves are not properly adjusted and should be reset.

Place the wristplate in the middle of its travel; adjust the valve connections so that the steam valves will have 5/16-inch lap, and the exhaust valves stand open 1/32 inch. Block the governor 3/16 inch above the rest, and with the engine turning over slowly adjust the knockoff rod so that the head-end valve will unhook and the crank-end valve hook will just touch the knockoff block.

Changing the length of the rod as you do will only throw the governor out of adjustment, without helping in any way, and may be the cause of a runaway engine with a light load.

Pitch of Grates

Why are the grates in a boiler furnace, pitched toward the back of the furnace?

C. H. M.

Grates are inclined toward the bridgewall for the purpose of making it easy to distribute the fuel and to rake and slice the fire. It also tends to make the fuel bed thicker at the back of the furnace where the air tends to pass most freely.

Vibration of Reach Rod

We have a Corliss engine the rod to the steam valves of which vibrates to such an extent that it is feared it may break. The rod to the exhaust valves does not vibrate. The rod in question at the carrier arm is reduced from 1¼ inches to ⅞ inch. Will you give an explanation and remedy for the vibration?

A. E. S.

Vibration in the reach rods of Corliss engines is frequently caused by insufficient lubrication of the steam valve. It is usually most severe during the first hour's run. The dimensions of the rod are carefully calculated by the designer and are, as a rule, safe for the work they have to do. The vibration may be stopped by hanging a small weight to the middle of the length of the rod by a cord which will allow it to swing clear of the floor, or by a light truss on the underside of the rod. There is, so far as is known, no record of the breaking of one of these rods from excessive vibration.

If the vibration is severe and attention to valve lubrication does not remedy it, the matter should be taken up with the engine builders.

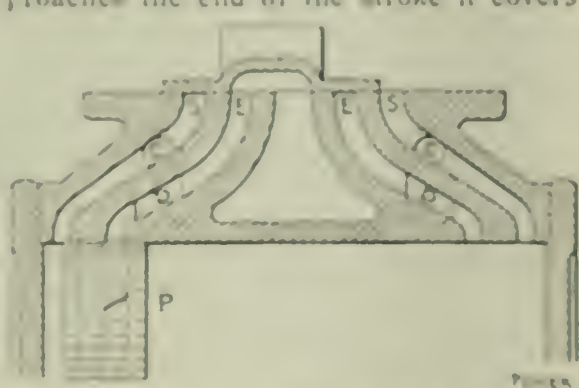
Duplex Pump Valves

Does increasing lost motion of a valve on a duplex steam pump lengthen the stroke? What keeps the piston from striking the head?

O. W. P.

Increasing the lost motion of a valve in a duplex steam pump lengthens the stroke.

In the duplex pump as the piston approaches the end of the stroke it covers



Section through Valve of Duplex Pump

the exhaust port, trapping some steam, which by compression stops the piston before it reaches the cylinder head, as may be seen by the sketch, in which *S S* are the steam and *E E* the exhaust ports. *D* is a cross passage from the steam to the exhaust port controlled by a valve at *C* which determines the amount of compression by regulating the flow of steam through the passage to the exhaust port after it has been closed by the piston.

Temperature Rise of Dynamos and Motors

What rise of temperature is safe for a dynamo or motor?

C. F. J.

Field-magnet coils and armature, 80 degrees; commutator and brushes, 90 degrees; bearings and other parts, 75 degrees, all Fahrenheit.

Effect of Service on Lamp Filaments.

When an incandescent lamp has been in service a long time, does it pass more current or less than it did when new, and why?

C. E. B.

It passes less current, because the filament wastes away during service, reducing its cross-section and thereby increasing its resistance. The candlepower decreases more rapidly than the filament section, however, so that the current *per candlepower* is greater than when new. A 16-candlepower lamp taking ½ ampere new will take about 0.47 of an ampere after burning 500 hours, but its candlepower will be reduced to about 13; the current per candle, therefore, is 0.03125 of an ampere when new and 0.03615 of an ampere after burning 500 hours.

Combined Motive Powers

Is it feasible to help out an overloaded steam engine by belting an electric motor to the line shaft to which the engine is belted?

B. S. Co.

Entirely so. It is only necessary to make the pulley ratio such that when the motor is running free, with normal field excitation, its speed will correspond to the normal speed of the line shaft. A small adjustable resistance in the field circuit of the motor will enable you to regulate the amount of power it delivers to the line shaft; cutting in resistance will increase the power delivered, by causing the motor to try to run faster, and thereby relieve the engine.

Why Allow Any Drop?

Why is any drop in voltage allowed in electrical circuits?

T. Y. H.

For the same reason that a bearing is "allowed" to consume power and heat is "allowed" to get away up the chimney of a steam boiler. Because it cannot be prevented. The drop in voltage is due to the electrical resistance of the conductors through which the current passes, and there is no material yet discovered which has no resistance.

Large Wire Gages

In speaking, how are the large wire sizes, such as Nos. 00, 000 and so on, expressed?

T. Y. H.

Number two naught, three naught, etc.

Baffles for Curtis Turbines

On the vertical Curtis turbine, a baffle similar to that shown in Fig. 1 is used between the oil pump and the step bearing. The oil, entering at the left, passes through a sieve of wire gauze and then through the threads of the helix *A* to the outlet. By screwing the bolt *B* further into the helix the latter is driven to the right and the tortuous path of the oil shortened. It serves, in effect, as a throttle valve for the oil, and prevents its sudden escape backward and the consequent sudden dropping of the step in case of the failure of the oil pressure.

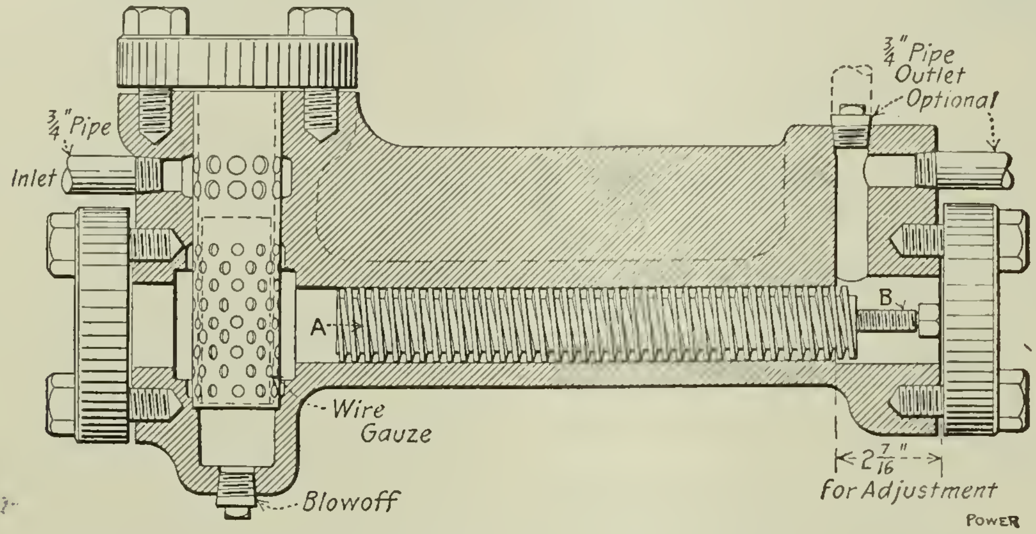


Fig. 1. Baffle Used between Oil Pump and Step Bearing

These baffles are ordinarily made of cast iron, and at a station where they are used under a pressure of 1500 pounds per square inch they failed after a year or two of service. An attempt was made to cast them in bronze to a pattern made to conform to Fig. 2, but out of a lot of 20 only one was found to withstand the required test pressure of 3000 pounds per square inch.

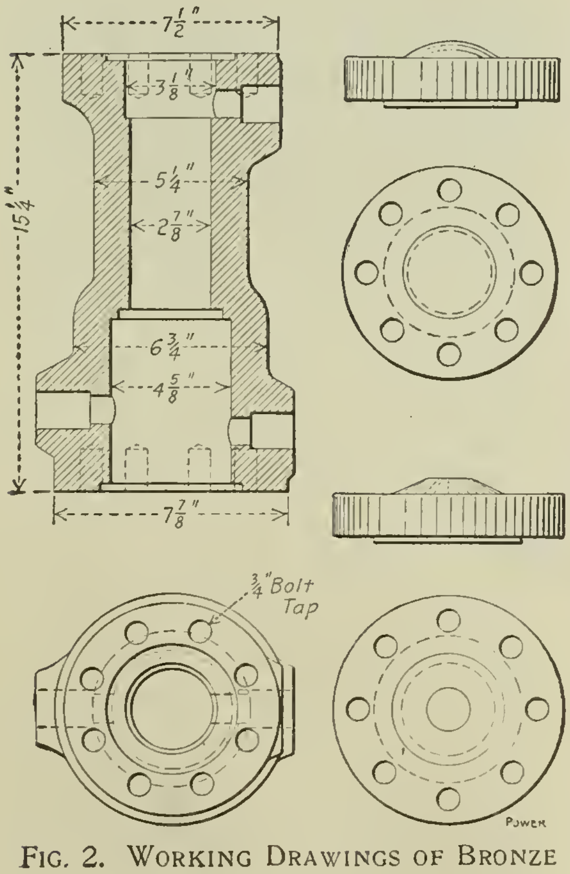

Fig. 2. Working Drawings of Bronze Baffle

An order was then placed with A. Allan & Son for 16 to be cast in manganese bronze to the same pattern. They cast one-half of these, and out of the lot of eight only two remained tight under the test pressure. They admitted their inability to fill the order and asked to be allowed to substitute for the manganese No. 2 Allan metal, an alloy consisting of 66 per cent. copper, 25 lead and 9 tin. Permission was accorded and out of 14 made in one cast 11 successfully withstood the application of the 3000 pounds. Five of these are now in use, and it remains to be seen whether they will endure the stress of continued service better than the cast-iron prototypes.

Fig. 3 shows one of the finished castings attached to the ram for testing. The ram is capable of exerting a pressure of 10,000 pounds per square inch, and is used for taking armatures off from and putting them on to the shafts.

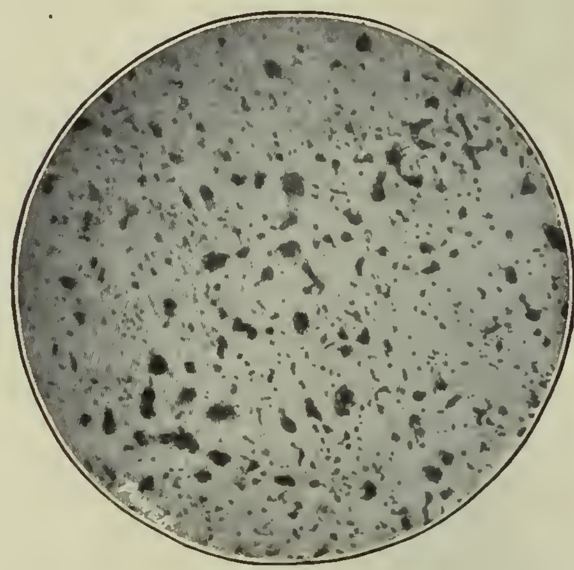

Fig. 4. Allan No. 2 Bronze Magnified 45 Diameters and Reduced from 2 3/4 Inches

The characteristics of the metal are given in the accompanying report of a test by Professor Pryor of samples, one from the commencement and the other from the end of the pour.

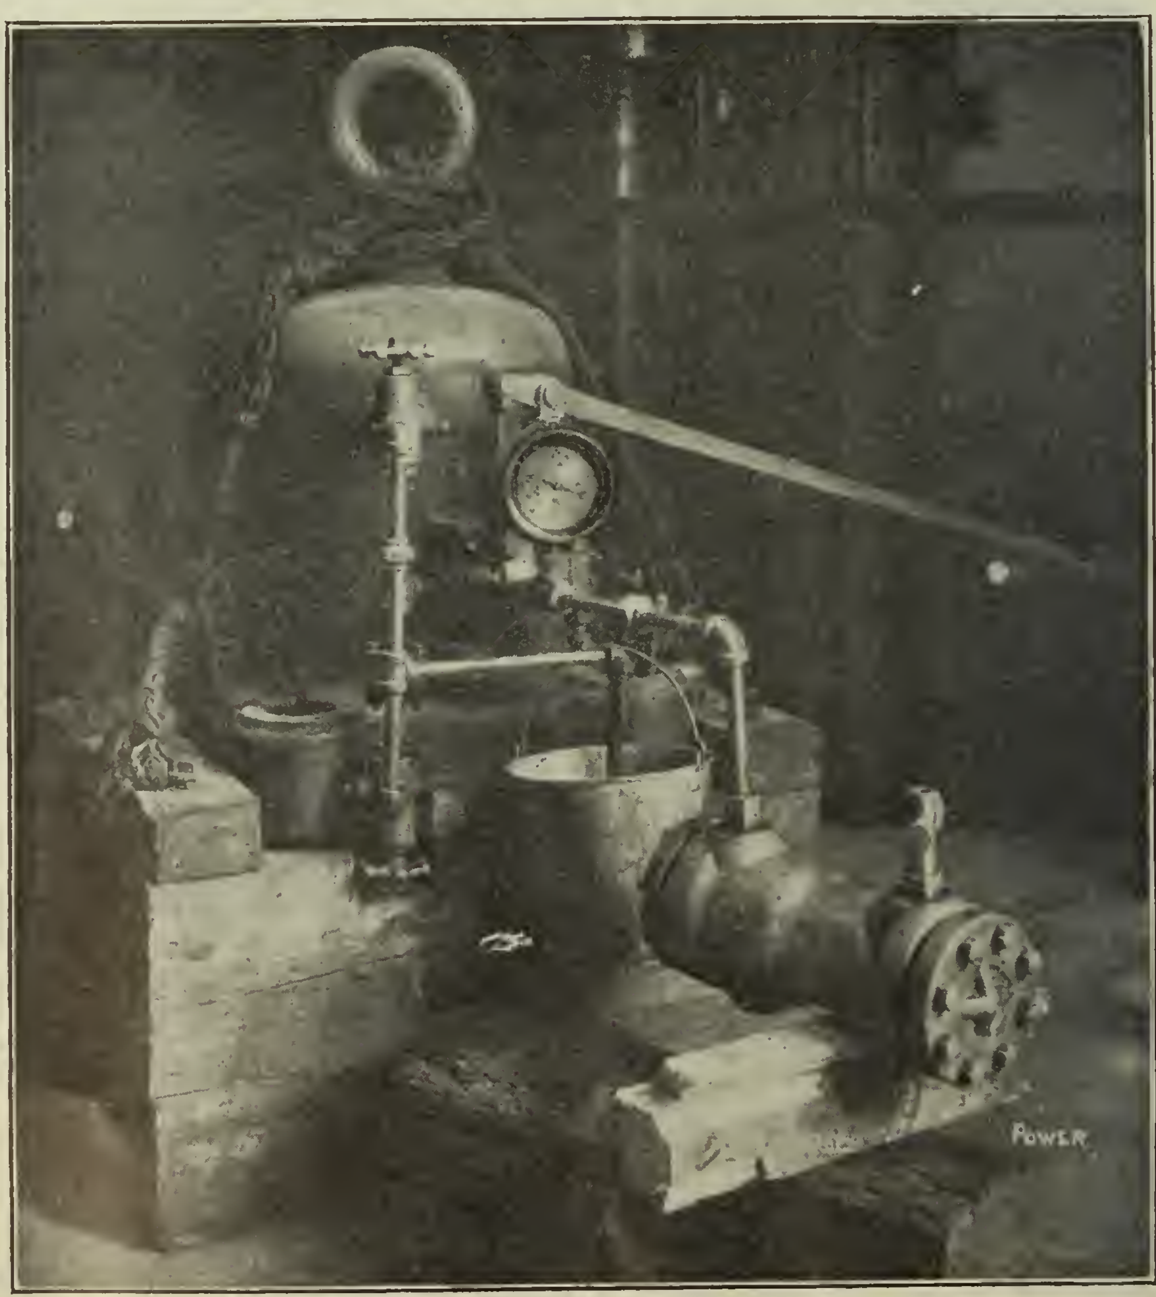

Fig. 3. Baffle Made of No. 2 Allan Metal under Test

RESULTS OF TESTS CONDUCTED BY PROFESSOR PRYOR

Designation of material	No. 1	No. 2
Diameter of specimen, inches.		
Original	1 496	1 498
Final	1 460	1 470
Area of specimen, square inches.		
Original	1 7577	1 7624
Final	1 6742	1 6972
Reduction of area, per cent	4 7	3 7
Elongation, measured over 9 inches, per cent	4 4	3 8
Elongation, measured over 8 inches, per cent	4 6	3 9
Yield point, pounds.		
Actual	25 500	21 750
Per square inch	14,370	12 340
Ultimate tensile strength, lb.		
Actual	30 710	30 100
Per square inch	17 470	17,080

A microphotograph taken by Prof. William Campbell, of Columbia University,

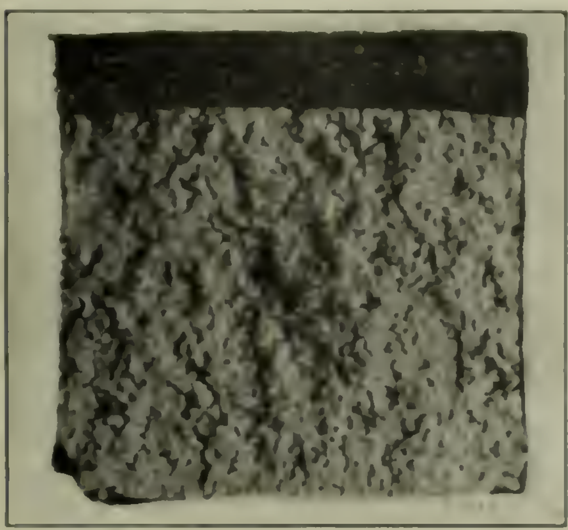

FIG. 5. A FRACTURE OF ALLAN NO. 2 BRONZE MAGNIFIED TO SHOW GRAIN OF ALLOY

and reproduced in Fig. 4, shows the density and character of the metal. The difficulty is not so much one of strength as of imperviousness or lack of porosity, and it is expected that the copper and tin will furnish the required strength and form a matrix for the lead, which will give the necessary density.

Engine Shaft Breaks

By CAREY GRANGER

Quite recently a remarkable accident occurred at the Anderson plant of the American Steel and Wire Company. The main shaft on a 36 and 72 by 18-inch Corliss engine broke while the engine was running under full load. The shaft was 22 inches in diameter and carried a rope pulley 18 feet in diameter and 30 inches wide, also two belt pulleys 20 feet in diameter by 48 inches wide. The engine was used to drive the 12- and 18-inch trains of rolls in the rod mill and ran at 100 revolutions per minute. The two 48-inch pulleys are clamped to the shaft with the rims fitting tightly together. This leaves a space of about 6 inches between the hubs, and it was in this space that the shaft broke. On account of the rims fitting together so closely, it was impossible for the pulleys to drop into the pit and no further damage was done to the engine.

The engineer stated that, when the shaft broke, it made a noise very much like the stripping of one of the pinions by which the rolls are driven. He shut down the engine and waited for orders from the millwright who has charge of the pinions. The millwright, wondering at the stop and denying that anything was wrong in his department, gave orders to proceed. The engine was started and ran almost up to speed before it was decided that the trouble was in the engine room and an investigation started. The break was soon located, and I heartily agree with the engineer that "it is better to be born lucky than rich."

Boiler Explosion at Arcadia, La.

By W. HOWSE

On May 8 a small portable boiler, used to drive a shingle mill near Arcadia, La., exploded, killing one man and seriously injuring another.

The boiler was of the locomotive type, 8[illegible] feet long, with a barrel 3 feet in diameter, and mounted on it was a small slide-valve engine. Its exact age was not known, but from all accounts, it appears to have been over twenty years old. One hundred pounds steam pressure was known to have been carried, although there appears to have been no safety valve nor water column attached. The imprudence displayed in carrying so high a pressure is magnified by the fact that the boiler had lain exposed to the elements for some time prior to being installed in the shingle mill, and was in a corroded condition.

The crown sheet, which was [illegible] inch thick, was ruptured in three places, each rupture extending lengthwise of the firebox. It is remarkable that very few of the threads on the staybolts were stripped, and, although some of the staybolts had been eaten away from an original diameter of [illegible] inch to that of a lead pencil, none was broken. The seams

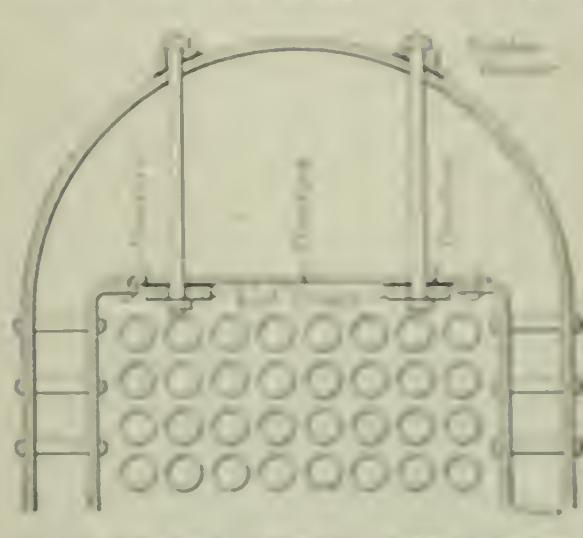

FIG. 3. SECTION THROUGH FIREBOX SHOWING POINTS OF RUPTURE

were single-riveted with [illegible]-inch rivets. These conditions, together with the fact that the crown sheet showed every evidence of having been overheated, leads to the conclusion that the explosion was caused by low water.

Feed water was supplied by an inspirator which was found after the explosion with all valves set for delivering water to the boiler; although, according to the statement of the injured man, he had just started over to the inspirator with the intention of turning it on when the explosion occurred.

The boiler had been leaking around the staybolts in the crown sheet and the owner of the mill had attempted to brace it by putting [illegible]-inch straps on the crown sheet. These were held by [illegible]-inch bolts extending through the top of the shell and some pieces of rubber belting were used as washers under the nuts to prevent leakage. He was tightening those nuts when the explosion occurred, which hurled him 125 feet and crushed in his skull as well as demolishing the entire building.

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

Improved Pressure Tubes for Recording Gages

The action of pressure on a tube or spring in a gage forces the sides apart, resulting in a greater radius of curvature,

Fig. 1. Showing Helical Gage Tube

following the motion of the free end. The principle of the helical form, shown in Fig. 1, is identical, for it is, in effect, a series of tubes placed end to end. When pressure is applied, it causes the tube to untwist and the free end to move a distance in proportion to the pressure applied.

In the improved helical pressure tube

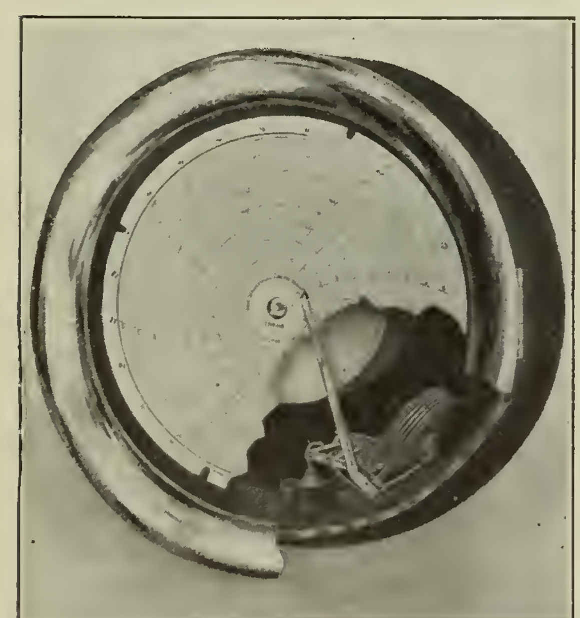

Fig. 2. Bellows Diaphragm

for pressure above six pounds, a simple but substantial support has been devised which supplies an axis of rotation, resulting in the precise travel of the pen over a definite predetermined arc. This support eliminates many of the possibilities of accident, as the support gives the required protection and ruggedness.

For minute pressures requiring reading in inches of water, a series of diaphragms built up into the form of a bellows are

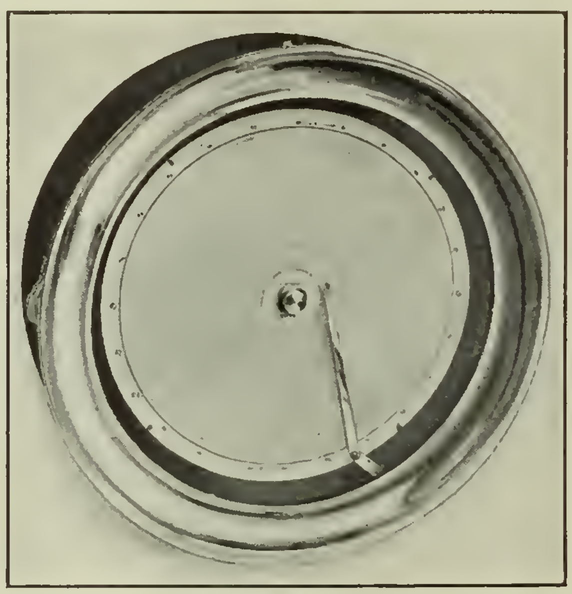

Fig. 3. Exterior View of the Gage

employed as shown in Fig. 2. Application of pressure tends to elongate the tube, but this motion is converted into a multiplied lateral motion by means of restraining coils secured to one side of the side of the tube. The motion thus obtained is transmitted through a very simple and effective device to the pen arm in such a way as to produce a uniform scale throughout the range of the chart. The feature of support similar to that employed with helical pressure tubes is of importance when it is used in conjunction with the diaphragms. It contributes to a marked degree to positive action of the recorder, at the same time giving strength and freedom from mechanical disturbance. Although designed for extreme sensitiveness and accuracy, the improved form insures great rigidity and durability under service. The exterior view of the gage is shown in Fig. 3.

These instruments are made by the Industrial Instrument Company, Foxboro, Mass.

"Durabla" Gage Glass

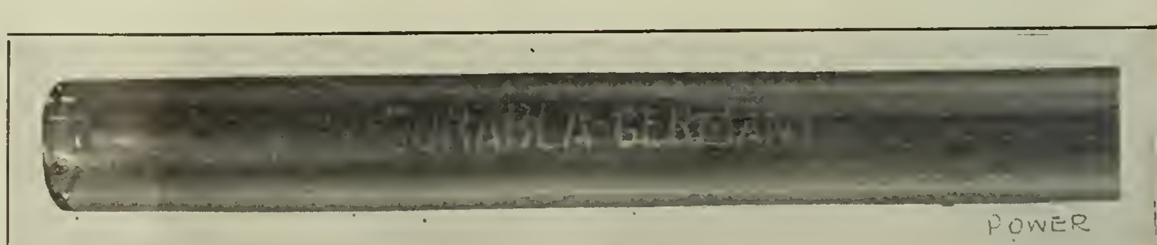
There is a demand for a gage glass that will be equal to the conditions now found in steam plants, and a gage glass to fill the new conditions must withstand high pressures and severe tests.

The Durabla high-pressure gage glass of the German navy has just made its appearance in America. This glass is used by such large plants as the Krupp iron works and the Hamburg-American line. The Durabla glass is claimed to be a peculiar scientific compound all its own.

As an example of its properties, the following results of an experiment made by a large testing station in this country may be of interest:

The glasses were immersed in oil at a temperature of 350 degrees Fahrenheit, and then dropped into water at a temperature of 40 degrees Fahrenheit. The experiment was repeated fifteen times, after which the same glasses were put into use on high-pressure boilers.

It is the mixture of different materials which gives certain glass the power to resist sudden changes in temperature, the action of steam, alkalis and impurities in water. It is the power to resist chemical action which keeps a glass clear for a long time under all conditions. The power to resist sudden changes in temperature reduces the possibility of accidents to a minimum.

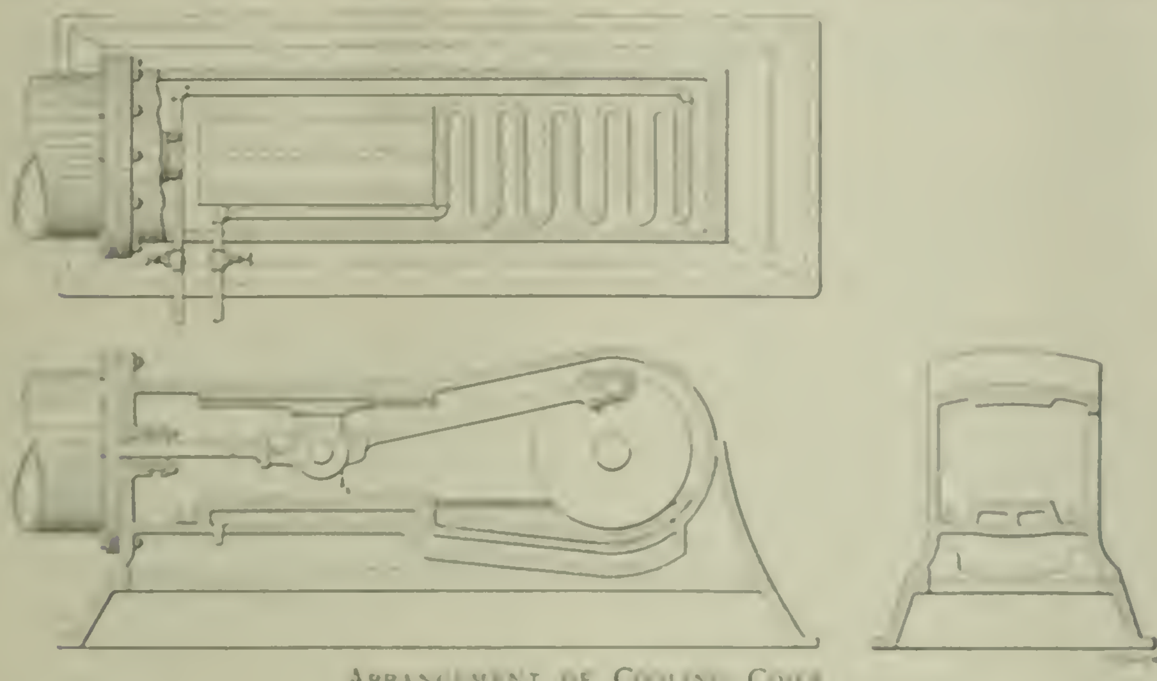


Durabla Gage Glass

The Durabla gage glass is manufactured by R. G. Von Kokeritz & Co., 114 Liberty street, New York City.

Oil Cooling Device for Steam Engines

This device consists of a flexible pipe entering the engine frame as illustrated, with a series of coils lying in the crank casing partly submerged in lubricating oil. A current of cool water is circulated through the pipe, after which the water may be discharged to the heater. The device is intended for application to inclosed, self-oiling engines. By regulating the amount of water flowing through the coil it is possible to keep the oil cool and eliminate, in a measure, the liability of heating journals.



Arrangement of Cooling Coils

This device is manufactured by W. J. O'Keefe, Foster building, Milwaukee, Wis.

Automatic Vacuum Breaker

A new design of automatic vacuum breaker is illustrated and described herewith. *A* is a pipe connecting with the exhaust or vacuum pump and is capped with a brass head on the upper end, as shown at *B*. The top of the cap is closed to the atmosphere by the cover *C*, which fits tight on the soft-rubber ring or seat *D*. The pressure of the atmosphere or suction of the vacuum holds this cap down on the seat *D* when running normally. The cap *C* extends back and is pivoted on the pin *E*.

The spring *H* has one end fastened in the extension arm of *C* and the other end is made fast to the tension adjustment *J* which is held by the projecting ear on the cap *B* and holds this spring in tension and acting as a resistance to the suction of the vacuum on the cap *C* so as to nearly counterbalance this suction. This tension can be adjusted by raising or lowering the pin *J* by changing the position of the lock nuts *K*. In this position the vacuum suction and the spring tension are nearly balanced, the force of the suction being somewhat greater so as to hold the cap *C* fast on the rubber seat *D*.

At the end of the extension of *C* is the loop *I*. *G* is a lever-like projection made fast to the rear stem of the stop valve proper, this stem being brought through the rear head for this purpose. The stem is in the position shown when the stop valve is open. The operation of the apparatus is as follows:

Closing the stop valve causes the rear valve stem *F* to rotate in the direction of the arrowhead, carrying the lever *G* with it. This lever strikes the link *I* when the valve is in a nearly closed position and when it has the most force due to the velocity of the steam rushing through the stop valve. The force of the blow with which the lever *G* strikes the link *I* is of sufficient force to overbalance the suction of the vacuum and lifting the cap *C* from the seat *D*. The spring *H*, now having nothing to counteract its tension, pulls the extension of the cap *C* down, opening the head *A* to the atmosphere,

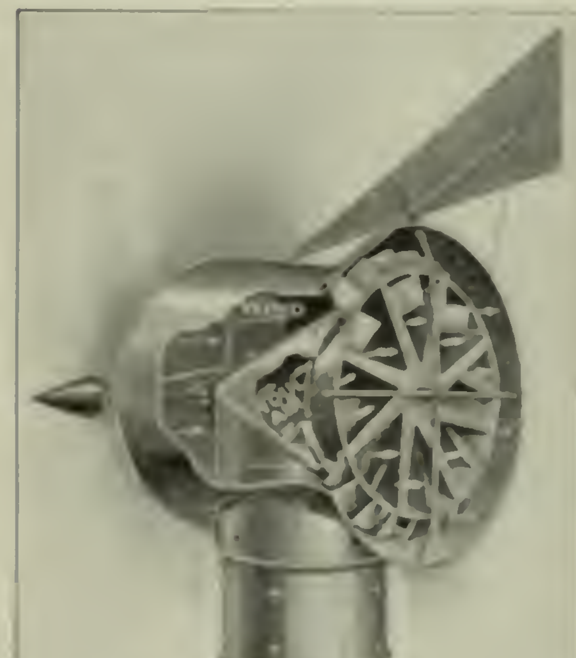
Automatic Vacuum Breaker

which, being in connection with the vacuum, breaks it at the same instant the steam line is shut off, thus doing away with danger of the engine cylinder filling up with water.

When the stop valve is opened by raising the hand lever, the lever *G* is brought back into place, carrying the extension on *C* with it and closing the head *A* so that when the vacuum pump is started the suction again holds the cap *C* to its seat, cutting the vacuum off from communication with the atmosphere. The head *A* is fastened to the rear head of the stop valve proper by means of cap screws. This device is manufactured by the Automatic Engine Stop Company, Sheboygan, Wis.

Bicalky Roof Fan Ventilator

The Bicalky ventilator fan does not depend upon any difference in temperature for its action, but a rotating fan



Semi-sectional View of Ventilator

wheel creates a vacuum and causes an upward circulation of air to insure ventilation.

A large area is exposed to the moving currents of air which the double cone-shaped opening brings into contact with the outer periphery of the fan wheel, while the inside portion of the wheel connects with the foul-air duct.

The intake and suction portions of the fan wheel are entirely separate, so that the current of air driving the wheel and the other exhausting the foul air from the building, in no way interfere with each other.

As no motor is required to operate this fan, there is no cost for repairs, and no power bills to pay.

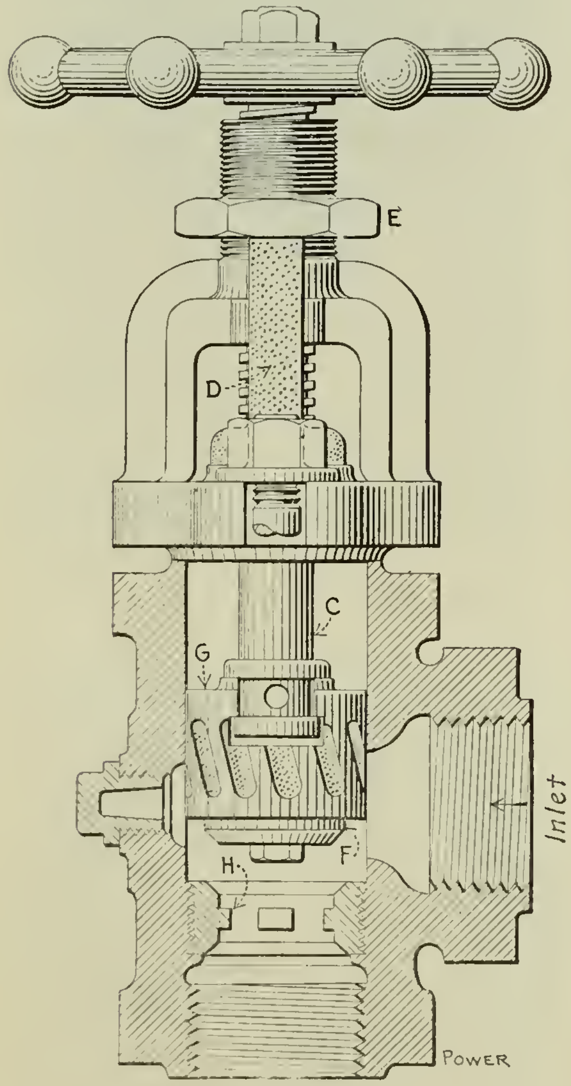
The fan wheel is mounted on ball bearings running in oil, which require lubricating once a year.

This fan is suitable for ventilating any kind of a room or building. It is manufactured by the Bicalky Fan Company, Buffalo, N. Y.

Cyclone Blowoff Valve

The body and yoke of the Cyclone blowoff valve are made of cast iron and are connected by steel studs and nuts. The sheet packing is housed in a recess in the body neck flange protecting it from a blowout, and is compressed by a projection on the yoke flange.

The stem *C* is made of a bronze composition and is cut with a square thread. The packing is secured and regulated by the pusher gland *D* which is operated by the outside screw nut *E* above the bridge of the yoke.



CYCLONE BLOWOFF VALVE

The disk and holder are made of noncorrosive bronze. They have two faces and are regrindable, reversible and renewable. The plunger disk holder *G* is of bronze composition, and is milled to receive the lower collar on the stem. This holder *G*, fitting snugly in the bed, is given a centrifugal motion by the steam striking the spiral grooves cast around the sides, when opening and closing the valve. This motion of the plunger tends to keep the inside walls of the valve clean and does not give scale or sediment a chance to collect. In closing the valve, the plunger, in passing the inlet orifice, shuts off all the steam before the disk reaches the seat and the vacuum created by the rush of matter through the valve prevents the lodgment of scale or silt.

The seat *H* is made of white bronze and is reversible, regrindable and renewable. The expansion and contraction of this metal are said to coincide with that of the iron casting, assuring a tight joint of the seat and body at all times. Each valve is tested to 250 pounds hydraulic pressure.

The valve is manufactured by the William Powell Company, Cincinnati, O.

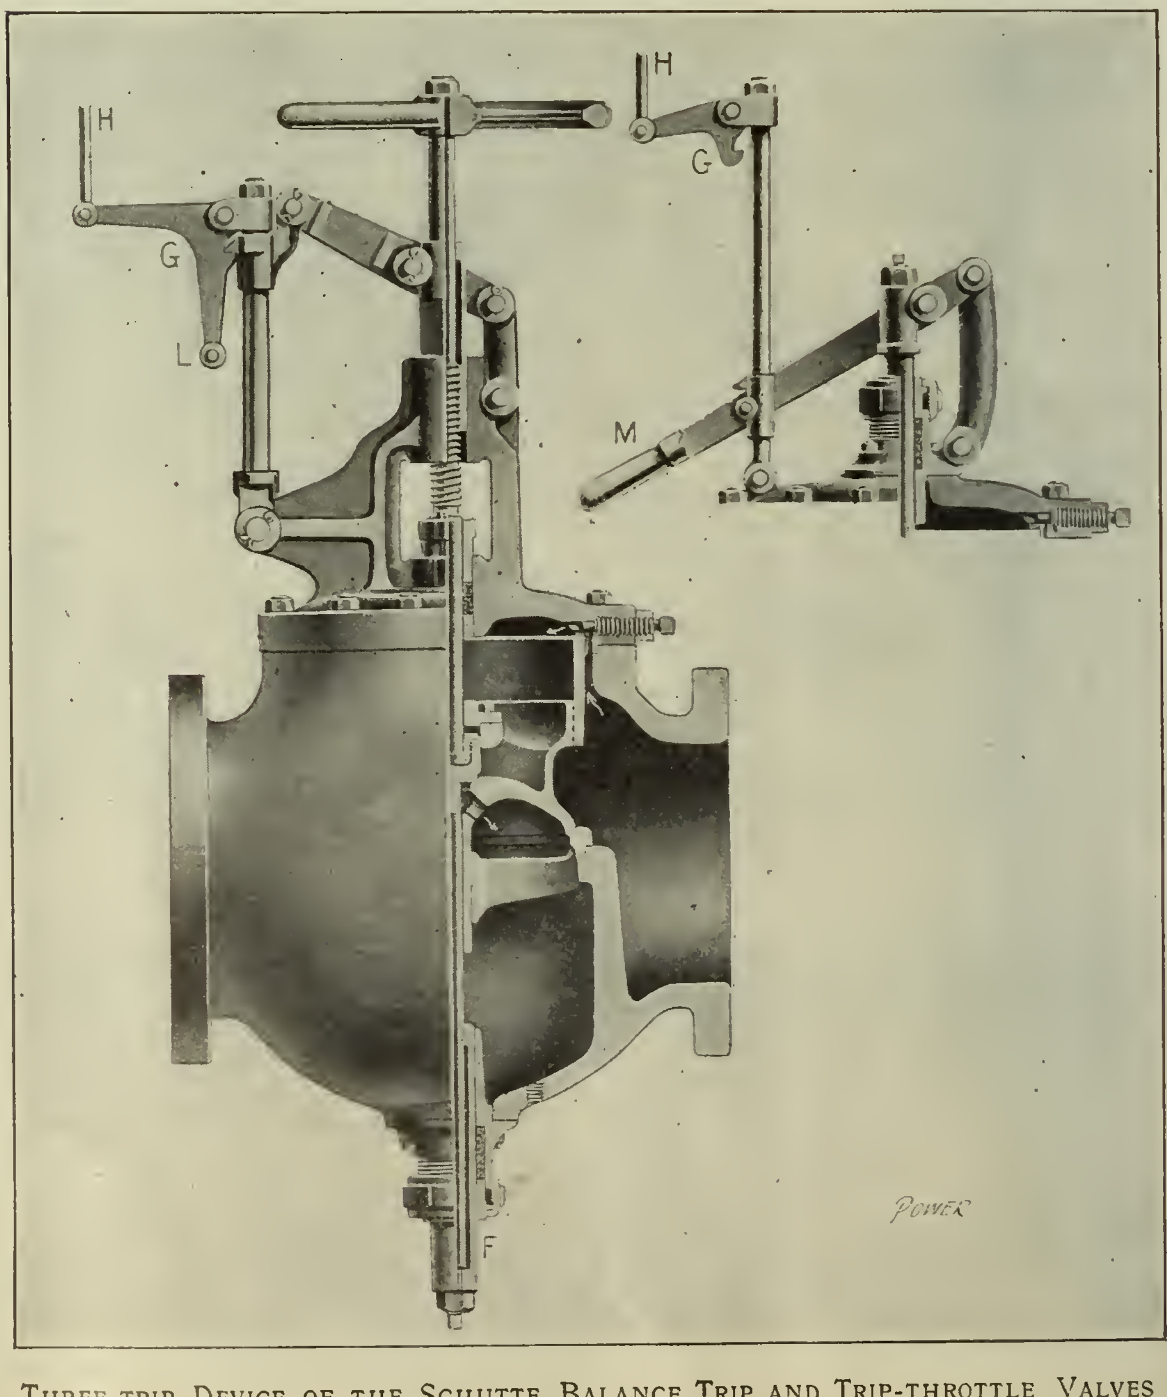
Schutte Balanced Trip and Trip Throttle Valves

These valves are intended as emergency shut-off or engine stop valves, and may be operated either by hand direct, with an electric solenoid and push button or automatically by the governor attached direct to the engine.

The trip valve is used in the steam-pipe connection to the engine and is operated independently of the throttle valve. The trip-throttle valve combines the features of a trip and throttle, thereby avoiding the necessity of two valves. It also has the advantage of being handled daily, thus assuring its being in operating condition; and will not, through lack of attention, or use from time to time, fail to operate when required.

The trip and throttle valve, shown herewith, when locked open, can be operated as a screw-spindle throttle valve. The screw is carried by a sliding trunnion that is connected by a lever and, when latched, forms a rigid connection with the yoke. The valve is then free to be operated by the handwheel and screw; should the valve be open or partially so, it may be instantly closed by tripping the latch *G*, either by a pull on the rod *H* or the handle *L*.

The balanced trip-valve locking device, shown at the right, is locked open by moving the handle lever until the catch on the same engages with the lever *G* that supports the upright bar. After the valve is open, steam pressure acts on the area of the piston *F*, shown at the bottom of the valve body, with a continuous downward force, which causes



THREE-TRIP DEVICE OF THE SCHUTTE BALANCE TRIP AND TRIP-THROTTLE VALVES the valve to close as soon as the catch is released. A hand lever *M* is attached to the rod *H* and the same rod extended to any desired location will permit operating the valve promptly and without effort.

These valves are manufactured by Schütte & Koerting Company, Thompson and Twelfth streets, Philadelphia, Penn.

The Short Flexible Stuffing Box

The Short flexible stuffing box shown in Fig. 1 is packed ready for the gland. The spring cases on the outside are fitted with caps of a standard size. When used for high pressure, or ammonia, the caps can be removed and oil fed to the rods.

Fig. 2. Sectional View of the Short Stuffing Box

Fig. 2 illustrates the box cut through the center and shows two of the four working bars. These bars are under the control of four master bars which are beveled at both ends and when the gland presses against them they slide on the 20-degree plane toward the center, taking four other bars together with the springs with them, leaving no opening or recess in which packing can catch. The position of the springs in relation to the bars is also shown. The bars are connected to the springs by means of a rod which is constantly pulling on them at an angle of 45 degrees. When it is necessary to repack, the gland is backed off and the springs pull the flexible parts back to place.

Fig. 3 shows an end view of the gland

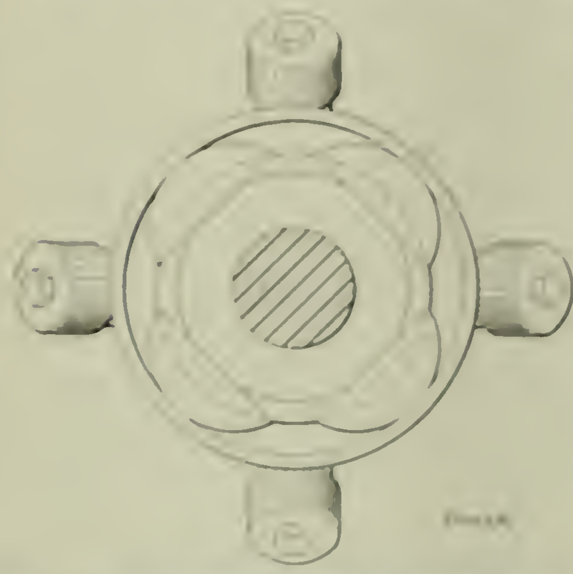


Fig. 3. End View of the Stuffing Box

and how it gets its flexibility. The master bars have a flat face against the packing and set; the bars to which the springs are attached have two flat sides that are at right angles with the packing

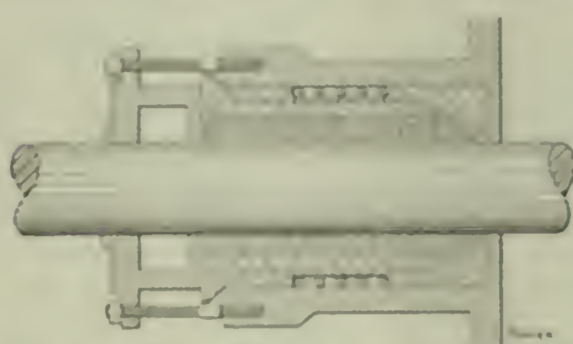

Fig. 4. Device as Applied to Ordinary Stuffing Box

rings. The sides that come in contact with the packing are cut so as to form a circle. These bars come in contact with the master bars with their right-angle sides tapering down to a feather edge. This allows a movement from one extreme to the other, keeping a steam-tight joint.

The method of placing the flexible parts into an ordinary stuffing box when a part of the cylinder or steam chest, is shown in Fig. 4.

This device is manufactured by W. C. Short, 1750 Park avenue, Denver, Colo.

Boilermakers Convention at Omaha

Pleasing and elaborate exercises marked the opening of the fifth annual convention of the International Master Boiler Makers Association, held at Omaha, May 23, 24, 25 and 26. Mayor J. C. Dahlman delivered the principal address of welcome, after which other prominent commercial and railroad men of the city spoke briefly to the visitors. A number of the leading members of the association responded, thanking the citizens of Omaha for their cordial welcome, and they were heartily seconded by President A. N. Lucas, in his annual address.

As the meeting extended over four days, it was arranged to have business sessions only in the morning, leaving the members free in the afternoons to take advantage of the liberal entertainment provided by the convention committee. As the temperature hovered around 90 degrees during the stay in Omaha, this was found to be a welcome arrangement.

Reports of various committees occupied the greater portion of the business sessions, the subjects having to do largely with railroad work, in which the membership is interested. Among the subjects discussed were: "Standardization of Shop Tools and Equipment," "Pipe Flanges and Templets for Drilling Same," "Advantages and Disadvantages of Fire Brick Arches," "Methods of Producing Better Circulation in Boilers," "Use of the Oxyacetylene Process Welding," "Best Method for Caring for Flues," "Best Methods for Staying Front of Crown Sheet," and "Steel Versus Iron Flues."

The entertainment program included visits to the Union Pacific Shops, Stock Exchange and Cudahy Packing Company, as well as numerous automobile rides and special excursions about the city, winding up with a banquet at the Rome hotel, followed by a dance in the convention hall. In all, the meeting was one of the most successful ever held by the organization.

The New York State Association of the National Association of Stationary Engineers will hold its annual convention at Albany on June 8 and 10. The committee of arrangements anticipates an unusually successful meeting.

Iowa State N. A. S. E. Convention

Ottumwa was the scene of the eighth annual State convention of the National Association of Stationary Engineers of Iowa, the dates being May 25, 26 and 27. The opening exercises included invocation, by Rev. W. D. Spiker, and addresses by S. H. Harper, mayor of Ottumwa, and M. B. Hutchison, president of the Commercial Association. F. W. Raven, national secretary, responded on behalf of the National Association of Stationary Engineers, after which C. A. Orr addressed the meeting for the local entertainment committee. E. P. Gould, secretary of the Central States Exhibitors' Association closed the opening exercises, with a few remarks on the possibilities of coöperation between the engineer and the supply man.

An illustrated lecture on "Petroleum—Its Products and their Manufacture," was given by W. A. Converse, of the Dearborn Drug and Chemical Company, and H. H. Dewey, of the General Electric Company, delivered an interesting talk on "Alternating Current Machinery."

The social features were well arranged and ample in every particular and culminated in a banquet given at the Hotel Ballingall, with Mayor Harper as toastmaster. One hundred and twenty delegates, their wives and visitors, sat down to the tables and partook of the full course dinner provided, after which F. W. Raven spoke on "The Objects of this Association." E. J. Doolittle, of Sioux City, was then called upon for some remarks in regard to the benefits to be derived from a license law, while others were called upon for five-minute talks on subjects of special interest to the members of the association.

Sioux City was chosen as the place of next meeting, the officers for the ensuing year being elected as follows: D. A. Coulson, of Sioux City, president; A. E. Powell, of Burlington, vice-president; Abner Davis, of Cedar Rapids, secretary, and George H. Beebe, of Marshalltown, treasurer.

The following firms had exhibits at convention hall: American Steam Gauge and Valve Manufacturing Company, Boston; Anchor Packing Company, Chicago; George B. Carpenter Company, Chicago; Commercial Lubricating Company, Philadelphia; Crandall Packing Company, Palmyra, N. Y.; Dearborn Drug and Chemical Works, Chicago; Fisher Governor Company, Marshalltown, Ia.; Garlock Packing Company, Palmyra, N. Y.; Greene, Tweed & Co., New York; Hawk-Eye Compound Company, Chicago; Hills-McCanna Company, Chicago; Hulson Grate Company, Keokuk, Ia.; Jenkins Brothers, New York; H. W. Johns-Manville Company, Milwaukee; Lunkenheimer Company, Cincinnati; Lyons Boiler Works, De Pere, Wis.; McMaster-Carr Supply Company, Chicago; Murray Iron Works, Burlington, Ia.; *National Engineer*, Chicago; Osborne High-Pressure Joint and Valve Company, Chicago; Ottumwa Iron Works, Ottumwa, Ia.; Penn Oil and Supply Company, Oil City, Penn.; POWER, New York; *Practical Engineer*, Chicago; The S. C. Regulator Company, Fostoria, O.; Standard Oil Company, New York; Stoersel Oil Works, Ottumwa, Ia.; Trapp Pressure Control Company, Sioux City, Ia.; Under-Feed Stoker Company of America, Chicago, and Viscosity Oil Company, Chicago.

STATE CONVENTION GROUP AT OTTUMWA, IOWA

Special Charter for Museum of Safety

A special charter has just been granted to the American Museum of Safety by the legislature of the State of New York, thus putting it in the same class with the Metropolitan Museum of Art and the Museum of Natural History.

Among the trustees of the museum are E. H. Gary, Philip T. Dodge, James Speyer, Thomas Lynch, Arthur Williams, Edson S. Lott, Frederick L. Hoffman, George F. Kunz, Charles Kirchhoff, T. C. Martin, Charles A. Doremus, Louis L. Seaman, Frederick R. Hutton, William H. Tolman.

The exhibits at the museum include protective devices for the safeguarding of human life in almost every field of labor, from the turning of a grindstone to the moving of a freight train. The collections are of interest even to the ordinary observer, and of great value to the manufacturer, for, at present, annually, in the United States, over 500,000 men are wiped out from the ranks of the wage earners.

A Correction

On page 762 of POWER for May 16, bottom of third column, the 90-inch boilers under discussion in Mr. Dean's article are credited with having tubes 18 feet long. The tubes are 20 feet long and this figure should have been given in the table.

N. A. S. E. to Meet at Cincinnati

The Cincinnati members are planning to make the convention of the National Association of Stationary Engineers, to be held in that city in September next, the best in the history of the organization. The headquarters' hotel will be the Sinton and the meetings will be held at the Music Hall, in one wing of which the Exhibitors' Association will have its display. A lunch will be served in the building to preclude the necessity of going back and forth between the hall and the hotel at noontime.

The program as tentatively laid out is as follows:

On Monday evening a reception at the Sinton, followed by dancing.

On Tuesday the formal opening of the convention with addresses by the governor and mayor.

On Wednesday the visitors will be the guests of the Lunkenheimer Company who will take them to the Government dam at Fernbank on the steamer "Island Queen" and from there to Coney Island where a barbecue will be held.

On Tuesday and Thursday evenings there will be entertainments at the Music Hall, one under the auspices of the local committee and one under the auspices of the Exhibitors' Association, and on Friday evening a ball, also at the Music Hall.

Liberal provision has been made for the entertainment of the ladies while the convention is in session.

PERSONAL

Frank E. Marcy, formerly with the Allis-Chalmers Company, has been appointed manager of the branch house of the Mine and Smelter Supply Company in Salt Lake City, Utah.

Messrs. Lucke and Ophuls have formed a partnership and have opened an office at 30 Church street, New York City, for the practice of engineering connected with the installation, operation and maintenance of breweries, cold-storage and ice making plants and other manufacturing establishments using mechanical refrigeration.

Joseph L. Hern, formerly superintendent of heating and ventilation with the school-house commission, Boston, and Francis J. Furlong, formerly superintendent of construction with the Claghorn Company, Bradlee & Chapman and J. P. Dwyer, have formed a partnership under the firm name of Hern, Furlong Company, engineers and contractors for power, heating and ventilation, 149 Pearl street, Boston, Mass.

C. E. Burgoon and H. W. Matthews have formed the Burgoon-Matthews Electric Company with headquarters at Atlanta, Ga. The company will conduct a general wholesale and retail electrical-supply business and will represent a number of manufacturers of power-station equipment. Mr. Burgoon was formerly chief engineer of the Federal building, Chicago; and Mr. Matthews was associated with the Westinghouse Electric and Manufacturing Company as an electrical engineer.

Fay Woodmansee, C. J. Davidson and E. O. Sessions announce their association under the firm name of Woodmansee, Davidson & Sessions, Incorporated, 1048 First National Bank building, Chicago.

Fay Woodmansee for nine years has been associated with Sargent & Lundy, as electrical engineer. C. J. Davidson for thirteen years has been in charge of the power-plant department and steam-heating department of the Milwaukee Electric Railway and Light Company, including during this period consulting work in St. Louis and other cities where the North American Company were interested. E. O. Sessions for twenty-three years has been associated with the General Electric Company in its engineering and sales departments.

It is the purpose of this firm to act in a consulting and supervising capacity in all branches of mechanical and electrical engineering, including designs and specifications for power plants, substations, hydroelectric equipments, transmission lines, electrical distribution systems and mechanical refrigeration. Reports on properties and appraisals will be made and particular attention will also be given to district-heating systems.

NEW PUBLICATIONS

THE "PRACTICAL ENGINEER" ELECTRICAL POCKETBOOK AND DIARY. Published by the Technical Publishing Company, London, 1911. Five hundred and sixty-seven pages, 3½x5½ inches; numerous illustrations and tables. Price, cloth, 1s.; leather, 1s. 6d.

A handy little book containing much valuable data and notes on current practice in electrical engineering, as well as the Board of Trade rules regarding the installation of electrical equipment. Several sections have been revised in this edition to keep pace with the developments in practice during the past twelve months.

MACHINE DRAWING. By Gardner C. Anthony. Published by D. C. Heath & Co., Boston, 1910. Cloth; 108 pages, 7¼x9½ inches; many illustrations; 10 tables. Price, $1.50.

This book is not for beginners but rather for those who are familiar with descriptive geometry. It contains considerable sound and good matter on the preparation of shop drawings. The tables are of practical value and enhance the worth of the book to the man in the drafting room. Some inconsistency is shown where the subject of lettering is treated. This, however, is unimportant. The book can be conscientiously recommended to all who would become efficient in the principles of this subject.

NOTES ON MECHANICAL DRAWING. By Horace P. Fry. Published by the University of Pennsylvania, 1910. Cloth; 57 pages, 6x9 inches; 51 illustrations.

Although this booklet is but an introduction to mechanical drawing, it should be correct and thorough for that very reason. Above all, it should not be irrational in dealing with points which must be left largely with judgment, even though the book is intended for specific use. The author claims to pattern after the Reinhardt system of lettering. This is slightly incorrect as the lettering displayed throughout is anything but after the Reinhardt system. Briefly, the book needs more careful revision than it has so far received.

ENGINEERING CHEMISTRY. By Thomas B. Stillman. Published by the Chemical Publishing Company, Easton, Penn., 1910. Cloth; 744 pages, 6x9 inches; 174 illustrations, numerous tables. Price, $5 net.

This is the fourth edition of Professor Stillman's manual dealing with chemistry as applied to the mechanic arts, and much of the text of the earlier editions has been amplified and brought up-to-date. The subjects covered are, coal analysis and specifications, feed-water heaters, economizers, flue-gas analysis, calorimetry, the manufacture of water gas, burning of natural gas under boilers, blast-furnace gas applied to internal-combustion motors, liquid fuel, lubricating oils, analysis of iron and steel, cement, asphalt, etc.

The book is not in any sense theoretical but deals, for the most part, with commercial processes, and as such should prove a valuable reference book for any engineer.

LOGARITHMS FOR BEGINNERS. By Charles N. Pickworth. Published by D. Van Nostrand Company, New York, 1910. Cloth; 53 pages, 4½x7¼ inches; three tables. Price, $1, net.

If the title of this book were "Logarithms," beginners would not have excuse for finding fault. As is indicated by the author in the preface, the increasing use of exponential and other complex formulas in the calculations involved in the later developments of thermodynamics and of the electrical, physical and chemical sciences, makes it highly important to have a thorough understanding of the logarithmic methods of calculation. Ability to make use of logarithms, however, does not presuppose great mathematical preparation. And it is because of this fact that we see the possibility of the beginner making complaint of the author's method of treating the subject. It is our opinion that to be benefited by this book, it is first necessary to have a considerable understanding of algebra; more of an understanding, perhaps, than would be needed to make use of logarithms.

Granting that the user has the necessary familiarity with algebra, this book fulfils its purpose admirably. Interspersed throughout are illustrative problems and the answers thereto. These add greatly to the worth of the book.

Applied Thermodynamics for Engineers. By William D. Ennis. Published by D. Van Nostrand Company, New York, 1910. Cloth; 450 pages, 6½x9 inches; 316 illustrations. Price, $4.50.

Nothing could better proclaim Professor Ennis' natural genius for the systematic exposition of scientific principles than this work. It is at once the most thorough, most lucid and simplest treatise on the subject that the reviewer has seen. There are numerous minor defects, of course; the days of miracles are long past. On page 7, for example, it would have been advisable to explain that the symbol for heat received is positive and that for heat rejected negative, in the general formula for heat transfer; on page 19, air is referred to as a gas and gases are said to "follow" Boyle's law; on page 20, Charles is properly given credit with Gay-Lussac for the law:

$$\frac{PV}{T} = constant$$

but nothing is said of how he derived it; on page 33 and elsewhere, specific heats are represented "in proper units" by the unusual symbols k and l and the letter R is given both the correct value of 53.36 (for air) and the inconsistent one of 53.36 ÷ 778, in conformity with the statements on page 37 that "no attention is paid to the ratio 778 as affecting the numerical values of constants in formulas involving both heat and work" and "the student should discern whether heat units or foot-pounds are intended." This is slovenly and cannot fail to blunt the student's regard for accuracy; it is the most serious lapse in the book.

It will be apparent from the foregoing that the flaws are not glaring; nearly all of them, in fact, are negligible in importance.

The book is very broad in scope. All known cycles are described and thoroughly analyzed (and the Rankine and Clausius cycles are not confused as is usually done in textbooks); the thermodynamics of all heat-converting engines, both positive and negative, are treated, and the relations between the abstract science and the actual conversion machines are very clearly presented. The book differs from most textbooks in being both an excellent tool for the college professor and a highly satisfactory reference book for practising engineers whose catholicity of ready knowledge has been impaired by specialization.

Steam Turbines. By Joseph Wickham Roe, M. E. Published by McGraw-Hill Book Company, New York, 1911. Cloth; 143 pages; illustrated. Price, $2.

The author, who is assistant professor of mechanical engineering at the Sheffield Scientific School, Yale University, has produced an excellent little work adapted to the needs of the engineer who wishes to inform himself on the principles and general design of turbines as well as for a textbook for a short course upon the subject. He who has wondered what all the velocity diagrams and velocity-pressure schemes so often published in connection with turbine discussions mean will find them explained here in all simplicity, requiring the possession of only a little elementary trigonometry for their comprehension. Each division of the subject is followed by a list of practical examples the solution of which requires the application of the principles which have been explained and the use of the formulas deduced, and a list of references to other works for those who wish to pursue that phase of the subject further.

The first chapter is devoted to the explanation of the energy in a jet. The consideration of the velocity derivable could have been improved by giving some of the simple formulas for the energy derivable from a pound of steam, which are precise within the limits of precision of the steam tables which are necessary for the working of the approximate formula which he gives.

The second chapter deals with the utilization of the kinetic energy in steam and shows by means of the velocity diagram how this energy is absorbed by the wheel. The method of finding the trajectory of the steam is also explained. About 30 pages are then devoted to "Calculations of Turbine Blading."

Under the title of "Mechanical Problems," the author takes up centrifugal strains but says little or nothing of critical speeds and balancing. Bearings and governing are treated in this section.

Chapter V is hardly a "Comparison of Types," but a description of the Curtis vertical, Terry, Kerr, Rateau, Zoelly and Allis-Chalmers machines, and of the Rateau regenerator and mixed-flow turbine.

The effect of superheat and vacuum, but not of pressure, is considered in the next chapter, which contains also a description of the Parsons augmentor. The concluding chapter deals with "The Position and Field of the Steam Turbine," giving the formula for potential efficiency and tables of test results and potential efficiencies of engines and turbines. The advantages and disadvantages of the turbine for various lines of service are considered and the fact pointed out that up to February, 1911, the sales of the three foremost manufacturers of large turbines in the United States had aggregated 4,100,000 kilowatts. Scarcely a dozen of the machines are over a dozen years old and the majority have been built within the last five years. The volume concludes with a heat-entropy chart and a summary of the bibliography of the subject.

BOOKS RECEIVED

Good Engineering Literature. By Harwood Frost. Chicago Book Company, Chicago, Ill. Cloth; 422 pages, 5x7½ inches; indexed. Price, $1.

Power. By Charles E. Lucke, PH. D. The Columbia University Press, New York. Cloth; 316 pages, 5¼x7¾ inches; 223 illustrations; indexed. Price, $2.

Monoplanes and Biplanes. By Grover Cleveland Loening. Munn & Co., New York. Cloth; 331 pages, 5½x8 inches; 278 illustrations; indexed. Price, $2.50.

Vacuum Cleaning. By Thomas D. Perry. The American School Board Journal, Milwaukee, Wis. Paper cover; 44 pages, 4½x6¼ inches; illustrated. Price, 15 cents.

Steam Turbines. By Joseph W. Roe. McGraw-Hill Book Company, New York. Cloth; 136 pages, 6x9 inches; 77 illustrations; tables and plate; indexed. Price, $2.

Seven Follies of Science. By John Phin. D. Van Nostrand Company, New York. Cloth; 231 pages, 5x7½ inches; second edition; 34 illustrations; indexed. Price, $1.25.

Hydro-Electric Practice. By H. A. E. C. von Schon. J. B. Lippincott Company, Philadelphia, Penn. Second edition; cloth; 383 pages, 6¾x9½ inches; 140 illustrations. Price, $6.

Storage Battery Engineering. By Lamar Lyndon. McGraw-Hill Book Company, New York. Third edition; cloth; 601 pages, 5¾x9 inches; 298 illustrations; tables; indexed. Price, $4.

Electric Crane Construction. By Claude W. Hill. J. B. Lippincott Company, Philadelphia, Penn. Cloth; 313 pages, 6x9 inches; 366 illustrations; 23 tables; plates; indexed. Price, $8.

A Treatise on Transformers. By Hermann Bohle and David Robertson. J. B. Lippincott Company, Philadelphia, Penn. Cloth; 356 pages, 6x9 inches; 332 illustrations; 18 plates; tables; indexed. Price, $7.50.

POWER

Vol. 33 NEW YORK, JUNE 13, 1911 No. 24

JUST what does and what does not constitute success is a question that has taxed the minds of men of many ages and if the various definitions which have been given had only been compiled it would have made a most interesting volume.

A few years ago a famous platform orator defined success as, "Finding your place and filling it," and this would appear to be all sufficient.

The speaker in illustrating his definition said that the question of money, while believed by the average layman to constitute the measure of success, was absolutely immaterial and that a crossing watchman doing his duty in such a manner as to leave nothing more desired, was more of a success than the man who, through greed, selfishness or mere chance, accumulates several million dollars in a comparatively short time.

Now, to apply this to the engineer,—is the man who is chief engineer of a large central station or large manufacturing establishment, more of a success than the plain engineer of a small but flourishing factory, in a quiet portion of the city, who feels that the small position is the limit of his capabilities and operates it accordingly, leaving nothing undone that could be done to better the operating conditions?

He is not. He may be making more money, but he is not keeping his plant any nearer, or perhaps as near, the goal of perfection, measured by the limitations of the plant, as the man in the smaller position.

Most men lack one or more of the necessary requisites to success. Some men have all the necessary skill and knowledge, but lack the power of stick-to-it-iveness; others may lack that rare gift of handling subordinates; others may have the last two and not know just what to do when they get the crew together.

Neither is success measured by a diploma from some technical or other school, or an engineer's license with a gold seal, conspicuously displayed, or by a vast library of books pertaining to the profession, or even by all the various rules and formulas in common practice, memorized. All these things, while very desirable, are not absolutely essential to success.

A certain engineer on the railroad quite frequently called upon the fireman to "keep 'er hot 'n' wet," and almost had to have the fireman call out the names of the stations as they arrived. He always had the fireman read the train orders to him, and was known to report "flews lakin" and "new diver braike chu" on his return from a trip, yet when he coupled on to the limited, he would get it over the road on schedule time if the train held together, and on the least amount of fuel possible. Out of some 150 engineers on the road, he was never below the first half dozen in the monthly "performance sheet." That man found his place and could fill it, he was a success.

And it is just so in stationary practice. How many of the older generation, now operating engineers, the "Dad Eldridge" class, are there who received a college or technical education? Very few. Many there are who did not get even a fair country school education. But they had those necessary native qualifications that go to make a man a success; grit, ambition and a determination to win, and, last but not least, horse sense.

To be a success, it is thus clear that it is not necessary to be chief of a 100,000-horsepower plant. The thing to do is to find your notch, stick to it, work, be on the job and leave nothing to be desired in economy of operation and general appearance of the plant.

Horsepower of a Fan Blower

By Albert E. Guy

The results of some tests showing the influence which the form of the vanes has upon the horsepower and the head produced. Formulas are given showing the approximate velocity of flow and horsepower developed.

A problem frequently met with is that of finding the horsepower of a fan blower when the diameter of the rotor, width of vanes at the tip, etc., are known. This typical problem may be solved only when the necessary data embodied in the "etc." are known; otherwise it may be readily shown that two fans, having the same inlet and outlet diameters, the same width of blades, revolving at the same rate of speed and delivering the same volume of free air per unit of time, may produce widely differing pressures. Thus, with the lower pressure, the air horsepower would be almost negligible, while with the higher pressure, which might be an extreme for the class of fan considered, the air horsepower, and consequently the shaft horsepower, would be matters of prime importance. This discrepancy is due simply to the fact that in either case the vanes, although of the same width, must be designed to suit the required conditions of pressure.

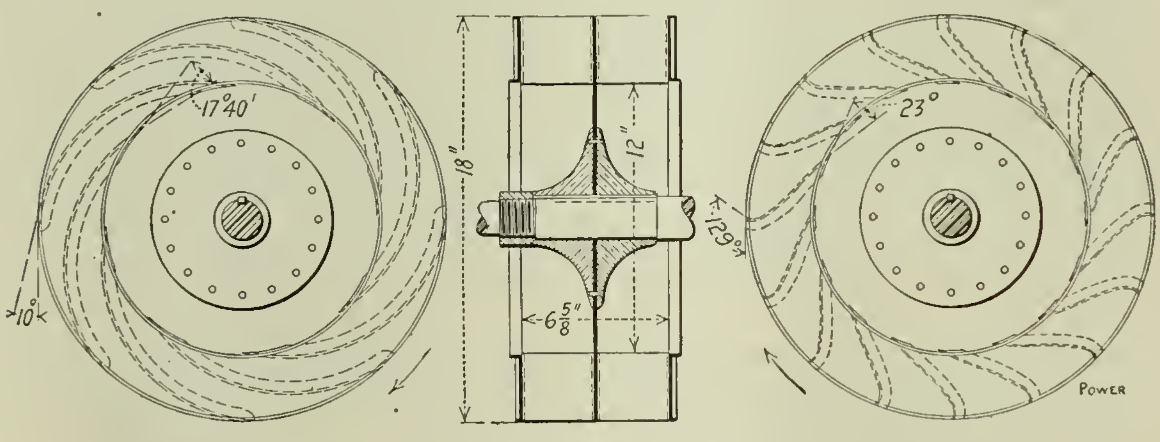

Fig. 1. Impellers Used Showing Curvature of Vanes

About two years ago the writer, to show the direct applicability of centrifugal-pump formulas to the design of fan blowers and to prove that a complete line of standard apparatus could be designed without making preliminary and special experiments for obtaining so called coefficients of correction, chose two extreme sets of conditions and designed special apparatus to meet them.

It was proposed in one case to furnish 7000 cubic feet of free air per minute at a static pressure of 22 inches of water, and in the other, 5250 cubic feet of air per minute at a pressure of 5 inches of water, the speed being 3600 revolutions per minute in both instances. A spiral form of casing was designed, and an impeller fitted into it, each set of conditions being met by a special impeller; but to add to the difficulties and to render the proofs more conclusive, the inlet and outlet diameters, and the width of the vanes, were kept the same for the two impellers. Fig. 1 shows the principal dimensions and forms of the impellers.

When completed, the apparatus was connected directly to a steam turbine and the high-pressure impeller driven at the specified speed. To determine the capacity of the fan and to obtain the curve showing the relation of volume to head, the speed was kept constant while the volume delivered was progressively increased by changing the nozzle areas at the end of the discharge pipe. The head was recorded simultaneously with the volume to which it corresponded. Various speeds above and below that specified were tried in the same way, the results being shown by the series of curves given in Fig. 2.

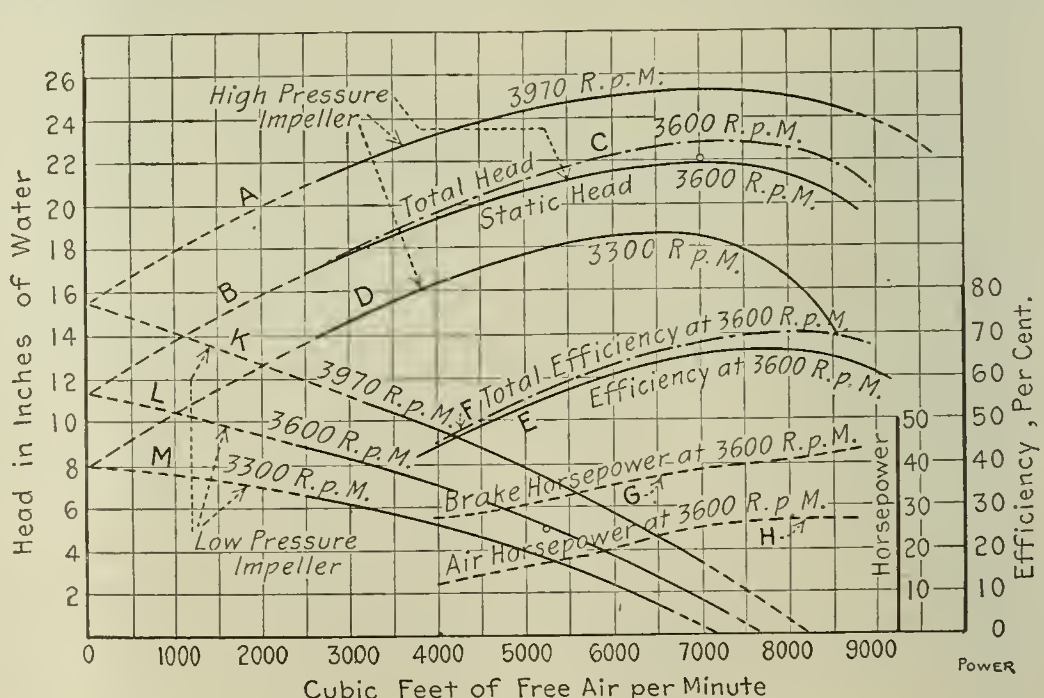

Fig. 2. Characteristics of the Two Impellers Tested

The steam and exhaust pressures at the turbine were recorded for each point of the curve, not for the purpose of ascertaining the steam consumption, but in order that later on, the blower being disconnected and replaced by a prony brake, the same steam and exhaust conditions could be reproduced at the proper speed and the corresponding brake horsepower recorded. With the latter data the efficiency of the apparatus was obtained and is represented by curves covering the useful range of the impeller.

The low-pressure impeller was tried next, but on account of the small amount of power required to drive it and the unsuitability of the turbine for the purpose of measuring that power, it was not possible to ascertain the efficiency with sufficient accuracy to permit representation by curves, as was done with the first impeller. However, it was observed that for the point aimed at in the design, the efficiency was not less than 60 per cent.

The curves *A* to *H* in Fig. 2 are for the high-pressure impeller and curves *K, L, M* are for the low-pressure impeller. It is apparent that neither impeller was suitable for the requirements of ordinary work. The usual requirements are that a practically constant head be maintained for a wide range of volume variation. In the present case such a condition could have been met only by varying the speed, and the turbine was not well adapted for such a speed variation.

However, a comparison of the capacities of these two fans is interesting. At 3600 revolutions per minute 7000 cubic feet of free air were delivered against a head of 21.8 inches of water by the high-pressure fan, while the same quantity was delivered against a head of 1.6 inches of water by the low-pressure fan. The air horsepowers were nearly proportional to the heads, or in the ratio of 13.6 to 1. At the same speed and for a volume of 5250 cubic feet of free air per minute, the brake-horsepower ratio would be about 4.5 to 1.

The impellers illustrated by Fig. 1 are not recommended for practical work. The speed of 3600 revolutions per minute is too low for the high-pressure impeller, or, the latter's diameter is too small for the speed. Moreover, the reversed form of vane is not desirable, as it entails a great frictional loss, and while it is theoretically correct for turbine work, it is not so for pumping purposes. The speed of 3600 revolutions per minute is far too high for the low-pressure impeller; the vanes are consequently too long and entail a frictional loss out of proportion to the head worked against.

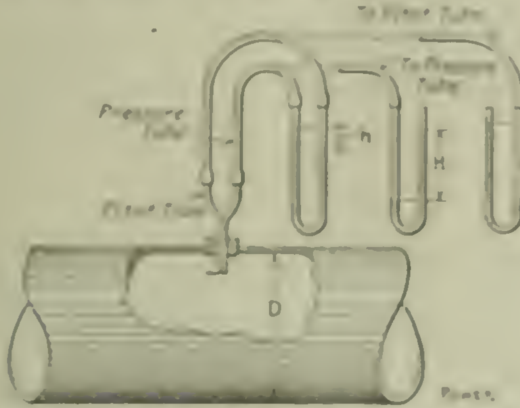

Fig. 3. Device for Measuring Pressure in Pipe

These two impellers, however, served to demonstrate the proposition as intended and further illustrate the fact that it is not possible to determine the horsepower required for a given blower, when only the diameter, width of blades and the number of revolutions per minute are known. It is necessary to know also the inlet and outlet angles of the vanes, the equation of their form, and the equation of the areas of passage from the inlet to the outlet of the impeller.

It is true that for a certain line of standard machines it is possible for the manufacturer to establish a set of approximate horsepower curves which are very useful for estimating; but such information is never given to the user of the machines.

When the fan takes the air from the atmosphere and delivers into a duct, and particularly when that duct or pipe is circular, it is comparatively easy to measure the approximate capacity of the apparatus when the air handled is at a moderate temperature. The instrument needed for the operation is very simple and can be easily made. Fig. 3 represents a combination of Pitot and pressure tubes connected to a glass U-tube containing water. The end of the assembled tubes should be inserted into the delivery pipe as shown. A straight part of the pipe should be selected where the flow is not likely to be disturbed by the influence of bends, valves, etc. The gage should be inserted into the pipe for about one-sixth the diameter and turned so that the open end of the Pitot tube is against the current. If the tube is not so placed the readings will not be correct.

With the two rubber tubes in place the difference in the hights of the columns of water in the U-tube shows the velocity head causing the flow in the duct. Disconnecting the Pitot tube from the glass gage and measuring the hight between the two levels, will indicate the pressure head against which the air is delivered. Again connecting the Pitot tube and disconnecting the pressure tube, will show, by the difference in the hights of the water columns, the total head produced by the fan. This total head is composed of the static head measured by the pressure tube, plus the velocity head shown when the two tubes are used together.

Calling the velocity of flow v feet per second, the velocity head h inches of water, and the static pressure head H inches of water,

$$v = \sqrt{2g\frac{p}{d}} = \sqrt{\frac{1,745,200 \times h}{406.7 + H}} =$$

$$1321\sqrt{\frac{h}{(406.7 + H)}}$$

where,

p = Pressure in pounds per square foot;

d = Weight, in pounds, of one cubic foot of free air at 50 degrees Fahrenheit = 0.077884;

406.7 = Inches of water corresponding to atmospheric pressure.

Knowing the inside diameter D, in inches, of the delivery pipe, the volume discharged in cubic feet per second is

$$\frac{\pi D^2}{4 \times 144} \times v$$

But this air is at a pressure H and the corresponding volume of free air per minute would be

$$\frac{\pi D^2 \times v \times 60 \times (406.7 + H)}{4 \times 144 \times 406.7} =$$

$$\frac{D^2 \times v \times (406.7 + H)}{1243}$$

cubic feet per minute

The horsepower in air delivered would be

$$\frac{\textit{Volume per minute} \times \textit{pressure per square foot}}{33,000}$$

One cubic foot of water weighs 62.35 pounds; one inch of water equals

$$\frac{62.35}{12} = 5.196 \textit{ pounds per square foot}$$

Hence,

$$\frac{\textit{Volume per minute} \times 5.196 \times H}{33,000} =$$

Air horsepower

or

$$\textit{Air horsepower} = \frac{\textit{Cubic feet per minute} \times H}{6350}$$

Substituting for the volume and velocity their respective values

Air horsepower =

$$\frac{D^2 \times v \times H \times (406.7 + H)}{1243 \times 6350} =$$

$$\frac{D^2 \times H \times \left(1321\sqrt{\frac{h}{406.7 + H}}\right) \times (406.7 + H)}{7,893,050}$$

$$= \frac{D^2 H \sqrt{h \times (406.7 + H)}}{5975}$$

As the efficiency of ordinary blowers is about 50 per cent., multiplying the air horsepower as just obtained by 2 gives approximately the shaft horsepower necessary to run the blower. While reading the gages the speed should be kept constant, and the time selected when the flow of air is uniform.

The gage readings and particularly that of the velocity head should be very close, for which reason it is preferable to use a U-tube of rather small diameter.

The formulas herein given are intended for approximate work only. The density of the air depends so much upon the temperature that the method would not apply to hot-blast work, for instance. Corrections should also be made for altitude and humidity. However, if the proper constants were determined to suit a given installation, the formula as modified would be found very useful.

Defects in Welded Flanges

In a paper presented at the May meeting of the Iron and Steel Institute by

Fig. 1. Metal Stripped at Drifting Tool, Showing No Fusion

Fig. 2. Section through Cracked Welded Pipe

Messrs. Lee, [illegible] and [illegible], some interesting facts are brought out regarding welded flanges. Two cases were considered: one a [illegible] weld and the other an arc weld, the observations of which serve to substantiate the stand taken by many consulting engineers in steadfastly refusing to employ welded flanges.

A welded pipe flange may be obviously mechanically imperfect, or it may be apparently perfect and capable of withstanding hydraulic-pressure tests. In the latter condition ignorance as to its internal condition produces a peace of mind which knowledge is liable to destroy.

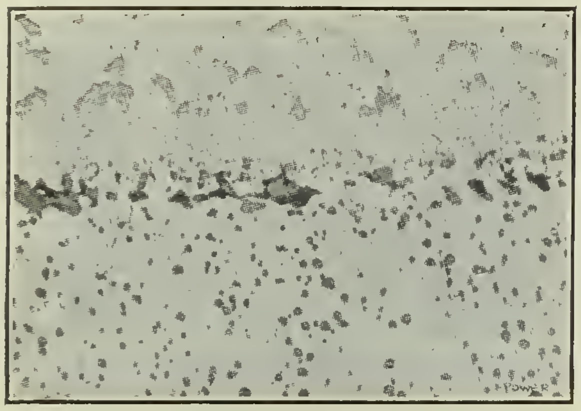

FIG 3. SLAG ALONG TRACK OF WELD

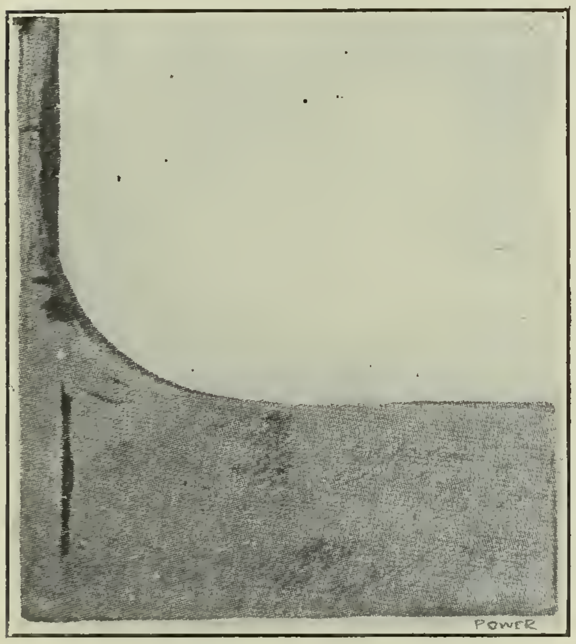

FIG. 4. ARC-WELDED FLANGE AFTER BEING SAWED AND ROUGHLY FILED

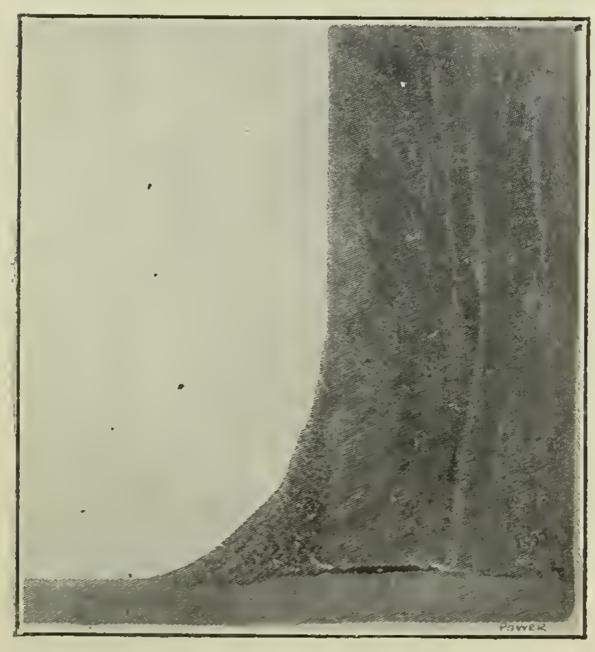

FIG. 5. ARC-WELDED FLANGE SHOWING DEMARCATIONS

Fig. 1 shows the segment of a wrought-iron flange nominally welded to a mild-steel pipe by the coke-fire process. As shown, it has been stripped away by the use of a drifting tool, and as there is no fusion of the metal it is only nominally welded. Fig. 2 shows another portion of the segment in which the pipe has not been mechanically forced away from the flange. The clear demarcation of the area shows that there has been no fusion of the metal. Fig. 3 shows, at one hundred magnifications, an accumulation of slag in the form of silicate along the track of the weld.

A segment of an arc-welded flange on a steel pipe is shown in Fig. 4, just as it had been sawed and roughly filed. It will be noted that the weld is only partial, over one-third of the area of junction having an air space. This pipe would probably have passed a reasonable hydraulic test and its defects would have been discovered only in service.

Fig. 5 represents the same view of the segment after polishing and etching. The excessive action of the corroding medium upon the area on which the arc has played, and the abrupt termination of these areas, are clearly shown.

Determining the Most Economical Vacuum

By THOMAS H. BROCKMAN

Assume a vacuum of 28 inches in the condenser. If this is reduced to 24 inches there will be a difference of some 40 degrees in the temperature of the hotwell. If this difference could be added to the temperature of the feed water it would mean a saving of about 3½ per cent. in the amount of fuel required to evaporate the same quantity of water.

Reducing the vacuum reduces the mean effective pressure in the cylinder and increases the temperature of the feed water. One means a loss and the other a gain. At what point do gain and loss so balance that an increase or decrease of the vacuum means loss? This question appeared in POWER a while back. In my spare moments I have been endeavoring to figure out what it all meant. The result shows the relation that exists between the temperature of the steam and the pressure.

Assume an indicator diagram as shown in Fig. 1 with the following:

$P_1 = 91$ pounds absolute;

$V_1 = 1$, $V_2 = 4$, $V_3 = 0.5$, $V_c = 0.04$;

$r =$ Ratio of stroke to cutoff $= 4$;

$r_c =$ Ratio of volume at exhaust closure to clearance volume

$$= \frac{0.5}{0.04} = 12.5;$$

$P_x =$ Some vacuum to be assumed;

$P_y =$ Some vacuum to be assumed.

Then, the mean effective pressure of the indicator diagram equals

$$\frac{\left(\begin{matrix} P_1V_1\,(1 + log.\,r) - P_xV_4 - P_1V_c - P_x \\ (V_2 - V_4)\,log.\,r \end{matrix}\right)}{(V_2 - V_c)}$$

Now, suppose that the vacuum has been reduced to P_y. Then the per cent. loss due to the increased pressure in the condenser will be,

$$\frac{\left(\begin{matrix} P_1V_1\,(1 + log.\,r) - P_xV_4 - P_1V_c - P_x \\ (V_2 - V_4)\,log.\,r_c - (P_1V_1\,(1 + log.\,r) - \\ P_yV_4 - P_1V_c - P_y\,(V_2 - V_4)\,log.\,r_c) \end{matrix}\right)}{\left(\begin{matrix} P_1V_1\,(1 + log.\,r) - P_xV_4 - P_1V_c - \\ P_x\,(V_2 - V_4)\,log.\,r_c \end{matrix}\right)}.$$

which reduces to,

$$\frac{4.725\,P_x - 4.725\,P_y}{213.26 - 4.725\,P_x} = \textit{per cent. loss of mean effective pressure} \qquad (1)$$

If $H =$ total heat in the steam at 91 pounds, and t_x = temperature of steam

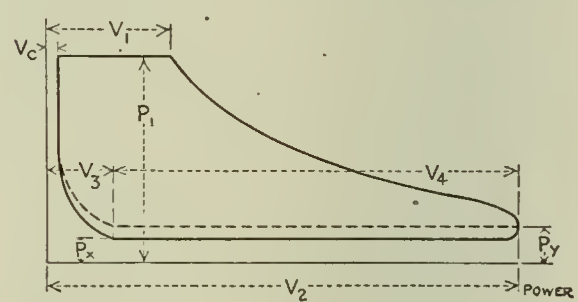

FIG. 1

corresponding to pressure P_x, t_y = temperature of steam corresponding to pressure P_y, and assuming that the temperature of the feed is the same as the temperature of the hotwell, the per cent. gain of fuel required to evaporate the same amount of water will be,

$$\frac{H - (t_x - 32) - (H - (t_y - 32)}{H - (t_x - 32)}$$

If $P_x = 1$ pound, $H = 1113.1$, $t_x = 102$; therefore,

$$\frac{t_y - 102}{1043} = \textit{per cent. gain in fuel} \qquad (2)$$

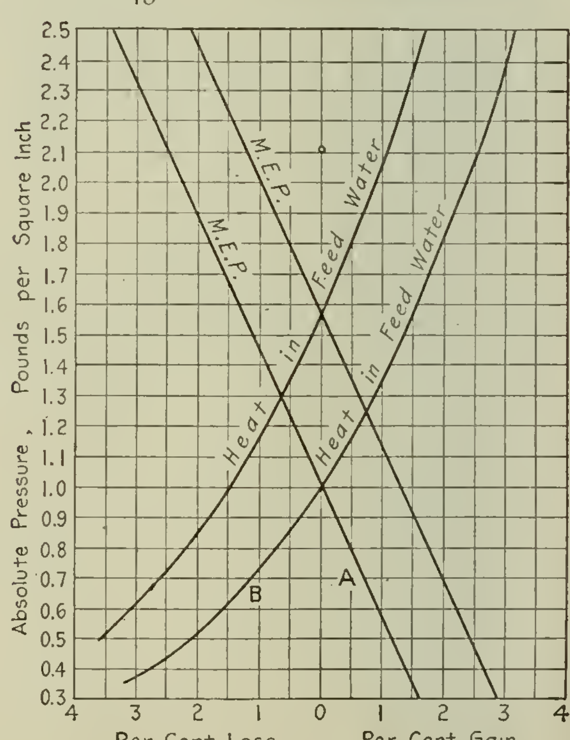

FIG. 2

By choosing values for P_y above and below 1 pound absolute in (1) and (2), the curves (A) and (B) in Fig. 2 were drawn. It was found by using two or three values for P_x that the curve (A) remained a straight line, while (B) only shifted to the right or left as P_x was increased or decreased. It will be seen by referring to Fig. 2 that there are two pressures at which the loss and gain are equal, at 1 pound and at 2.11 pounds. Any pressure below 1 pound means a loss and any pressure above 2.11 pounds means a loss. Therefore, halfway between these two points is a pressure where loss and gain so balance that any increase or decrease of pressure means a loss. This is shown by the two curves that pass through 1.56 pounds. They were platted by taking P_x equals 1.56, and choosing values of P_y above and below P_x.

Curves (A) and (B) show at a glance between what pressures a vacuum can be maintained without a loss. Of course, the foregoing is theoretical. The temperature of the hotwell is never the temperature of the feed water, but a few observations would give this relation.

Wave Motors and Compression

By F. L. Johnson

"This is he bald-head section. I have segregated these specimens for the purpose of collecting data on the growth of hair on wood," said the "Old Man" to a companion, as he swung open the door of our "box stall" one pleasant winter day. The door swung back as he passed on and it was not noticed that someone had entered, until, with a pleasant New Hampshire drawl, the visitor said:

"I suppose that is the way John A. expresses his appreciation of your efforts to keep on the pay roll. Well! All soils will not grow both hair and brains at the same time." It was Sawyer, and his trim, well-dressed figure, clean-cut face, alert glance and half satirical smile looked good to all of us. After shaking hands all around, exchanging the usual midwinter holiday greetings and good wishes, his attention was monopolized by the Dean, who always takes upon himself to settle offhand all questions, financial, social and ethical. He eliminates the other fellow by starting in first and keeps at it until all of the available time, as well as the listener's, is exhausted.

"I see that Professor Heck," he started this time by saying, "has taken most of the wind out of the sails of the noncompressionists, which, of course, includes you and Dwelshauvers-Dery. Mr. Heck is undoubtedly right for, as he says in the issue of September 13 and again in that of December 27 in his reply to Dery's criticism that"—Just here one of the counter girls announced that a gentleman was waiting in the library to see the dean.

"I saw an old friend of mine at Atlantic City the other day," Sawyer turned to me and said as the dean left the room, "in the form of the United States Wave Power Company's wave motor. You doubtless have not forgotten what I told you of boyhood experiences years ago at the foot of Gas House road. One of our motors was made by loading a 50-gallon tar barrel with about 400 pounds of water and running a rope from it over a sheave and around a drum fastened to the overhead timbers of the coal shed.

"A counterweight made by filling a bag with sand was fastened to the end of the rope which passed over the drum. On one end of the drum shaft there was a crank from which a connecting rod led to the handle of a twin-cylinder force pump. The whole apparatus was like this." As he talked along, he rapidly sketched a picture of his boyhood achievement in the wave-motor line.

"The pump was submerged for the purpose of making it reliable. No air leaks in the suction pipe could interfere with the flow of water to the cylinders, nor could air collect in the clearance spaces and keep the water out.

"Any movement whatever of the pump pistons forced some water up through the discharge pipe, which we designed later to connect with an elevated tank from which a stream could be drawn to run a small waterwheel. The thing would pump and I think it developed as much as one full catpower.

"There was a rise and fall of the tide of about eight feet which was all utilized in operating the pump as well as the rise and fall of the little waves; any movement of the barrel, whether vertical, horizontal or at any angle, was sure to move the pump pistons through a part of a stroke and a complete revolution of the drum corresponding to a rise or fall of the barrel through a space of about 18 inches would give a full stroke to the pump. It would do its best work when the waves rolled in at a hight of about two feet.

"At Atlantic City the machine is quite complex, and the same provision is made for all sorts of movement of the floats which furnish the power that I had, only they are more elaborate.

"A barker explained the operation to me and gave me some of the details. He said the floats weigh approximately 3000 pounds each and that the six floats would, with 2-foot high waves coming at the rate of eleven per minute, give an output of 120 horsepower. No one tried to sell me any stock and I came away mentally computing how much power could be gotten from the fall of six 3000-pound floats through a distance of two feet eleven times a minute. As all the energy that the floats could give up was that of falling from the hight to which the waves lifted them, I concluded that the claim of 120 horsepower from this machine was about 2000 per cent. higher than a reliable dynamometer would register."

Just here the dean returned and as he was about to start in again at the point where he was cut off, Sawyer said to him:

Sawyer's Wave Motor Made in Boyhood Days

"I have read both of Mr. Heck's contributions to the defense of his untenable premises. He practically begins by saying that Boyle's law does not apply to steam and then uses deductions from this same law to prove wrong what Dwelshauvers-Dery knows and what every engineer who has tried it knows to be true. He gets all tangled up in the labyrinth of his own logic and finally admits that more than a little compression may not be economical.

"It is not a question of vital importance but it is one that cannot be settled by discussion; and as long as mechanical engineers who have the equipment necessary for an exhaustive and competent test prefer argument to experiment, I shall believe that no one dares to try it. I have tried it on a commercial scale and know that compression saves money.

while not one of all the talented and educated gentlemen who believe otherwise has ever made even laboratory experiments, nor do I think they ever will.

"Something along this line may be done by the United States Geological Survey, but by any educational institution now flooding the country with sheepskin mechanical engineers, Nit.

"I am sorry I cannot stay the rest of the afternoon and tell you of several interesting little experiences in this line, but I must leave you for today." And without giving the dean, who had been on nettles all the while Sawyer was talking, time to put in a word, he winked to Rogers as he buttoned his overcoat and, saying good-by, went to the elevator.

Overcoming a Pound in the Cylinder

By A. J. Dixon

A pound caused by a loose liner in the high-pressure cylinder was stopped by placing setscrews between the end of the liner and the cylinder head, thus keeping the former in place.

The power equipment of a newly erected electric-railway generating station included a cross-compound condensing Corliss engine. About a week after this engine had been put in commission for regular service, a peculiar pound was noticed, but could not at first be located in any particular part of the machine. The pound was indistinct and scarcely noticeable at the beginning, but became more and more pronounced as the days passed. The various adjustments of crossheads, wrist- and crankpin brasses, main bearings, etc., having all been carefully attended to without producing any mitigating effect, the engineer finally decided to refer the trouble to the firm which supplied the engine. The manufacturers, accordingly, despatched the designer of the engine, together with a machinist and the engineering salesman, to look into the matter. By the time this trio appeared upon the scene, the pound had so increased as to leave no doubt that its origin was somewhere on the high-pressure side of the engine, with the indications pointing strongly to the cylinder end of the structure.

After pottering around for some time, the coterie of experts concluded that the source of the trouble lay in the connection between the piston rod and the crosshead. The rod was accordingly disconnected, the operation involving much time and labor, owing to peculiarities of construction, and then the parts were carefully put together again. However, when the engine was started again the pound was just as prominent as before. As this unit was the only one available for service at the time, it was imperative that it run until the next day, when the experts again went at it. This time they removed the caps from the main bearings, took out the quarter boxes and, finding nothing wrong, put them back again and started up, but with the same result. This procedure went on for several days, the experts tinkering first with one part and then with another, taking out the piston follower and packing rings and putting them back again; tightening every bearing, etc., but without any abatement of the pound which, on the contrary, continued to increase.

The high-pressure cylinder, which had a diameter of 24 inches, contained a steel liner, as shown in Fig. 1. It was claimed that this liner, which was 1¼ inches thick, had been set in the mold and the cylinder barrel cast around it, the steel thus becoming fused with the molten cast iron. The engineer advanced the supposition that this liner was probably the cause of all the trouble. The designer and his associates declared this to be utterly impossible, stating with much emphasis that inasmuch as the steel liner was not separate from the iron cylinder barrel it could not be the cause of the disturbance, as the mere

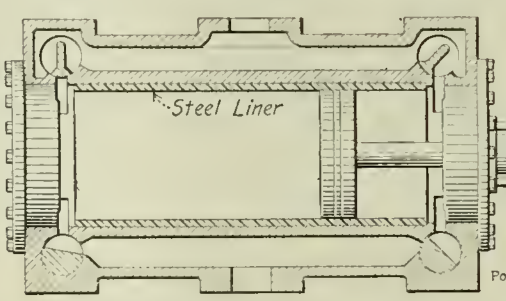

FIG. 1. SECTION THROUGH CYLINDER BEFORE MAKING REPAIR

fact of it becoming loose would mean a broken cylinder.

Nevertheless, the engineer steadfastly maintained that as every other part of the machine, in which a pound of this nature might possibly originate, had been inspected and nothing had been found

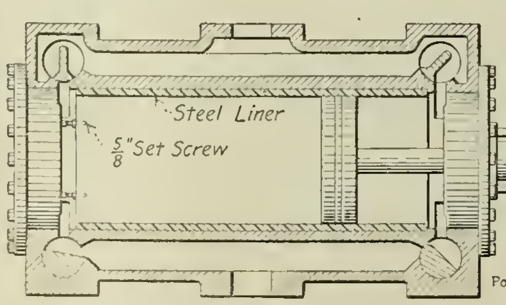

FIG. 2. CYLINDER SHOWING SETSCREWS HOLDING LINER

amiss, the only logical thing to do was to inspect the liner.

As the pound continued to increase at an alarming rate, keeping pace with the strokes of the piston with occasional muffled lapses as it apparently missed a stroke, the engineer finally concluded to take the matter into his own hands. Accordingly, he removed the cylinder head, ran out a timber with a screw jack behind it, between the edge of the bushing and the wall of the room, tightened up on the jack, and, as anticipated, the liner was found to be loose. Consternation reigned for a moment among the engine company's representatives, for it appeared at first that the only way to restore the engine to good order was to put on a new cylinder. The designer soon recovered his equilibrium, however, and began to devise plans for a serviceable repair with the least possible expense and delay. It was finally decided to patch the cylinder as shown in Fig. 2.

The edge of the liner was drilled at four equidistant points, the holes threaded by $\frac{5}{8}$-inch standard taps, and case-hardened setscrews secured with locknuts, were inserted as shown. The liner was forced firmly against the shoulder at the crank end of the cylinder, and then the setscrews were so adjusted that their heads bore solidly against the face of the cylinder head, at the same time permitting steam-tight contact in the ground joint between the head and the cylinder. This was a rather delicate adjustment and necessitated a dozen or more removals and replacings of the cylinder head before completion.

The engine continued in service and ran fairly well with this arrangement, but the engineer had a tedious job on his hands every Saturday night readjusting the setscrews after the previous week's run, for the thrust on the liner at each return stroke of the piston naturally tended to ram the screw heads hard against the cylinder head, wearing recesses in the comparatively soft metal and permitting a slight shuttling of the liner and the reappearance of the original pound.

A 16-horsepower internal-combustion motor is being tried for underground traction in the Langlaagte Deep mine, Transvaal. A special form of exhaust condenser is used, in which part of the cooling water is used to condense the products of the explosion, so that the vitiation of the air is stated to be less than would be the case if the many men required to deal with the load were at work.

Test of a High-Duty Pumping Engine

By Prof. R. W. Angus

The results of a twenty-four-hour duty trial on a new triple-expansion pumping engine at the Toronto city water works.

The supply of water for the city of Toronto is drawn from Lake Ontario, the water first passing through a steel pipe from the intake to Toronto island and thence through a large concrete tunnel under the bay to the well at the main pumping station. The tunnel is some distance below the bed of the bay so as to avoid seepage from the bay.

The engines of the main pumping station deliver directly to the mains, but the pressure is limited, due to the fact that a reservoir forms part of the system and is located at the opposite side of the city from the pumping station. The pressure maintained on the discharge main by the pumps at the main station is about 100 pounds per square inch.

The ground rises steadily from the bay northward through the city, and at the northern part, due to the high elevation, the water pressure is so far reduced as to make it necessary to provide some means of increasing it materially in order to furnish a satisfactory domestic supply. Hence, a high-level station was erected in which the pumps receive water direct from the mains supplied by the main pumping station, and discharge it into a separate system which serves the region named. The growth of this part of the city has been so rapid within the last few years, however, that it was found necessary to increase the equipment of the high-level station by the addition of new pumps, and it is to one of these that the present article refers.

FIG. 1. DIAGRAM OF ENGINE CYLINDERS AND PIPING

This pumping engine was built by the John Inglis Company, of Toronto, and is of the vertical, triple-expansion crank and flywheel type with three single-acting plungers and has a capacity of six million imperial gallons per 24 hours against a discharge pressure of 75 pounds per square inch, the suction pressure being 20 pounds. Dry saturated steam is supplied at a boiler pressure of 150 pounds.

A diagram of the steam cylinders and piping showing the path of the steam for the jackets, coils and cylinders is shown in Fig. 1. There are three steam cylinders, each of which is jacketed on the barrel only, but the design is such that the steam entering each cylinder passes over one-half of the corresponding head while the exhaust from the cylinder passes over the other half of the same head.

Corliss valves with separate eccentrics for steam and exhaust are used in all cases, except the exhaust from the low-pressure cylinder, where flat valves are used. The latter are opened by cams, the top pair being closed by compressed air and the lower ones by gravity. The exhaust steam may be passed through a feed-water heater on its way to the condenser if desired.

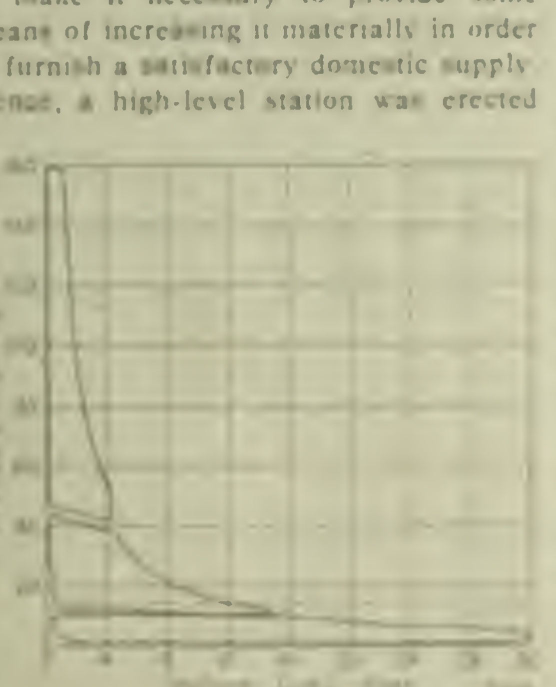

FIG. 2. COMBINED DIAGRAM, HEAD END

The air pump, boiler-feed pump and air compressor are attached to the low-pressure plunger, the compressor furnishing air for closing the low-pressure exhaust valves and also for replenishing the air in the pump-discharge chambers.

TABLE 1. PRINCIPAL RESULTS OF THE TRIAL

Pressure at engine throttle	[illegible]
Pressure in first receiver, pounds	[illegible]
Pressure in second receiver, pounds	[illegible] (below atmosphere)
Pressure in intermediate jacket, pounds	[illegible]
Pressure in low-pressure jacket, pounds	[illegible]
Vacuum, inches	[illegible]
Barometer, inches	[illegible]
Net pressure on pumps, pounds	[illegible]
Temperature of engine room, degrees Fahrenheit	[illegible]
Moisture in steam, per cent.	[illegible]
Average speed, revolutions per minute	[illegible]
Average plunger speed, feet per minute	[illegible]
Plunger displacement per 24 hours, imperial gallons	[illegible]
Work done per 24 hours, foot-pounds	[illegible]
Water horsepower	[illegible]
Steam used in jackets, etc., pounds	[illegible]
Steam condensed in condenser, pounds	[illegible]
Total steam used per 24 hours, pounds	[illegible]
Steam used per water horsepower per hour, pounds	[illegible]
Duty in foot-pounds of work done per 1000 pounds of steam used	[illegible]

There are three outside-packed, single-acting plungers of 21½-inch nominal diameter, the pump having a 24-inch suction and a 20-inch delivery pipe. All the water pumped passes through the surface condenser and is used as cooling water. The principal dimensions of the engine are as follows:

Cylinders	[illegible]
Diameter of piston rods, inches	[illegible]
Clearance volume, total: top end, high-pressure cylinder, per cent.; bottom or crank end, same cylinder, per cent.	[illegible]
First receiver, inches	[illegible]
Second receiver, inches	[illegible]
Condenser, cooling surface, square feet	[illegible]

DUTY TRIAL

A 24-hour duty trial of the engine was recently conducted by the writer. According to the contract the engine was to show a duty of [illegible] foot-pounds of work per 1000 pounds of steam used by the engine and auxiliary pumps. The steam to contain not over 1½ per cent.

FIG. 3. COMBINED DIAGRAM, CRANK END

moisture and to have a pressure of 150 pounds at the boiler, this pressure corresponding to 148.5 pounds at the engine.

Without going fully into the method of making the test it may be stated that great care was taken in getting the exact diameters and strokes of the several plungers, and special care was taken with other quantities used in computing the duty so as to insure accuracy in the results.

The water pressure averaged 74.92 pounds on the discharge main and 20.02 pounds on the suction main, and as these pressures were maintained very steady and the readings taken at five-minute intervals during the trial, these readings represent quite closely the true results. Table 1 gives the principal results of the trial.

This represents an extremely good performance in view of the fact that the power of the engine was so small, due to the low net water pressure. A set of combined indicator diagrams is given in Figs. 2 and 3 which show very good steam distribution.

Corrosion of Steam Boilers

By Walter C. Edge

Some of the common impurities found in feed water, their corrosive and scale-forming qualities, and the simple methods of treatment.

Water in a natural state always contains a great many other things than two parts hydrogen and one part oxygen. Sometimes it contains free nitric and sulphuric acids. River water, as a rule, is heavily loaded with vegetable and organic matter; nearly all lake waters contain limestone, and artesian and spring waters often contain soda as well as other foreign matter. These mineral substances are dissolved by the water in passing through the soil. The weight of the impurities in water varies greatly, but in moderately good water it is often from 20 to 50 grains per gallon. An analysis of a certain feed water showed it to contain the following impurities:

	Grains per Gallon
Silica	0.105
Oxide of iron and aluminum	0.362
Carbonate of Magnesia	13.794
Carbonate of lime	11.481
Sodium and potassium sulphate	3.569
Sulphate of lime	trace
Sodium and potassium chloride	3.300
Total solids	32.611

The total solid matter amounted to 4.65 pounds per 1000 gallons. A grain is 0.007 of a pound; hence, a steam boiler evaporating 600 gallons per hour (about 160 horsepower) would collect a deposit of

$$\frac{600 \times 4.65}{1000} = 2.80 \text{ pounds}$$

This is the approximate amount of impurities collected in one hour. Part of this would form sludge and the remainder would be converted into hard scale. If this boiler were worked a week of 60 hours, 168 pounds of solid matter would collect, and in less than three months this would amount to more than a ton.

The following table shows the principal impurities to be found in waters, some of them being in all waters and all of them being in some waters:

Impurities	Causing
Sulphate and bicarbonate of lime	Hard incrustation
Sulphate, chloride and bicarbonate of magnesia	Incrustation and corrosion
Chloride of sodium and carbonate of soda	Priming, foaming and incrustation
Bicarbonate and peroxide of iron	Incrustation and corrosion
Dissolved carbonic acid and oxygen	Corrosion
Sediment, mud, clay, etc.	Incrustation
Organic matter, sewage, etc.	Priming and corrosion
Grease	Corrosion
Nitric and sulphuric acids	Corrosion

The scale in a boiler is formed by lime, chalk and iron. While these solids are in solution in the original waters and cannot be detected by the eye, yet they are always left behind by the steam, and accumulate rapidly unless some means are taken to get rid of them.

Some of the evil effects of impure feed water are loss of fuel, loss of power and danger. The loss of fuel caused by a coating of scale on the heating surfaces of a boiler varies considerably, because it depends on the composition of the scale; some scales resist the transmission of heat many times as much as a boiler plate of the same thickness. It has been estimated that there is a reduction of from 2 to 4 per cent. a week in the quantity of water evaporated per pound of coal, due to the accumulation of scale. According to this, a boiler after working for four weeks would probably evaporate 8 to 16 per cent. less water per pound of coal than when in a clean condition, thus showing how important it is for the boilers to be kept clean.

If the feed water is of a corrosive nature it is advantageous to permit the formation of very thin scale as a preventive against corrosion. Corrosion, or the wasting away of the plates, is caused mostly by gases absorbed by the water, such as sulphurated hydrogen, and carbonic acid; grease and organic matter also promote corrosion. Even the purest waters when containing air, will cause pitting. More or less air is found in all waters, and this air escapes into the steam space when liberated by boiling, and being heavier than the steam, collects in bubbles, forming a layer between the water and steam and rapidly corroding the plate in the vicinity of the water line. The engineer should be careful to prevent the feed pump from drawing air, and should also be on the alert to prevent valve stems, etc., from leaking water on top of the boiler, as a great number of cases of external corrosion have been caused by a little neglect or carelessness regarding small leaks.

No doubt much corrosion in boilers is due to galvanic action; that is, when two different metals are placed in a solution capable of acting chemically on both of them an electric current is set up. The metal which is rapidly attacked and wasted away is known as the positive electrode, and in a galvanic battery, iron is always positive in the presence of copper. The inactive plate is known as the negative electrode. Iron is both positive and negative in the absence of other metals. In the presence of zinc, however, iron becomes negative.

Zinc then effectively protects iron from one form of corrosion. The presence of a small quantity is sufficient, a good proportion being a 12x6x½-inch slab for every 70 boiler horsepower. These slabs are usually attached to a stay, and should be renewed at regular intervals. Galvanic action is not nearly so common as some people seem to think, and it is doubtful if the action on the zinc slabs is always electrical, yet, if the corrosion of the boiler plates is lessened, their use should be continued even though the action is not fully understood.

In every section of the country the water has a different class of impurities, but the most common are the lime and magnesia. These substances are the principal cause of incrustation (hard scale formation) in boilers. Carbonate of lime (marble) and magnesia are almost insoluble in pure water, but dissolve readily in water containing carbonic-acid gas. This gas is driven off by boiling, and the lime and magnesia, before held in solution, are thrown in the solid form as insoluble deposits. A part of the mineral matter is deposited in the form of a fine powder, which forms mud, and the remainder settles on the plates of the boiler as hard scale.

The impurities are not all set free from the water at the same temperature. Thus the carbonates of lime are precipitated when a temperature of from 300 to 400 degrees Fahrenheit (corresponding to about 150 pounds pressure) is reached.

The small solid particles when set free remain for a time suspended in the water, being carried around by the circulation, but they settle down gradually on the tubes, plates and other internal surfaces. The lime matter then becomes scale, which soon bakes to the plates, and if no means of prevention are used a crust from $\frac{1}{16}$ inch to $\frac{1}{2}$ inch thick is formed on the inner surface of the boiler.

A good feed-water heater will serve to keep out the impurities which precipitate at temperatures in the neighborhood of 200 degrees Fahrenheit; this includes both the carbonates of lime and magnesia. The water will not hold these solids in solution when it is at 200 degrees or more, and consequently they are precipitated. But they are still held suspended in the water, and, unless given time to settle, will go to the boiler just as they would if still in solution. For this reason all purifiers should have space for from 5 to 15 minutes' supply of feed water.

Soda is the common antidote for carbonates of lime and sulphates of lime, the two most common impurities of water. Under the name of soda several substances are used as preventives of scale in steam boilers. The cheapest and most common is carbonate of soda, commonly known as soda ash. When soda ash is crystallized by dissolving in water, it becomes sal soda, which is synonymous with washing soda. Caustic soda is made by heating carbonate of soda with slacked lime. A solution of caustic soda in water is known as soda lye. For ordinary cases, 40 pounds of soda ash, 100 pounds of sal soda or 35 pounds of caustic soda per 1000 gallons of water will be sufficient to precipitate most of the scale-forming matter.

The cost of treatment with soda is very low, only about one grain of soda ash being required for each grain of sulphate.

If there are any free acids present they should be neutralized by additional soda. An excess of soda will impair the steaming facilities and will also have a corrosive effect on the iron. This is indicated by foaming, leaks, and the white salts of sodium oozing through the joints.

Boiler Plant Considered as a Factory

By Paul A. Bancel

Considering the coal, water and air as raw materials and steam as the finished product, the various losses in the process of manufacture are traced. The value of a CO_2 recorder for indicating these losses is discussed.

A boiler plant may be considered as a factory for making steam, from which standpoint an increase in boiler efficiency represents a decreased cost of production of the finished product—steam.

The raw materials supplied to the steam factory are coal, water and air. Of these, coal is expensive; water is expensive in some cases, but as the amount of water used is the same per pound of steam turned out, practically regardless of the method of operating the plant or its efficiency, it may be omitted at the outset from this discussion; finally, the third material, air, costs nothing except to move it.

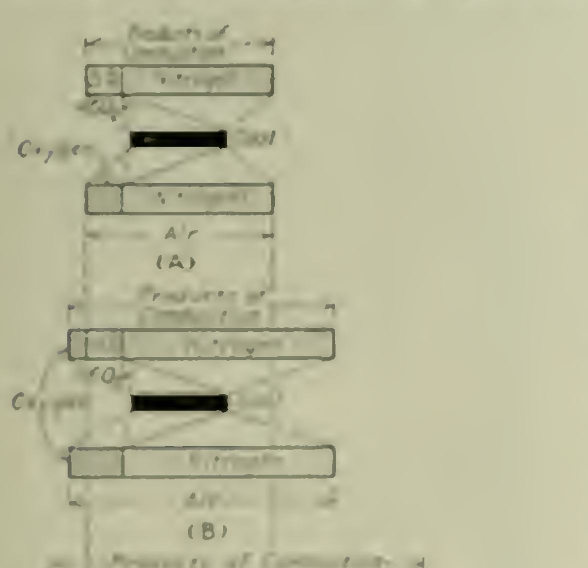

Fig. 1. Graphical Representation of Products of Combustion and Excess Air

The process of making steam may best be analyzed in two steps: First, the combination of the coal and air to form hot gases; second, the transference of the heat in the hot gases to the boiler surfaces, thence to the water and the formation of steam.

As with any other process of manufacture, there are wastes occurring in both steps of the process. These wastes occur due to the imperfect nature of the machinery used, the imperfect use of the materials, the formation of a waste product and the fact that the best of labor is careless. The waste or losses occurring in the process of making hot gases out of coal and air, may be summarized for the average plant as follows:

	Per Cent.
Loss due to incomplete burning of smoke	1
Loss due to unburned combustible gases such as hydrogen and carbon monoxide and hydrocarbons	[illegible]
Loss due to unconsumed carbon dropping through the grates with the ash	[illegible]
Loss due to radiation	[illegible]
Total losses	10

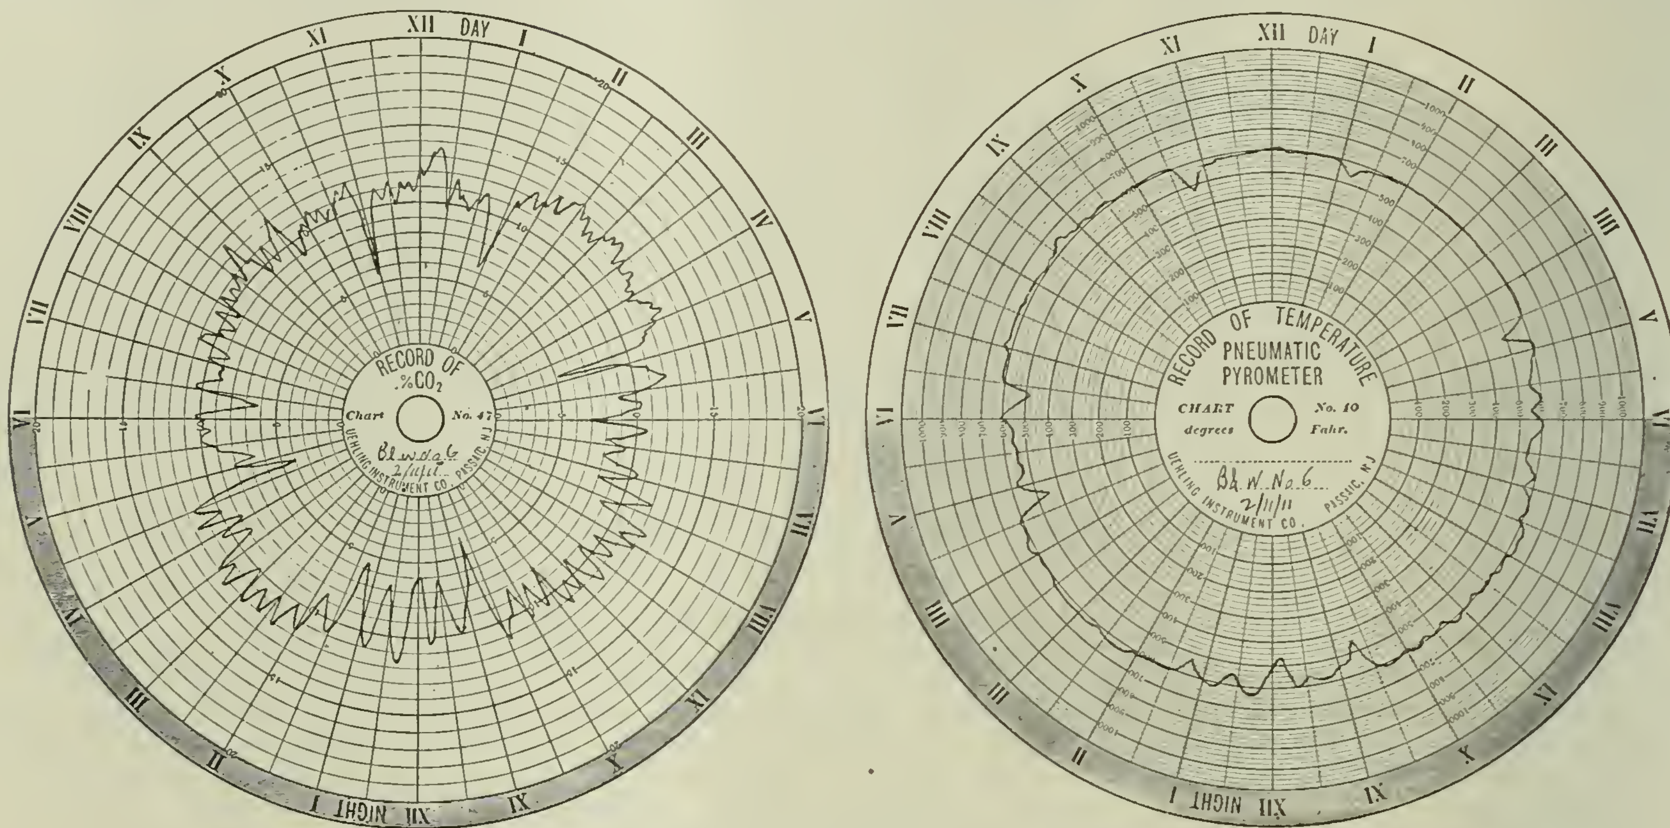
As is seen, the sum of all these losses amounts to 10 per cent. of the heat in the coal. If all the heat in the hot gases could be transferred to the water in the boiler, efficiencies of 90 per cent. or better would be obtained. It is in the second step of the process of steam manufacture that is found the chief cause of low efficiency.

The water within a boiler is at some temperature near 400 degrees Fahrenheit. The hot gases give up part of their heat to the water within the boiler, and are cooled down an amount depending upon the amount of surface used. If boilers were very large, then it would be possible to cool the gases to nearly the temperature of the steam and water. Unfortunately, it does not pay to put so much surface into a boiler, and gases are emitted from the chimney at temperatures near 500 or 600 degrees Fahrenheit. Thus the hot gases formed in the first part of the process with an efficiency of 90 per cent., are of no use for making steam under ordinary conditions, when their temperature has dropped below 500 or 600 degrees Fahrenheit. These gases are then a waste product of the steam factory, but not necessarily a useless product. They are valuable for heating cold water, cold air, for making draft in a chimney and for evaporating a liquid such as ammonia.

Fig. 2. Combustion Diagram

The amount of heat carried away from the boiler plant depends evidently upon the temperature of the gases, their specific heat and their weight. The specific heat is practically constant at 0.24 but the weight of the gases depends on how much air is used to burn the coal. Calculations will show that the heat value of the waste product in a boiler plant may run as high as 30 per cent. of the total heat of the coal. The very nature of this loss makes direct measurements difficult. If it were possible, the best method of determining the amount of heat in the waste gases would be to take the temperature of the gases going up the chimney and to measure their weight for each pound of coal burned.

The weight of the gases going up the chimney, however, cannot be readily measured and it is difficult to determine just how much coal is actually being burned at any time corresponding to the moment at which the weight of the gases is taken. There is no direct means, therefore, of measuring the amount of heat in the waste product emitted from the steam factory, or boiler plant. On the other hand, an indirect means of obtaining the weight of the waste product per pound of coal burned lies in the measurement of the carbon dioxide contained in the flue gases.



FIGS. 3 AND 4. DAILY CHARTS SHOWING PERCENTAGES OF CO_2 AND THE FLUE TEMPERATURES

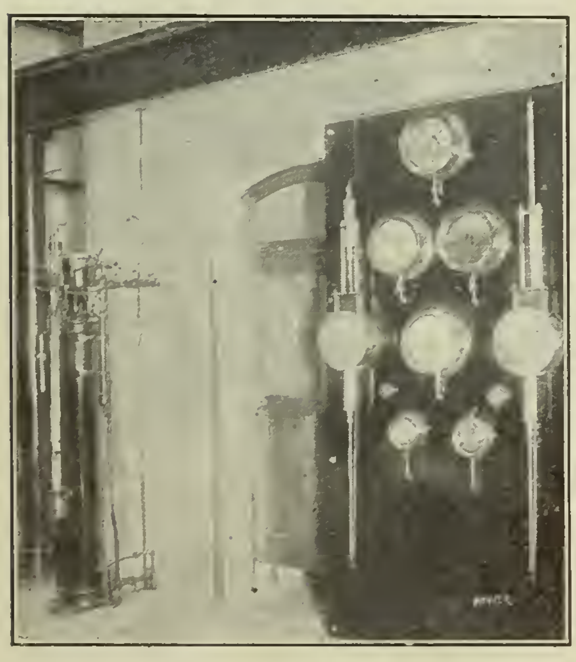


FIG. 5. UEHLING WASTE METER AND RECORDING GAGES

Air consists of oxygen and nitrogen. Only oxygen is necessary for combustion, but the nitrogen must be carried along with the oxygen into the furnace without entering into the process of combustion. Coal consists of carbon, hydrogen, ash and minor constituents, the first two entering into the process of combustion, the latter being mineral material not combining with the oxygen and not developing heat. The carbon in the coal combines with a definite amount of oxygen to form carbon dioxide gas or CO_2. Furthermore, it is an established fact that when a cubic foot of oxygen combines with carbon to form carbon dioxide, the volume of the carbon dioxide formed is also one cubic foot, the temperature of oxygen and carbon dioxide being the same. As the volume of all the gases varies in the same way with the temperature changes, any volumetric relations holding true when the temperature of the products of combustion as 500 or 600 degrees will also hold true when their temperature is that of the atmosphere.

Referring to Chart A, Fig. 1, assume that the coal consists of carbon only and below the coal bed a certain amount of air consisting of oxygen and nitrogen is supplied, the coal burning so that the products of combustion consist of carbon dioxide and nitrogen. If the combustion were complete with just enough air supplied to effect complete combustion, then as the carbon dioxide displaces the oxygen, the volumetric relations of the gases in the products of combustion would be the same as the relations of the gases in the air. The percentage by volume of oxygen in the air is 21, and with theoretically perfect combustion of carbon, the products would consist of 79 per cent. of nitrogen, 21 per cent. of carbon dioxide and no percentage of oxygen. Charts B, C and D, Fig. 1, show the relations when more than the theoretical amount of air has been supplied. The amount of coal burned being the same, the same amount of carbon dioxide must be formed. But as more than the theoretical supply of air has been furnished, a part of the oxygen, together with all the nitrogen, must go through the coal without entering into the process of combustion. The products of combustion consist then of nitrogen, carbon dioxide and also a supply of uncombined oxygen. If twice as much air and oxygen as is theoretically needed were supplied, then as shown in Chart C, the volume of carbon dioxide formed would be half the volume of the oxygen originally in the air. The percentage of carbon dioxide in the gases formed would then be, instead of 21 per cent., one-half of 21 per cent. or 10½ per cent.

These relations may also be shown by the charts in Fig. 2. The area of the circles in each case represents the amount of gas going up the chimney for one pound of carbon burned. As it requires a definite amount of oxygen to burn a pound of carbon and a definite amount of carbon dioxide is formed, the volume of carbon dioxide remains the same in each

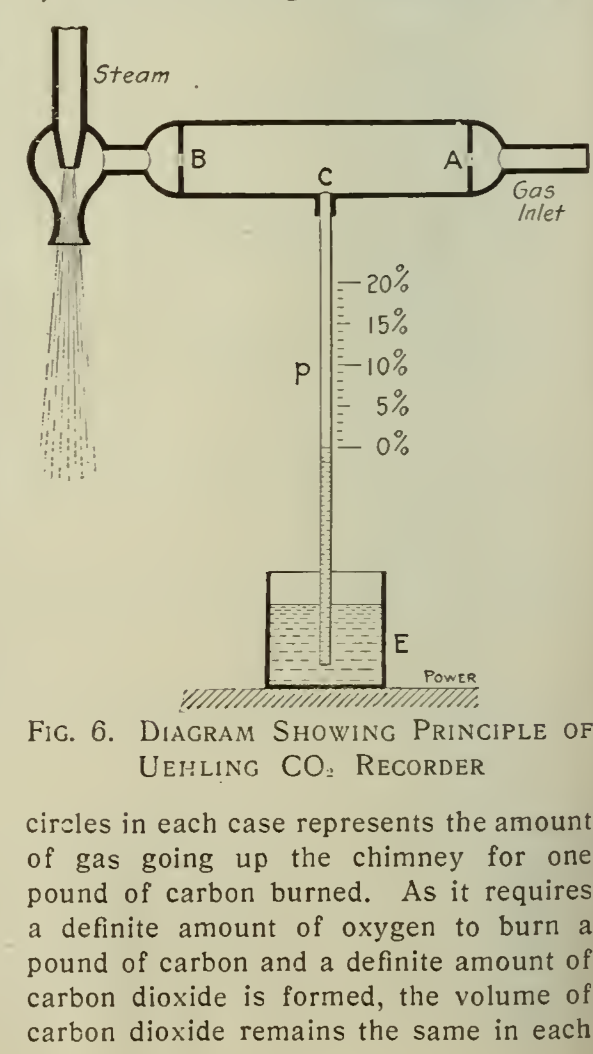

FIG. 6. DIAGRAM SHOWING PRINCIPLE OF UEHLING CO_2 RECORDER

case, shown by the small shaded area. In the case of Chart A, all the oxygen is transformed into carbon dioxide and all the remaining area is nitrogen, the percentage of carbon dioxide in the flue gases being 21 per cent. In Chart B the total volume has increased, the amount of nitrogen being increased and the the amount of oxygen available for burning one pound of carbon increased; the amount of carbon dioxide formed remains the same as in the first case.

Just as the factory manager can look over his books and note the value of his raw materials, the cost of manufacture, the price of the finished product, the profit, the value of the waste product, etc., so can the engineer record, in connection with the plant load, the draft, thickness of fire, kind of labor, coal burned, amount of water used, temperature of the flue gases and percentage of carbon dioxide; and thus be guided in running his steam factory so as to turn out the finished product at the least cost.

Typical records of carbon dioxide and temperature are shown in Figs. 3 and 4, which were obtained from a Uehling combined CO_2 machine and pyrometer, or "waste meter," installed in the Edgewater plant of the Corn Products Refining Company. This waste meter is shown in Fig. 5, where also the recording gages can be seen mounted on the board. The recording gages are simply vacuum-recording gages, and it is because this waste meter measures both carbon dioxide and temperatures by changes in partial vacuum, that it is possible to record by independent gages and indicate by water columns, and also that continuous measurement is obtained.

Referring to the sketch of Fig. 6, the flue gas is drawn through the two apertures A and B by constant suction produced by a steam aspirator. The suction in chamber C will remain constant so long as the same amount of gas passes through both apertures. If, however, part of the gas, that is, the CO_2, be absorbed in the space between the two apertures, the vacuum will increase in proportion to the amount of gas absorbed. All that is necessary then in order to measure the percentage of CO_2 is to connect chamber C with an indicating water column, or a light vacuum-recording gage.

The engineer aided by a waste meter of this kind is guided in operating his plant so as to cut down the cost of steam production to the least amount compatible with the cost of coal, character of coal, kind of grates, draft available, kind of boiler, etc.

Progress in Return Tubular Boilers

By William Kavanagh

Showing the improvements that have been made in the settings and fittings of horizontal return tubular boilers during late years.

Improvements in the design of horizontal tubular boilers and settings have been slow as compared with other types. Those improvements that have been made in late years, however, include dispensing with staggered tubes, leaving out the middle vertical row of tubes, placing manholes above and below the tubes, dispensing with the handhole in the rear head, the proper protection of the blowoff pipe against overheating, omitting the steam dome and carrying the boiler on rollers or suspending it from girders.

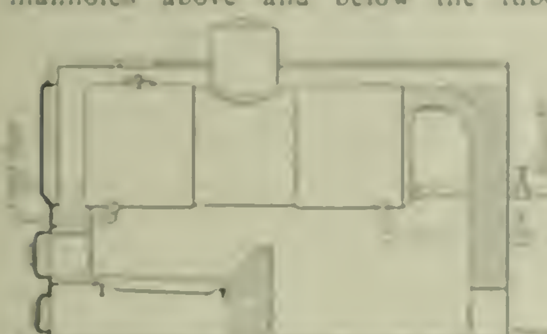

Fig. 1. Old Method of Connecting Feed and Blowoff

Fig. 1 represents what may be termed an "old time" setting in which the feed pipe is attached to the bottom sheet, directly over the fire, the object being to heat the feed water before entering the boiler. The blowoff is attached to the rear head some distance above the bottom sheet, which arrangement prevents, to a large extent, the mud and scale from being forced out of the boiler. The dotted lines, Fig. 1, represent the feed introduced through the lower part of the front head; also, the proper connection for the blowoff pipe which is protected by a sleeve or covering of asbestos.

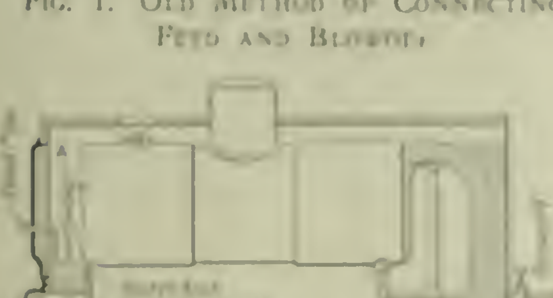

Fig. 2. Water Arch at Front and Continuous Circulation through Blowoff

In Fig. 2, the blowoff pipe is protected from overheating by a circulation of water through it. Here, also, the feed is admitted through a water arch, thence through pipe A to the boiler at some distance below the water line.

Fig. 3. Water Arches at Both Front and Rear

A progressive step toward utilizing waste heat and preventing cracked walls and falling fronts and rear arches, is shown in Fig. 3. Both front and rear water arches are supplied; the feed entering at B and after circulating through the rear arch, which is exposed to the hot gases, passes to the front arch and thence into the boiler where it is discharged through a perforated pipe. The main blowoff pipe, besides being protected by the circulation of water, is fitted with an asbestos-packed cock, an auxiliary blowoff valve and a "tell tale." When the latter indicates leakage, the auxiliary blowoff may be closed and the

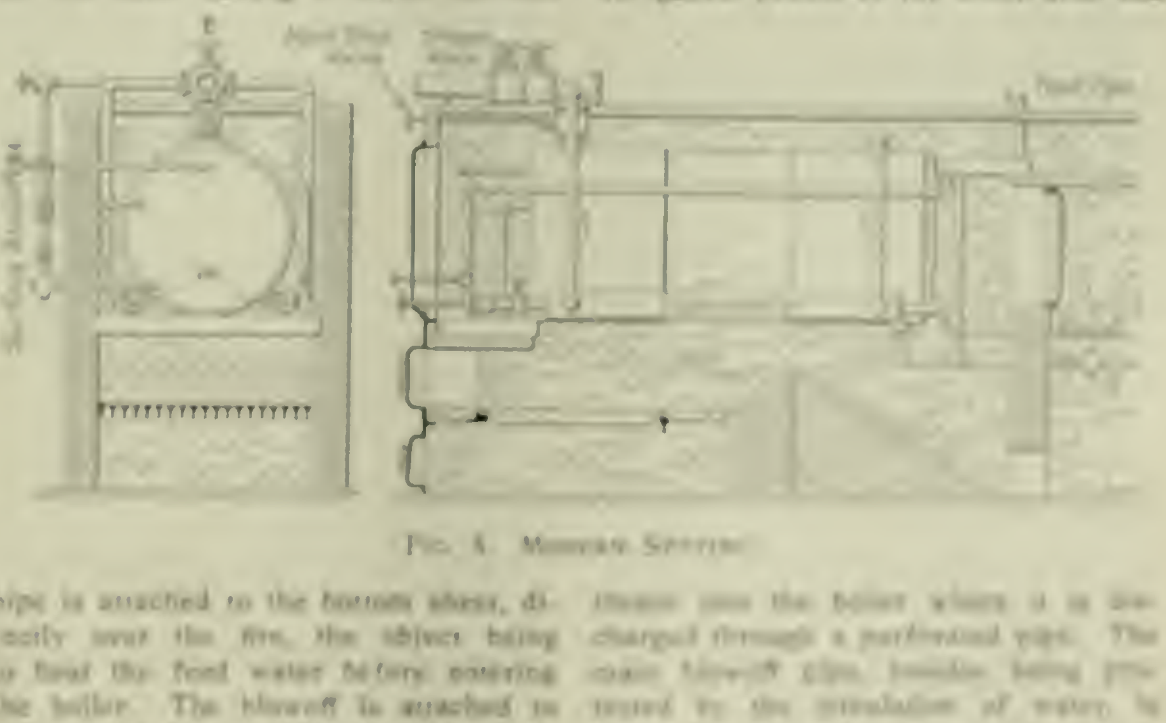

Fig. 4. Modern Setting

main blowoff repaired. Previous to the use of auxiliary blowoff valves there was no way of making repairs to the main blowoff cock without shutting down the boiler.

The boiler shown in Fig. 4 embodies the good points gained through many years of experience and represents probably the most uptodate practice with return-tubular boilers. The lugs rest on rollers allowing free longitudinal expansion and contraction of the boiler and both front and rear water arches are fitted. The rear wall has a door permitting inspection and cleaning of the rear head. The steam is taken from the rear of the steam space and passes through a superheater extending the whole length of the boiler, thence to the main header which is also connected directly to the steam space of the boiler. Both an ordinary steam gage and a recording steam gage are fitted.

The furnace is hand fired and at the rear of the grate is a dead plate used for banking and cleaning the fires. The damper shaft is carried on roller bearings which permit a very sensitive regulation of the steam pressure. A surface blowoff is attached at the front of the boiler and an improved arrangement of regular blowoff, similar to that shown in Fig. 3, is fitted at the rear.

The water column is fitted with both a high- and a low-water alarm in addition to self-closing gage-glass valves. Also, the water connection to the column is fitted with a tee and brass plug for use when cleaning the connection.

In raising steam the valves *W W* are first opened to allow a circulation of water through the superheater and after the desired pressure has been reached they are closed and any water in the superheater is blown out at the rear, through the valve *I*. Near this valve is placed a small valve *J*, used to indicate the quality of the steam in the superheater. When this valve shows dry or superheated steam the main valves *E E* are opened, and the boiler is put into service.

The boiler-feed pump should be fitted with a safety valve to prevent excessive pressure on the feed line; also, a bypass allowing the pump to run at practically constant speed, any surplus water being discharged back into the suction line. The check valve on the feed line should be placed between two globe valves, thus permitting repairs at any time.

An essential feature with the foregoing equipment is that all pipes and fittings are extra heavy and the connections allow movement and compensate for expansion and contraction. Furthermore, no expansion joints are used, the connections being so arranged as to screw and unscrew in the direction of the stress.

Determining the Value of Fuel

By R. L. Ellis

It is pointed out that the method of purchasing coal upon either the analysis basis or upon an evaporation basis alone, is inadequate, but a combination of the two has been found to give excellent results.

Discussions upon the subject of fuel have, in general, advocated some particular theory as to the best method of determining the value of the fuel to be purchased, the best method of combustion, or a reduction of the smoke nuisance, etc., rather than a sincere desire to ascertain the facts in the case. There is the man who is bent on the elimination of smoke and who has tried to show that all the profits go up the stack in the form of smoke. As a matter of fact, the visible element in smoke amounts at most to but a very small percentage of the total heat and it is easily possible to have absolutely smokeless combustion and far from economical operation, although from certain standpoints the elimination of smoke is desirable.

There are others who maintain that the B.t.u. in the coal is the proper basis of purchase, attempting to class the whole carload or more from a sample weighing a gram or less. The contract of a certain concern which proposes to purchase coal on B.t.u. specifications, provides for certain penalties for excess of ash, a deviation in the proximate analysis from that specified, an excess of sulphur and for deficiencies in the heat contents. But might not the coal vary rather considerably in each particular and there be no marked difference in the actual results obtained? Also, if these penalties and bonuses apply, how are the amounts to be determined for the variations? Certainly the penalties and bonuses should represent not arbitrary amounts but only real variations in the worth of the coal to the consumer.

Again, there are those who are opposed to the scientific analysis and buying of coal; they contend that the only measure of the value of a coal is the quantity of water it will evaporate per pound. There is a measure of truth in each treatment of the subject, but the solution of the problem lies in a combination of the practical and the scientific methods. It is desirable to eliminate smoke but it is more important to secure economical combustion. It is important to obtain a high percentage of CO_2 in the flue gases but one may get too much for the overall economy. It may be desirable to know the character of coal used and its heat contents, but for the particular furnace conditions in which the fuel is to be used this may not furnish a true guide as to the desirability of the coal. On the other hand, without the analysis one may fail to get the proper results from a really economical coal and discard it as worthless on account of not being able to interpret the facts furnished by the scientific analysis.

The real measure of the value of coal for commercial use is its cost per unit of finished product. The total cost of the coal includes its cost at the mine, cost of delivery, unloading, stoking and handling the ashes, together with any other expense due to the use of the coal. The finished product may be supplying a certain number of square feet of radiation at a given temperature, yards of cloth made, kilowatt-hours, etc.

Coal as usually specified by analysis contains a certain amount of moisture, volatile matter, fixed carbon and ash, with a separate determination of the sulphur, and finally, a certain number of B.t.u. per pound. Usually with the dealer this means a mine sample or a sample taken by cross-cutting the seam and a careful elimination of any dirt above or below the seam, but with the purchaser it should mean an average car sample, which is an entirely different proposition.

Some contracts make deductions for moisture, but unless the coal be weighed at the point of delivery this is manifestly unfair for the reason that the excess moisture may represent water in the form of rain which fell after the coal left the mines. On the other hand, if the coal be shipped in fair weather and remain several days on the road it might be flooded with water at the mine and be practically dry upon delivery, which would afford the seller a very large advantage. Unless the quantity of coal is sufficient to warrant scales at the point of delivery, it is inexpedient to make any provision for correcting for moisture in the coal. About the only thing that can be done is to weigh an occasional car under different weather conditions to ascertain whether the mine owners are attempting to act unfairly in the matter and, if so, it has been the experience of the writer that the sooner a contract with a concern of such character is broken the better.

In the proximate analysis it is desirable to know if the volatile matter be determined with or without a previous drying-out process; the results may be markedly different in the two cases. Furthermore, it should be known whether the volatile matter is all combustible and whether it distils off quickly or slowly. These affect the adaptability of the coal for a particular furnace unless the furnace be designed to handle economically coals of widely different characteristics, but very few of the commercial forms are so arranged.

At the plant with which the writer is connected, the average cost of coal stoked and the ash removed was $2.76 per ton, and the coal per kilowatt-hour averaged for the year 8.60 pounds. With this information at hand, several carloads of coal were ordered and placed in the bin, samples being taken during unloading. These samples were sealed in quart jars, labeled by car numbers and sent to a chemist for analysis. The coal was then burned under the boilers and data taken as to the evaporation and the kilowatt-hours delivered at the switchboard.

Having done this, the question then arose as to what had actually been accomplished. It was known that a certain amount of coal had been burned per kilowatt-hour at a certain cost per ton of coal fired. But what of it? The results were not of such a character as to determine whether the coal was or was not desirable for the particular conditions. It was known that the coal ran about 8 per cent. in ash, 35 per cent. in volatile and 57 per cent in fixed carbon, with less than 1 per cent. of sulphur and a heat content of 13,750 B.t.u., but the actual performance of the coal could not be correlated with the results of the analysis, and, furthermore, wide variations were observed from day to day in the actual results with apparently no change in load or weather conditions. Manifestly there were the personal equation of the fireman and other factors to consider.

To this end, a thermometer was placed in the feed-water supply, another in the uptake of the stack, a gas-sampling apparatus in the base of the stack and at several places in the furnace proper, an Orsat apparatus was purchased, the engines were reindicated and the integrating meters on the switchboard recalibrated. A water-weighing apparatus was installed on the feed-water line and the coal scales were overhauled and calibrated. Some more coal was bought and the conditions of the whole plant were studied thoroughly. It was then found that coal from different mines behaved very differently in the boiler and in order to obtain the cheapest and most economical fuel it would be necessary to design a furnace that would economically handle coal of wide variation in character. This work took quite some time, but finally a furnace was produced that would successfully handle coal varying all the way from coke to the highly volatile coal from the Alabama fields.

It is now the practice at this plant when purchasing coal to take a sample from each car for analysis. In a day or two, after the fireman has become familiar with the coal, results are noted. Of course, records of all conditions are taken daily but the results are expected to be poor with a given coal until the fireman has learned to handle it properly; hence in estimating the value of the coal these experimenting days are eliminated.

After the fireman has become familiar with the coal, frequent readings are taken of the thermometer in the uptake, also frequent determinations of the flue gas, as well as a 12-hour sample. The temperature of the feed water is so nearly constant at 212 degrees Fahrenheit that it is not recorded and only checked occasionally to see that the heater is in good working order. The amount of water fed to the boilers is noted at the end of each 12 hours and corrected for difference in the level of water in the boiler. The coal is also corrected for the amount on the firing floor at the end of each 12 hours. Readings are taken on the integrating wattmeter as are also readings on the indicating meters to ascertain if the load conditions are normal.

Having previously determined the most economical percentage of CO_2 in the flue gases for the particular coal, it is kept as nearly as possible at that point. It has been found unnecessary to make a complete analysis of the flue gases except occasionally, as the furnace efficiency follows very closely the CO_2 content up to a certain point. The density of the smoke is noted, but this is a very minor consideration since there is no smoke ordinance and with practically perfect combustion the smoke is rather negligible.

The uptake temperature indicates the heat loss through the stack; the record of feed water checks the boiler performance as distinguished from the engine and generator performance; and by weighing and examining the unconsumed portion of the coal, its clinkering character is noted; also, it can be ascertained if there is any considerable amount of unconsumed fuel mixed with it.

From the foregoing, it will be seen that the coal tests at this plant are a cross between the rule-of-thumb methods of the so-called practical school and the refinements of the scientific school. The combination might properly be termed the commercial method of testing. To sum up, in determining what coal shall be purchased, the analysis and heat determination as supplied by the seller are gone over and it is ascertained whether the mine owner is willing to guarantee this as an average car-sample analysis. The financial condition of the mine is then looked into, also the railroad facilities for a continuous supply of coal. These factors serve as a general guide as to what may reasonably be expected of the coal. If the ash be low, the B.t.u. contents reasonably high, and the coal from a field that has given good results and the price attractive, several cars will be purchased for trial. It is usually possible to purchase with the price on the sample cars open and to be determined by the results in comparison with the coal then in use; in other words, at so much per kilowatt-hour for coal cost.

In making up an estimate as to the probable value of the coal, the proposed price of the coal plus the freight, the cost of unloading the coal and the cost of handling the ashes for each per cent. of ash in the coal are considered; this total is divided by the number of B.t.u. The result is strictly arbitrary, since the costs are per ton and the B.t.u. are per pound. This figure, however, in comparison with figures previously obtained from other coals gives a fairly accurate predetermination of the probable value of the coal in comparison with others.

At the time of testing the coal commercially, if the results are good, the samples are analyzed and compared with the mine analysis, each other and the actual commercial results. If the results all told show that the fuel is a desirable one a contract is made.

The existing contract is ideal for simplicity and practically gives results that are believed to be equally as good if not better than those obtained by the more involved contracts, and it is manifestly fair to both concerns. It provides that the coal to be furnished shall not differ materially from that sent as a sample in the proportion of volatile matter and fixed carbon; it shall be from the same seam and furnished with regularity at a specified rate. The price is specified. In the particular coal now being purchased the ash from the sample cars did not exceed 8 per cent. and the B.t.u. did not fall below 14,000. It is, therefore, specified that if the ash habitually exceeds 10 per cent. and the B.t.u. falls below 13,500, the purchaser shall have the right to reject the coal and cancel the contract, or a new price shall be agreed upon between the parties to the contract.

In this it will be seen that the actual value of the coal is determined by its use in the plant in which it is to be used and the conditions are checked to ascertain if the shortcomings of any sample are due to lack of quality or improper handling. The analysis of the coal is only used as a check and to insure the furnishing of coal on the contract of substantially similar character.

Electrical Department

Especially conducted to be of interest and service to the men in charge of the electrical equipment

A New Interpole Dynamo

The development of heavy electric traction and large factory equipments has created an extensive demand for direct-current dynamos that will work sparklessly under widely and rapidly fluctuating loads and abnormal overloads and for meeting such requirements the interpole construction, now well known, is admirably fitted. The accompanying engravings show the essential features of a machine of this type which has been recently brought out by the Westinghouse Electric and Manufacturing Company for direct mounting on the extension of the prime-mover shaft.

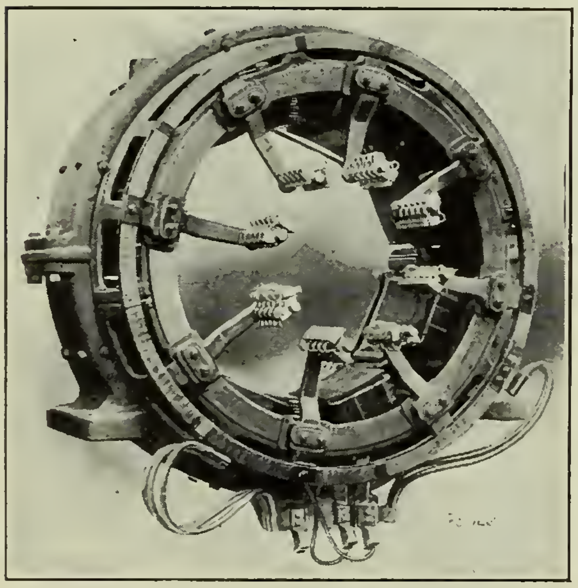

Fig. 1. Interpole Field Magnet

The complete field magnet is shown in Fig. 1, from which it will be evident that the brushes are not provided with the means for adjustment which is always found on ordinary generators without interpoles. The brush rigging is set accurately at the factory and the field-magnet yoke and the ring which carries the brush holders are marked so that this position can be duplicated instantly when the machine is erected in its working position. The magnet yoke ring is of cast steel and only a little wider than the magnet poles; consequently, the field-magnet coils extend beyond the yoke edges and their heat is readily radiated. The projecting portions of the coils are protected from mechanical injury by a skeleton framework at each side of the yoke ring and the brush rigging is supported by one of these frames, as shown in Fig. 1.

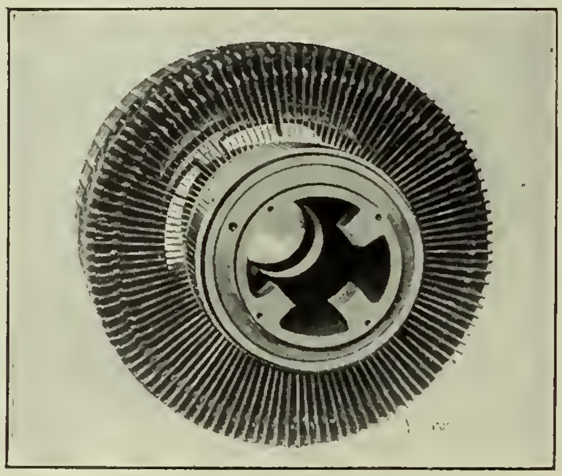

Fig. 4. Commutator End of Complete Armature

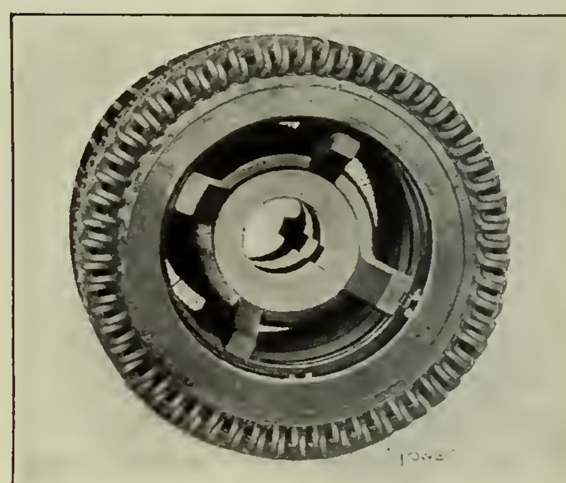

Fig. 5. Rear End of Complete Armature

The main magnet poles are built up of thin steel sheets riveted into a solid mass, as indicated in Fig. 2; these are bolted to the inner face of the yoke ring, which is machined smooth all the way around and across the face. The interpoles are solid steel blocks, also bolted to the yoke ring.

The armature core is built up of annular segments dovetailed to ribs on the central spider and the latter is cast with internal ribs also, instead of being solid down to the shaft. Fig. 3 shows this construction; the barrel projecting toward the observer supports the commutator, forming the drum and one flange of the commutator core. The armature core is provided with spacers at intervals along its length, as usual in large machines, forming ventilating ducts between the adjacent laminations of the core. The core is, of course, slotted to take the coils, which are form-wound and individually insulated. The winding is of the straight-out or barrel type, leaving

Fig. 2. Magnet Pole

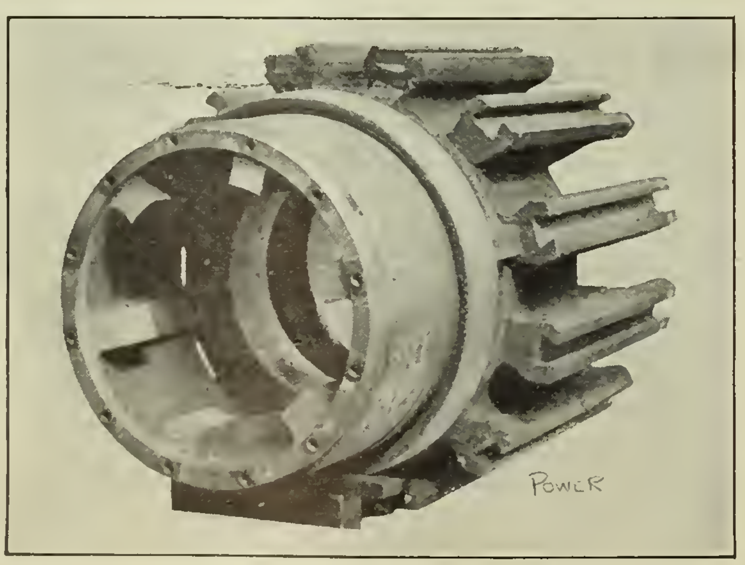

Fig. 3. Armature Spider and Commutator Core

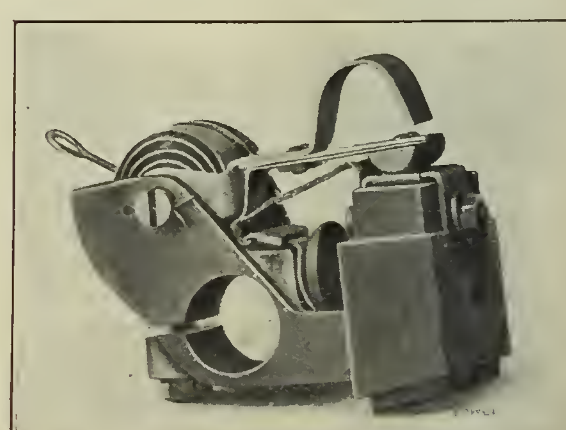

Fig. 6. Brush and Holder

the heads of the core open to the surrounding air, as Figs. 4 and 5 show; these views indicate how clean-cut and well ventilated the armature and commutator are.

The brush holders might be characterized as "the usual pocket type," but there are several details which, though relatively minor, deserve special consideration. The "pigtail," for example, which is of flat copper-wire braid, is attached to the frame of the brush holder by means of a large thumbscrew and to the brush by means of a through bolt; moreover, the "pigtail" is so located that it cannot foul the spring or interfere with the movement of the brush, although it is easily accessible for removal. See Fig. 6. The bolt which attaches the "pigtail" to the brush passes through the ends of a ∩-shaped strap which straddles the top end of the brush and affords a seat for the end of the pressure finger; the latter is equipped with a rounded pressure block which touches the brush along a line, no matter what the position of the brush, and therefore does not tend to tilt the brush or jam it against the wall of the pocket. The pressure finger is forced against the brush by a flat spiral spring the tension of which is adjustable by the usual spindle and lever.

These machines are built in sizes ranging from 25 to 1000 kilowatts and of the standard direct-current voltages. They are compounded to give a rise of 7 volts in the low-voltage machines, 20 volts in the middle-voltage machines and 50 volts in the railway machines.

National Electric Light Convention

The thirty-fourth convention of the National Electric Light Association was held this year at the headquarters of that body, the Engineering Societies building, New York. The convention was opened on May 30 with the usual formalities; the delegates were welcomed to the city by acting mayor John Purroy Mitchell, the president of the association delivered his annual address and several important committees presented their reports.

Overhead Line Construction

The report of the committee on overhead-line construction was an admirable piece of work, embracing detailed specifications for materials and methods to be used in building overhead lines for 2300-volt alternating-current distribution and for street-lighting circuits. Because of the completeness of these specifications it is impracticable to abstract or summarize them beyond stating that they cover the dimensions and appearance of chestnut, white-cedar and yellow-pine poles; dimensions and quality of pine, cypress and fir crossarms; sizes and quality of wooden and metal insulator pins, pole-steps and guywires; copper, aluminum and copper-covered steel wires and cables, bare and insulated. Methods of putting up poles and stringing wires are also described and illustrated. The report is really an encyclopedia of modern line construction and worthy of a substantial binding to withstand the constant reference which it justifies.

Meters

The report of the meter committee, presented at the afternoon session of the first day's proceedings, contained some excellent material on the practical care of meters which will be published very fully in an early number of Power.

Grounding Low-tension Circuits

In a paper of the above title, Paul M. Lincoln pointed out the advisability of grounding low-tension alternating-current circuits for protection to life and explained how and why breakdowns frequently occur between the high-tension and low-tension windings of transformers.

The fundamental reason why breakdowns of this sort occur simultaneously with disturbances on the high-tension system, he said, is that transformers act to a considerable extent as condensers because of the interleafing of the sections of the winding; that is, the high-tension "pancakes" act as one set of condenser plates and the low-tension sections as the other. Under such conditions, an alternating difference of potential between the high-tension system and the ground will induce a corresponding difference of potential between the low-tension system and ground.

The amount of potential difference between the low-tension winding and the ground will depend on the relative static capacity between the two windings and between the low-tension winding and ground; also on the average departure from ground potential by the high-tension windings. In a transformer of the shell type with coils arranged as indicated in Fig. 1, the condenser capacity between the low-tension windings and the ground was three times the capacity between the two windings. When the external circuit connected to the low-tension windings also has capacity with respect to the ground, this modifies the danger of breakdown; the maximum danger exists, therefore, when the low-tension windings are entirely disconnected from the external circuit.

Fig. 1. Sandwiched Transformer Coils

The remedy, or preventive, for the evil under discussion is to ground the low-tension windings of the transformers and thereby give the induced static potential an easy and harmless path instead of giving it a chance to break down the insulation. Increasing the insulation of the low-tension windings does no good; it merely increases the relation between the primary-secondary capacity and the capacity between the low-tension windings and the ground, the increase being such as to increase the dangerous static potential between the low-tension windings and the ground.

Improvements in Single Phase Motors

Under this title, W. A. Layman presented an interesting analytical description of a type of self-starting single-phase motor which the Wagner Company is developing under the patents of Val. A. Fynn. The rotor contains two distinct windings, one a simple squirrel cage and the other a polar winding, in the same slots. The polar winding is connected, through a commutator and brushes, in series with the stator winding and serves to produce the torque necessary for starting; at normal speed an automatic switch connects the brushes to an auxiliary stator winding which "compensates" the inductive effect of the main winding and raises the power factor of the machine. The construction and principle of operation will be described in this department in the near future.

Relation of Load to Power Station Equipment

J. D. Newbury presented a paper dealing with the effect of the character of the load upon the equipment of a generating station and with the adaptation of the station equipment to meet the requirements of the kind of load with which the present day station has to deal.

In the alternating-current system the characteristic that has led to more trouble in the generating equipment than any other was that of the effects of low power factor. A simple way of considering this question is to assume that the actual load can be divided into two components, one equivalent to the noninductive load and the other equivalent to the combined leading and lagging wattless load.

The wattless component of the load may be a demagnetizing component, such as required by induction motors and inductive loads in general; or it may be a magnetizing component supplied by overexcited synchronous motors or static condensers.

A distinction should be made between raising the power factor by increasing the energy load and by decreasing the wattless load. While the former is desirable the latter is more desirable, since a low power factor is a positive detriment only when the load is a maximum and station capacity is at a premium, while a decrease in the wattless load is always of advantage, since it means an increase in operating efficiency.

Practically all loads supplied by central stations have a demagnetizing component. Power factors above 95 per cent. are obtainable only when the load consists of synchronous motors or rotary converters. Power factors of 90 to 95 per cent. can be expected only when the load is entirely noninductive or when synchronous motors are supplied together with a relatively small proportion of inductive apparatus. For the average central station carrying a lighting and power load, 80 per cent. power factor should be assumed [in considering the station equipment]. For a plant to supply a large proportion of induction motors, arc lamps and other inductive apparatus, 70 per cent. is a fair estimate.

It is necessary to estimate the power factor of the load in order to choose the relative rating of the generators and engines intelligently, because the engine rating should correspond to the generator ability in true power at the power factor that will be imposed by the load.

When it is a question of adding new load to an existing station the probable power factor of the load may be estimated as follows:

Kind of Load	Probable Power Factor
Incandescent lighting with small transformers.	From 90 to 95 per cent.
Alternating-current inclosed arc lamps with constant-current transformers.	From 60 to 75 per cent., depending upon the proportion of full load on transformers. An average figure would be 70 per cent.
Direct-current metallic arc lamps with rectifiers.	From 55 to 70 per cent., depending upon load on rectifiers. An average figure would be 65 per cent.
Single-phase induction motors; squirrel-cage rotors, 1/20 to 1 horsepower.	From 55 to 75 per cent.; average 68 per cent., at rated load.
Single-phase induction motors; squirrel-cage rotors, 1 to 10 horsepower.	From 75 to 86 per cent.; average 82 per cent., at rated load.
Polyphase induction motors; squirrel-cage, 1 to 10 horsepower.	From 75 to 91 per cent.; average 85 per cent., at rated load.
Polyphase induction motors; squirrel-cage, 10 to 50 horsepower.	From 85 to 92 per cent.; average 89 per cent., at rated load.
Polyphase induction motors; phase-wound rotors, 5 to 20 horsepower.	From 80 to 89 per cent.; average 86 per cent., at rated load.
Polyphase induction motors; phase-wound rotors, 20 to 100 horsepower.	From 82 to 90 per cent.; average 87 per cent., at rated load.
Rotary converters, compound wound.	At full load the power factor can be adjusted to practically 100 per cent. At light loads it will be lagging, and at overloads slightly leading.
Rotary converters, shunt wound.	The power factor can be adjusted to any desired value, and will be fairly constant at all loads with the same field rheostat adjustment. Rotary converters, however, should not be operated below 95 per cent. power factor leading, or lagging, at full load or overload.
Small heating apparatus.	The power factor of the load is practically unity, but the distributing transformers will lower it to some extent.
Arc furnaces.	From 80 to 90 per cent.
Induction furnaces.	From 60 to 70 per cent.
Welding transformers.	From 50 to 70 per cent.
Synchronous motors.	Adjustment between practically zero power factor leading, to zero power factor lagging.

From the foregoing table it is evident that the only kind of load which affords any control over power factor is the synchronous motor. This fact has led to an increasing use of synchronous motors by central stations in order to improve the power factor of the system. Unfortunately, the complication of a separate exciting source and the ability to start only under a comparatively small load restricts the use of synchronous motors largely to location at the station, where skilled attendance is at hand, or to motor-generator sets.

Synchronous motors have been operated without load to improve the power factors of systems but it is more economical to utilize the motors to do mechanical work at the same time. The required capacity of such a motor is the vector sum of the required wattless and energy inputs; that is, the total input in kilovolt-amperes is equal to the square root of the sum of the squares of the wattless kilovolt-amperes and the kilowatts. For example, if the wattless intake from the line be 600 kilovolt-amperes and the energy intake, converted into mechanical work, be 800 kilowatts, the total intake will be 1000 kilovolt-amperes.

To determine the proper size of synchronous motor to use for effecting a given improvement in station power factor and to do some mechanical work also, it is necessary to consider the characteristics and size of the station load. To the existing station load must be added the true kilowatts that the motor will require to do the mechanical work and supply its own losses. From the *desired* power factor and the total load in kilowatts the total kilovolt-amperes and the future wattless kilovolt-amperes are obtained and subtracting these from the existing wattless kilovolt-amperes gives the wattless component to be supplied by [to] the motor.

For example, with a load of 1200 kilowatts and a power factor of 70 per cent., the wattless kilovolt-amperes will be 1220 [1224 is the theoretically accurate figure. —Ed.]. If the synchronous motor is to do work (including its losses) requiring 240 kilowatts intake, the future energy load will be 1440 kilowatts. If a power factor of 90 per cent. is to be obtained, the future wattless kilovolt-amperes will be 698 and the difference between 1220 and 698 being 522, that is the number of wattless kilovolt-amperes for the motor to take. The total intake of the motor, then, must be

$$\sqrt{240^2 + 522^2} = 575$$

kilovolt-amperes. In general, it will not be found worth while to raise a station power factor above 90 per cent., since the investment necessary is seldom warranted by the improvement in operation.

Power Required by Industrial Machinery

The report of the committee on power should be of immense value to central power stations. It contains an extensive list of industries which are operated by electricity from central stations in various cities widely distributed about the country, in which the kind of machinery, type of drive, service hours per week and kilowatt-hours of actual service per year are stated; also, an astonishingly full list of motor ratings for industrial machines of all kinds and sizes, from a ⅛-horsepower pamphlet stitcher up to a 250-horsepower stone crusher. In between are printing presses, wood-working machines, cement machinery, boiler-shop machines, textile machinery, laundry equipment, etc.

Ventilation of Turbine-driven Generators

A paper on this subject was read by R. B. Williamson. The author pointed out that alternators driven by steam turbines are very small for their output, because of their high speed, and that therefore the problem of getting rid of the heat developed in the windings is a difficult one. Forced air circulation is the means commonly applied in this country. The generator is completely inclosed and the air is conveyed through passages to the parts where heat is evolved.

Theoretically, the cubic feet of air required to be passed through the machine per minute for each kilowatt of loss in the machine would be equal to 1650 divided by the temperature rise in Centigrade degrees, but as all of the air is not uniformly heated and the heat-developing parts of the machine are hotter than the discharged air, a larger amount is necessary. For the usual limit of temperature rise, cooling air should be supplied at a rate of from 100 to 150 cubic feet per minute for each kilowatt of internal losses; 125 is a fair average figure.

The total internal loss will usually be from 4 to 6 per cent. of the rated kilovolt-ampere output, being larger for the smaller machines. As a rough estimate, therefore, the allowance of cooling air may be taken as 5 to 7½ cubic feet per minute per kilovolt-ampere of rated output. In some cases from 4 to 6 cubic feet per kilovolt-ampere will be sufficient, but the larger allowance is preferable, especially if the turbine has to operate in a hot locality.

In order to handle such large quantities of air, careful attention must be paid to the pipes through which it is supplied and the air should be as clean and cool as practicable. In some cases it may be drawn directly from the basement, but this should not be done if the space below the generator is occupied by auxiliaries which heat the air. Good results have been obtained by partitioning off the generator end of the basement so that the heat from the auxiliaries will be confined to the steam end.

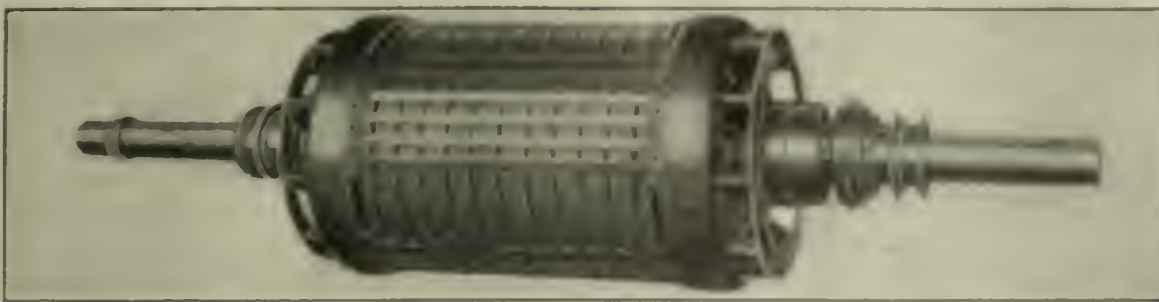

Fig. 2. Circulating Fans Attached to Field Magnet

In case cool air cannot be obtained from the basement, a pipe or duct should be run outdoors and the opening protected so that rain or dirt cannot be drawn in. Ducts should be as straight as possible and of such cross-section that the air velocity will not exceed 1000 to 1200 feet per minute. When air is drawn from outdoors, it is advisable to have dampers arranged so that it can, if necessary, be taken from the basement in cold winter weather.

It is important that the air be clean. The quantity of air passed through these generators is so large that even a small percentage of dust soon results in a large amount of dirt within the machine. Cheese-cloth filtering screens over the intake or in a box in the air duct are a good means of keeping out dust. These must be easily removable so that they can be frequently cleaned without requiring too much time and effort.

A number of methods of forcing the air through the generator have been tried but the most common one is to drive a centrifugal fan at each end of the rotor, the fans being built on the rotor spider, as shown in Fig. 2.

The air discharged by the fans must be passed through the machine with great rapidity and in such manner that all parts will be reached and the heat carried off. This is not easy, because air friction is by no means negligible in its heating effect and any attempt to force large quantities of air through long restricted passages will lead to unsatisfactory results.

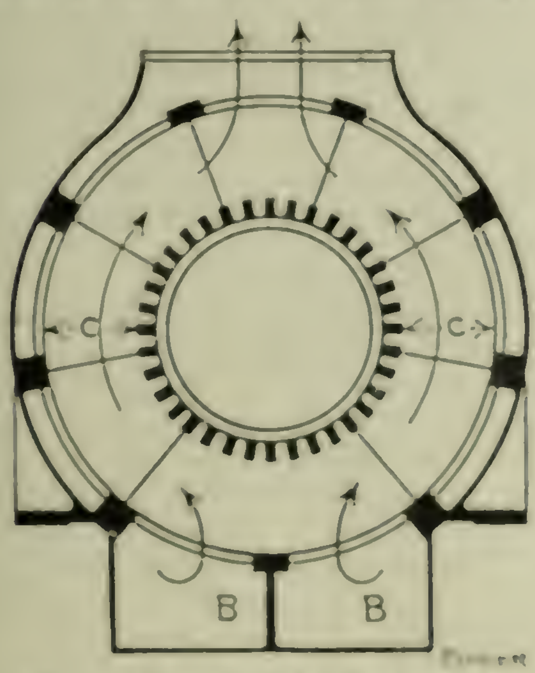

Fig. 3. Air Circulation in Small Machines

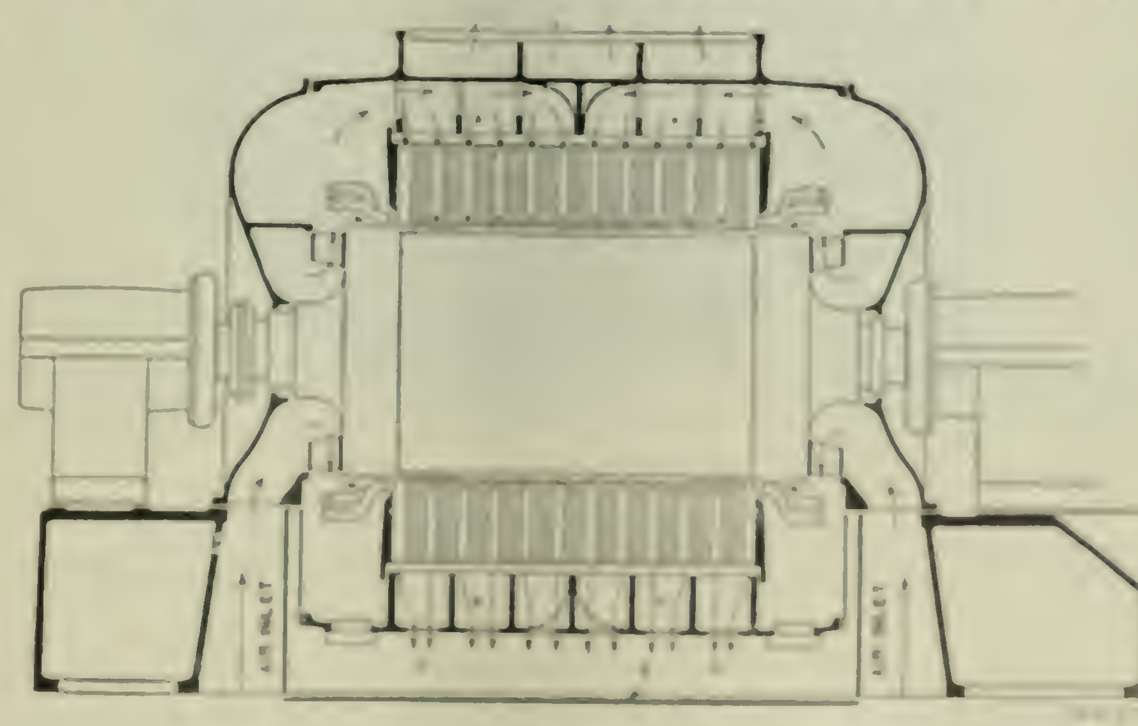

Fig. 4. Multipath Air Circulation through Generator

The greatest loss is in air friction and core loss; hence the greater part of the cooling air is required for the stator. The loss in the rotor is comparatively small, and in high-speed machines little can be done in the way of ventilating the rotor core by means of air ducts. In fact, in generators running at 3600 revolutions per minute, the rotor core is usually a solid forging without ducts of any kind. However, if the heat developed in the rotor windings is passed into the surrounding mass of metal, it is rapidly conducted to the outer surface and is thence carried off by the scrubbing action of the air.

Fig. 3 illustrates diagrammatically a method of ventilating that has been extensively used and is satisfactory for machines of moderate output. For large high-speed generators, however, the arrangement illustrated in Figs. 4 and 5 gives better results. With the arrangement indicated in Fig. 3 the air passes in two streams through the machine, one stream on each side of the shaft, and if the generator is of large diameter the air becomes heated before it reaches the upper parts; these parts, therefore, are inadequately cooled.

The arrangement shown in Fig. 4 is such that the air is divided into several streams, entering the core ducts through directive passages *A A*, and emerging into the outlet chambers through the passages *B B*. These passages *A* and *B* alternate all the way around the circumference; they are not arranged in two groups at the top and bottom of the structure, as the longitudinal section would seem to indicate. The final discharge can be taken out at the top, bottom or side of the housing. The stator shown in Fig. 5 is provided with this arrangement; an air intake is provided on each side of the bottom of the housing and the outlet is at the top.

This multipath method of ventilation for large machines has a number of advantages. One-half of the outside circumference of the stator punchings is exposed directly to air from the fans and the stator is not dependent for its cooling on hot air that has already passed over the rotor before reaching it. The use of a number of short paths in parallel through the core greatly reduces the resistance offered to the flow of air, and at a given pressure, therefore, a much larger quantity of air will pass through the machine. The air, from the time it enters until it leaves the machine, does not have to pass through a long path and, being divided into a number of parallel streams, the velocity in the ducts is very moderate compared with that in the two-path arrangement. The whole mass of iron directly behind the teeth and coils is maintained at a low temperature and any slight inequalities in temperature are equalized by the ready flow of heat in the plane of the laminations. Extensive tests made with this arrangement show that machines of large output can be cooled very evenly.

Prime Movers

The committee on prime movers presented an extensive report which contained a good deal of important information. As the committee had no new types of prime mover to investigate, it confined its attention to the performance of existing types in the stations of the member companies, or such of them as could be prevailed upon to supply the desired information.

No troubles which would seriously affect continuity of service have been reported in steam power plants. A number of minor defects have been mentioned which are discussed in the report, but it would seem that insofar as steam turbines are concerned this type of apparatus is rapidly reaching a standard which leaves very little room for criticism in the way of economy of operation or reliability of service. The auxiliaries, however, were the subject of some criticism from the operating companies, and these criticisms were referred by the committee to the makers of the various machines, who either announced changes in design to correct the troubles or offered to make such changes as were necessary in the machines. An abstract of the report on steam turbines will be printed next week.

Very little new development has been found in gas-power apparatus, and like steam power the general tendency has been toward the perfection of the apparatus. A detailed report on that subject, prepared chiefly by J. B. Klumpp, of the committee, formed a part of the general reports; this special discussion will be printed in abstract in the Gas Power Department next week.

Protection from Lightning

In its annual report, the committee on protection from lightning stated that those transmission lines having overhead ground wires seem to suffer the least damage; in fact, one operator reports that the troubles from broken insulators, shattered poles, burned-off wires and crossarms on lines protected in this manner are less than 20 per cent. of those on the lines without this type of protection. Similar results are reported in a great many other cases, and, in fact, the importance and value of the overhead ground wire is now so firmly established by experience that in almost every case where new lines are constructed provision is made for it.

In some particular cases, where an unusual amount of trouble was experienced from insulators spilling over, special devices have been developed as an alternative of the overhead ground wire. One of these devices is in the form of a grounded metal ring for each insulator. These are reported as being effective, though the use of them has not eliminated all line disturbances and is no protection against the direct stroke. In some other cases a grounded spark gap has been provided for each insulator; still another form is that of installing a grounded wire on each pole and carrying this wire well above the top of the pole. Some of these devices are used in connection with and others without the overhead ground wire, so there are few definite data at hand on which to base judgment as to their relative value. These experiments are reported as being more or less successful, and especially to the end of reducing the interruptions to the service, but it is still a question if the expense of installation will be justified in all cases.

In some few instances attempts have been made to protect the transmission lines by the installation of arresters at points far removed from the stations, but in most cases these experiments have resulted in failure. The tendency of the older type of arresters to arc over and short-circuit the line and the frequent inspection and care required for the electrolytic type reduce their usefulness to a minimum for use at remote points.

A special device known as the arcing-ground suppressor is now being experimented with for the relief of transmission-line troubles, due to an arc around the insulator. This device is designed to be used at the busbars of the principal station, to take care of the entire system. The arcing-ground suppressor consists essentially of an electrostatic and electromagnetic selective relay. This selective device picks out the faulty phase and closes the release circuit of a single-pole oil switch which is connected between the faulty phase and ground. The oil switch shunts out the accidental arc at the insulator and opens up again immediately. If the insulator is properly designed, the arc will invariably take place around the porcelain skirts, and, therefore, the arcing-ground suppressor will entirely eliminate the trouble. If the insulator should be punctured, the switch of the arcing-ground suppressor is again automatically closed and thereby prevents the high-frequency oscillations in the circuit which would otherwise result, due to the make-and-break of the arc at the faulty insulator.

The committee recommended that where lines are operated separately each line should be provided with a lightning arrester, installed beyond all station apparatus; where several lines are invariably supplied from common busbars, a lightning arrester at each busbar is sufficient. In addition to lightning arresters, the committee recommended the use of choke coils on every circuit leaving a generating station. For stations to be equipped newly with lightning arresters, the committee favors the electrolytic type; also for stations where other types of arrester have not afforded satisfactory

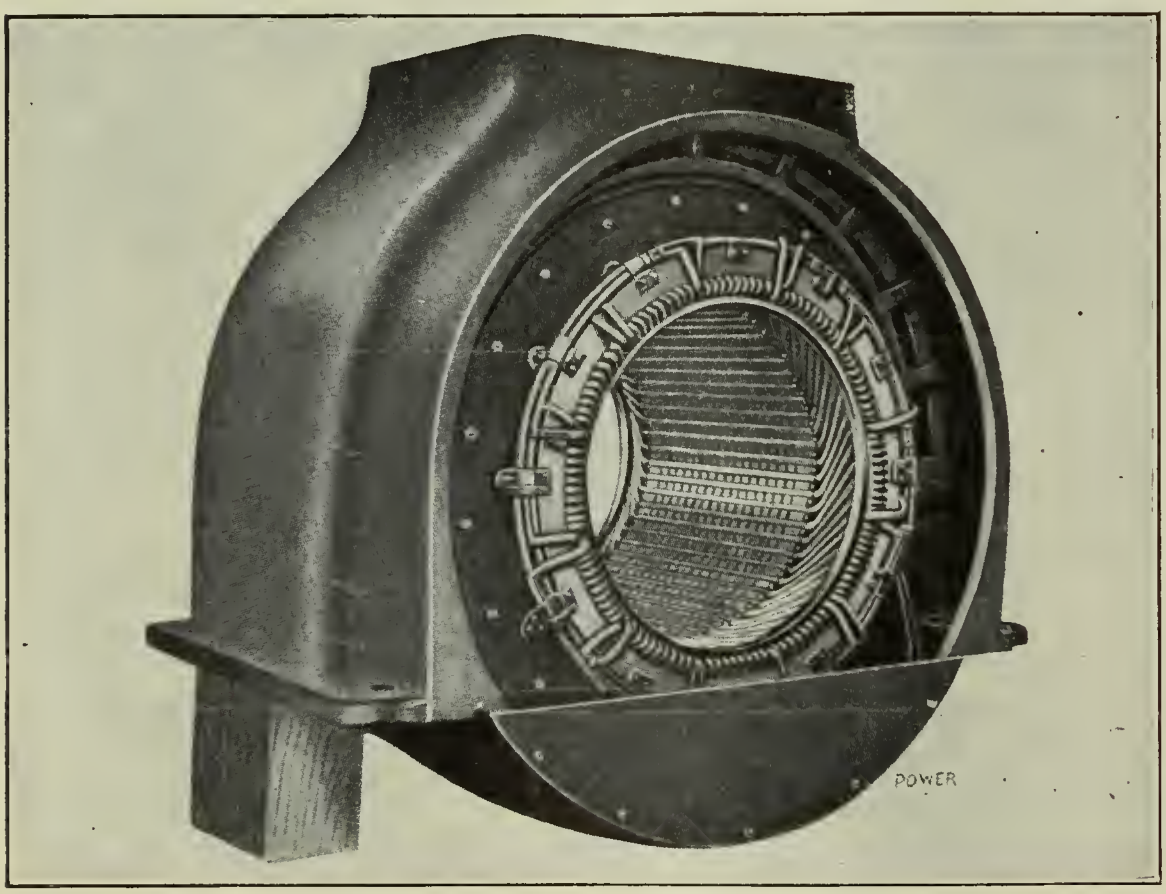

Fig. 5. Stator Equipped for Multipath Air Circulation

protection, if investigation shows that the arresters have been properly installed and maintained.

Lightning arresters on distribution systems do not usually protect any apparatus that is appreciably more than 500 feet distant. On four of the larger systems, where arresters are installed an average of 2000 or 3000 feet apart, the minimum distance being about 1000 feet, the losses of arresters vary from 0.07 per cent. to 0.7 per cent. of those installed, while in other places, where the spacing is about one mile, the losses run as high as 3 per cent. of the arresters installed.

Election of Officers

The annual election of officers held on the final working day of the convention resulted as follows:

John F. Gilchrist, of Chicago, president; Frank M. Tait, of Dayton, Ohio, first vice-president; Arthur S. Huey, of Oklahoma, second vice-president; T. C. Martin, of New York, secretary; George H. Harries, of Washington, D. C., treasurer.

Conduit Wiring Data

By O. B. Arland

Although the National Board of Fire Underwriters and various municipal inspection bureaus have established extensive rules thoroughly covering the quality and thickness of the rubber insulation, as well as the strength of braiding, for interior light and power conductors installed in unlined metal conduits, as a rule, they leave the proper size of such conduits to the judgment of the individual engineer or contractor.

This is an important matter and one that is not always sufficiently appreciated, with the frequent result that, through ignorance or unwise economy, a conduit of too small an internal diameter is used, causing injury to the conductors and their insulation by reason of excessive friction on the covering and tensile stresses imposed upon the conductor while being hauled into such a conduit.

A table of conduit wiring data based on an experience and observation of several years was worked out by the writer in 1900 for his personal use and has since been successfully used by several contractors and construction men.

This table has been revised this year and is based on the present requirements of the National Board of Fire Underwriters for interior low-potential wiring for voltages up to 600. It is reproduced here in convenient form for use.

The wire diameter and conduit sizes below the first six horizontal rows are restricted to stranded conductors because it is not good practice in conduit work to use solid conductors for sizes larger than No. 8 Brown & Sharpe gage.

Although no conductor smaller than No. 14 is permitted by the fire underwriters for this class of work, two smaller sizes are given because they are frequently used in signaling systems.

The carrying capacities of wires with weatherproof insulation are given in the fourth column of the table for convenience in other work. This kind of insulation is not permitted in conduit work.

The diameters specified in the fifth column in thirty-seconds of an inch are the over-all measurements, outside of the finishing braid.

given up to 21 conductors. The conduit diameters are carried up to 6 inches, although, as a rule, conduits of 4 inches internal diameter are the limit of ordinary practice. ½-inch conduits are also given, but these are permitted only under special conditions.

A supplementary table is added in the lower right-hand corner, showing how many circuits consisting of No. 14 B. & S. gage duplex cables can safely be put into one conduit.

CONDUIT WIRING DATA

	Size: B. & S. Gage	Size: Circular Mils	Amperes: Rubber Insulated	Amperes: Weather Proof	Diam. Rubb. Insul. Double Braid in 32ds Inch	Size of Conduit—Inches, for Wires Rubber Insulated and Double Braided: Permissible Number of Wires in One Conduit

Table for Conduit Sizes for No. 14 B. & S. Duplex [illegible]

Internal Diameter of Conduit	No. of Duplex Cables [illegible]
[illegible]	[illegible]

The succeeding columns give the safe internal diameters of conduits to be used for all ordinary construction in buildings of any description where the total number of 90-degree turns in one line of conduit does not exceed four. Where special conditions necessitate a lead armor over the rubber insulation, slightly larger conduits must be used.

Ordinarily, the fire underwriters do not allow more than four two-wire circuits or three three-wire circuits in one conduit, but it frequently becomes desirable under special conditions to install a larger number of circuits in a common conduit; the required conduit sizes are therefore

The conduit sizes in the main table, as will be observed, are calculated on the assumption that the various conductors will be all of the same size. If, therefore, in laying out a conduit for a three-wire system having a neutral of double the capacity of each of the two outside wires, the proper internal diameter of the conduit will be found by using the conduit required for four wires of the size of the main wires of the system. For instance, the conduit for a three-wire feeder of two No. 0000 outside and one 350,000-circ. mil neutral should be sufficiently large to contain four No. 0000 cables, or 3 inches in diameter.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Taking Gas Samples with an Aspirator

By J. C. Parmely

An aspirator may be used to good advantage at times around a gas-producer plant; I once found it very convenient, for example, in making a test of a suction producer and engine. In this test it was desired to operate a Junkers calorimeter to determine the heat value of the gas made by the producer. The usual method of taking samples of gas by the use of aspirator bottles could not be employed in this case because a continuous sample was required and because, in addition to taking the sample from the suction main, where it was at a pressure less than that of the atmosphere by about two inches of water, a pressure of nearly 0.3 of an inch of water was required to force the sample through the meter and other parts of the calorimeter outfit. It was decided, therefore, to use an aspirator to take the sample from the main.

As the aspirator operates upon the principle of the injector, the gas it draws from the main passing from it with the water, it was necessary to provide a chamber in which the gas could separate from the water and where the pressure necessary to force it through the calorimeter apparatus could be applied. This was easily provided by the use of a few pipe fittings, as shown in Fig. 1. A piece of 6-inch pipe *A* was cut about 8 inches long and threaded on both ends, which were capped, as shown; a hole was drilled and tapped in the side about two inches from the bottom, into which a long nipple of ½-inch pipe was screwed; an angle valve *B* was put on its outer end and into the upper outlet of the valve was screwed a ½-inch nipple long enough to reach about half-way up the 6-inch "barrel." Just below the upper cap another hole was drilled and tapped in the side of the chamber to take a ⅛-inch nipple *D*, which provided a connection for the removal of the gas from the chamber. A hole was drilled and tapped in the center of the top cap and a plug was fitted in this hole, the plug affording sufficient metal to take the aspirator outlet in one end and a ½-inch pipe in the other. This pipe reached nearly to the bottom of the separator chamber and provided a water seal which would prevent the leakage of air into the gas main in case the water supply for the aspirator should fail.

The arrangement was connected up as shown in Fig. 2 and its operation was essentially as follows: The aspirator, operating like an injector, drew the sample of gas from the main and this gas passed into the chamber *A* mixed with the water. In the chamber the gas separated from the water, rose to the top of the chamber and passed out through the ⅛-inch connection *D* to the calorimeter. By throttling the water outlet of the chamber at the valve *B*, pressure was applied to the gas to force it through the calorimeter. The apparatus was tried by connecting U-tubes containing mercury to both the suction *E* of the aspirator and the outlet *D* of the separator. By adjusting the valve *C* the suction pressure shown by the column attached at *E* could be varied within the necessary limits and the pressure at *D* could be varied by adjustment of the valve *B*. When the tube *E* was left open, the pressure at *D* could be maintained, as before, and the air taken in through *E* escaped in the form of bubbles in the water.

Having constructed the apparatus and being convinced that it would operate

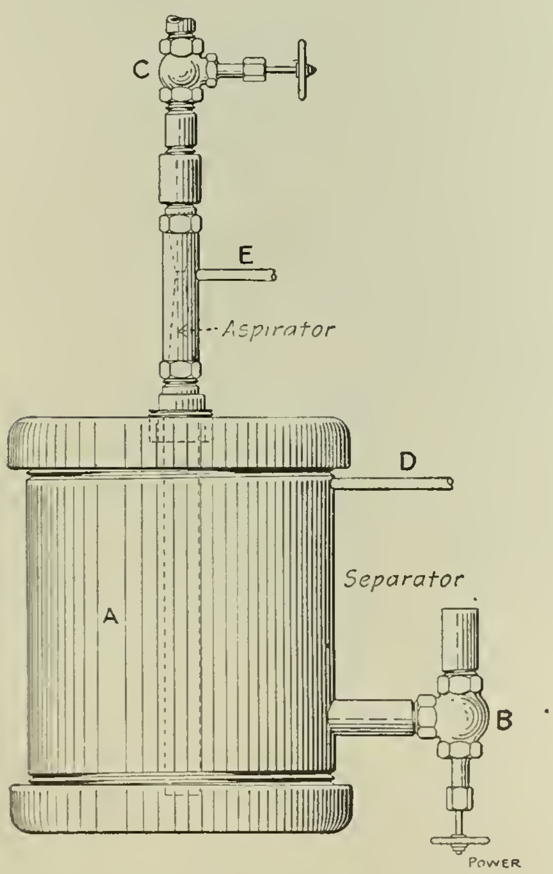

Fig. 1. Aspirator and Separator

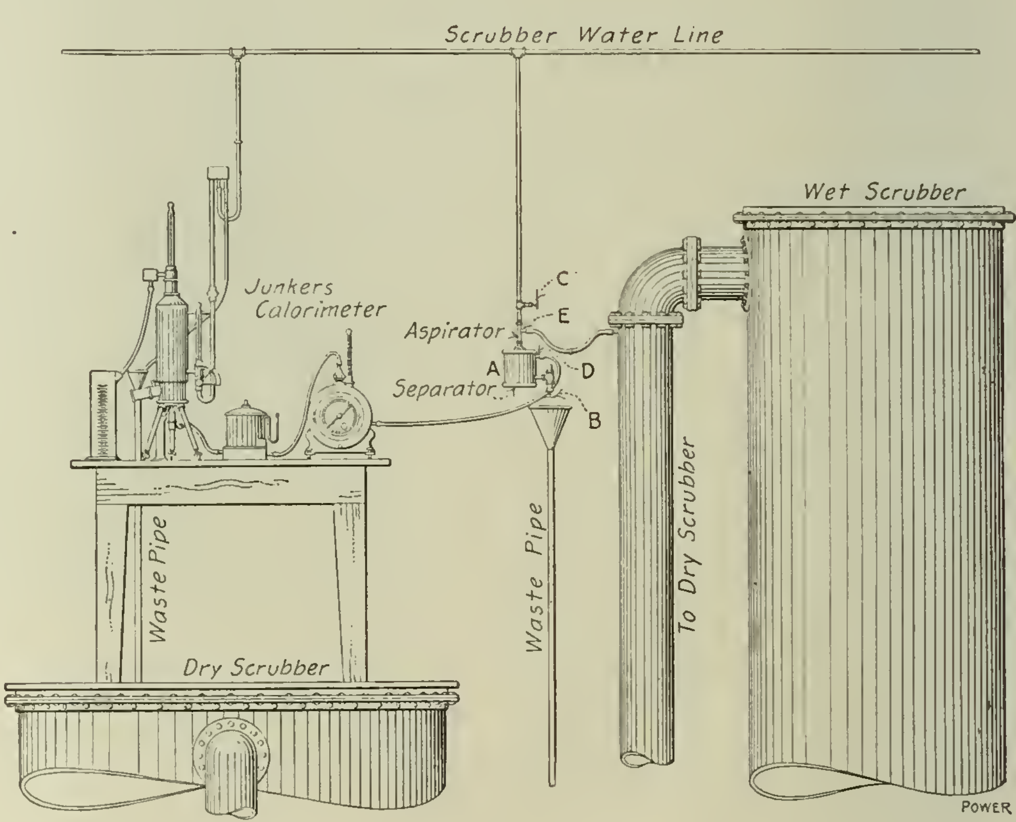

Fig. 2. Complete Equipment for Continuous Gas Sampling

successfully, the next task was to install it at the plant to be tested in a place where it would be readily accessible, be safe from damage and not interfere with the operation of the plant. As shown in Fig. 2, the wet and dry scrubbers were located side by side and it was decided to place the apparatus on the top of the dry scrubber and take the sample from the main connecting the two scrubbers. It was found to be necessary to provide a platform across the top of the scrubber so that the vibrations of the top of the scrubber due to the varying pressure within it would not affect the apparatus. As shown in the sketch, tees were inserted in the scrubber water line and the aspirator and separator were suspended temporarily by the pipe connecting them to this line. A sampling tube similar to that used with a steam calorimeter was inserted in the main and rubber tubing was used to make all connections. One-inch pipes carrying funnels in their open ends were used to carry away the water from the sampling apparatus and the calorimeter.

Due to the fact that the water used in this plant was supplied from a tank upon the roof of the building, the head upon the apparatus did not exceed 15 feet at any time during the tests and this was only sufficient to give a pressure of about two-tenths of an inch of water upon the gas at the meter, which was somewhat below that desired; but it was sufficient to operate the calorimeter successfully, though slowly. With the exception of one stop due to the clogging of the burner, the calorimeter was operated satisfactorily throughout three 24-hour tests.

Oil Engines for Ships

At the spring meeting in London of the Institution of Naval Architects, J. T. Milton contributed a paper on "Diesel Engines for Sea-going Vessels," in which he maintained that, apart from the relative cost and facilities for obtaining supplies of oil fuel and coal, an internal-combustion engine using oil possesses advantages for marine work over one using gas made from coal. The comparatively bulky gas producers and scrubbers are not required, there is no trouble with dust in the cylinders and there should be none with tar on the valve faces. Compared with coal, weight for weight, oil has at least 50 per cent. more heat value, occupies less space, can be carried in double bottoms and other spaces unsuitable for coal and cargo, requires no "trimming" and lessens the number of stokers. Moreover, it is more easily loaded and without the dust and labor of coaling.

In the employment of the Diesel engine the developed horsepower has to overcome the friction of the mechanism, to work the fuel pump and to compress the air necessary for injecting the fuel; in the two-stroke cycle engine it has also to work the scavenging pump. These, Mr. Milton points out, take up more of the gross power than do the accessories of a steam engine; consequently, a less proportion of the indicated power is transmitted to the shaft. For this reason, the power of a Diesel engine is more usually expressed in terms of brake horsepower. On the basis of 0.4 pound of oil consumed per brake horsepower-hour when the engine is working at full power, and assuming that with a modern steam engine and boiler the consumption of coal is 1.25 pounds per indicated horsepower per hour (which he says corresponds to about 1.47 pounds per brake horsepower-hour), the weight of fuel to be carried for the same voyage in a vessel fitted with Diesel engines will be only 28 per cent. of the weight of coal necessary with the steam power.

Mr. Milton cites as the more important auxiliaries in vessels fitted with Diesel propelling machinery: Steering gear; whistle; donkey pumps for bilge and fire service; electric-light machinery; distillers; steam-heating apparatus; water-ballast pump, winches and windlass; ventilating apparatus in passenger vessels. Alternatives proposed for the steering gear, whistle, distiller and heating appliances are: (1) A donkey boiler separately fired by oil fuel continuously at work at sea for all these purposes; (2) utilizing the heat of the exhaust gases by passing them through an auxiliary boiler and raising sufficient steam for the purpose; (3) working the steering gear and whistle by compressed air from the first stage of the compressor, which would be made larger for this purpose. The second alternative, the author says, has much to recommend it in view of the great quantity of heat which passes off with the exhaust gases.

Discussion of Mr. Milton's paper was opened by Doctor Diesel, who said the marine Diesel engine of the future will be of the two-stroke type. The air cooling of the cylinders must be accompanied by a back cooling of the oil itself in apparatus of the surface-condenser type. With regard to balancing in the Diesel engine, difficulties arise, particularly at low speeds, but by adding two scavenging pumps on both ends it is possible to completely balance the engine. In comparison with the whole output of Diesel engines the proportion of marine engines is comparatively small, the most important field being in the submarine, and the Diesel engine is now being nearly universally adopted for this class of ship by all countries except Great Britain and the United States.

It is a coincidence that before the Liverpool Engineering Society, in Lancashire, in a paper on "The Economics of Steamship Propulsion," Andrew Hamilton makes special reference to the use of oil fuel. He shows that, except for special purposes and in the navy, where cost is not so important, oil fuel under present conditions can be used in Great Britain only to a moderate extent. With regard to oil engines, he says it has recently been proposed to fit a vessel with engines of 150 to 180 total horsepower. Two engines speeded at 200 revolutions per minute would cost £2200, which, with the cost of settings, oil tanks, two sets of propeller shafts, etc., will be increased to £3000. The annual fixed charges at 15 per cent. on (say) £3000 will be £450. Compound steam engines of similar power will cost £900, which, with setting, etc., will be increased to £1280. Fifteen per cent. on (say) £1300 will be £195, showing a debit of £255 against the oil engines on capital account. Taking the consumption of oil at 0.8 pound per indicated horsepower-hour, 150 horsepower would require 120 pounds per hour, which at £1 15s. per ton would amount to 1s. 10½d. per hour; the fuel for 180 days will cost £405. The cost of coal for 150 indicated horsepower, taking 3 pounds per hour at 12s. per ton, will be about £518 for a similar period. Therefore, the capital charges and cost of fuel would be £855 for oil engines and £713 for steam; but in the case of the former, credits on account of extra cargo capacity and less labor (£230) reduce the total to £625, or £88 below the corresponding figures for steam power.

[Putting the oil consumption at ½ pound per brake horsepower-hour, which is much nearer to actual performance, the fuel expense for the Diesel engines would be £203 instead of £405 and the total operating expense £423 (instead of the author's £625) as against £713 for steam.—Editor.]

Gas and Oil Power in Phosphate Mining

The internal-combustion engine appears to be especially appreciated by the companies operating in the phosphate-mining district of southern Florida. The Prairie Pebble Phosphate Mining Company, at Mulberry, Fla., is operating eight Diesel engine units and expects to add eight more, each having a rating of 300 horsepower. The Pierce Phosphate Company has installed a 1200-horsepower Westinghouse producer and gas engine and contemplates installing another of the same capacity during the present year. The Pembroke Company is installing two Diesel engines of 300 horsepower each and one of 200 horsepower at its plant near Fort Meade, Fla.

The Diesel engines of the Prairie Pebble Phosphate Company have made a fine record during the time they have been in use and we shall publish shortly a detailed report of their performance.

Readers with Something to Say

Practical information from the man on the job. A letter good enough to print here will be paid for. Ideas, not mere words wanted

Air Pump Valve Froze

I once had occasion to use a double-acting pump for mine purposes, using air at 90 pounds gage pressure. But I was continually bothered with the valves freezing, which stopped the pump.

Then it was the old story of burning a piece of oily waste to thaw them out and get the pump started again. This method, however, has often caused cracked and broken pumps, due to the unequal expansion.

I finally tried the scheme of tapping a 3/8-inch connection on the discharge pipe, near the pump, and leading the same around and over the air chest, branching off over each chest. Then I put in a 1/4-inch pet cock about 4 inches above each chest so as to get a small stream of warm mine water to flow over the top of each valve chest while the pump was working. This ended the trouble.

Chignecto, N. S.

A Puzzling Oil Trouble

I once had an unusual experience with an engine using the splash method of lubrication.

It ran with very satisfactory results for about six months.

The crank case holds about seven gallons of oil. It was my custom to empty all of the oil out of the crank case every three weeks and renew with new oil. The dirty oil was filtered and used on the other engines.

On one occasion I had changed the oil as usual and after running about three hours a bad pound developed on the crosshead pin. This became so bad that in about half an hour I had to shut down and key up the brasses.

I started again and in two hours the engine was pounding like a steam hammer. This time I took out the crosshead pin and boxes and found that while there was nothing hot and no apparent cutting, the oil grooves in the boxes had completely disappeared. I dressed up the boxes and the next day I had to stop three times. The third time I removed the pin and brasses and found that the oil grooves were gone again, and the pin so badly flattened that it had to be turned up. This trouble continued for some time. I changed oil again and again, but the pound still remained.

I was badly puzzled, and, while looking in the side door in the frame, I saw tiny particles of zinc floating on the oil.

I stopped the engine and keyed up again and after getting some oil from one of the other engine rooms started again, and, presto, the trouble was gone, and the engine ran nine weeks before the crosshead pin needed keying up again.

I then suspected the cause of my trouble and, procuring some barium chloride, made a test and found the oil strongly impregnated with sulphuric acid.

The crosshead boxes were of a composition containing about 90 per cent. zinc, for which sulphuric acid and water have a strong affinity.

On starting up with the new oil there was no water present and in consequence the contained acid remained inert. The metallic packing on the piston rod allowed a little water to escape and travel along the rod, whence it dropped down inside of the engine frame and mixed with the oil.

After a couple of hours sufficient water accumulated to form a corrosive mixture when combined with the acid, and this combination is what caused the brasses to waste away so rapidly.

I ran this engine for about 18 months after that, and never had a recurrence of the trouble, as I took the precaution to test each barrel of oil. I rejected two which I found contained traces of acid.

On taking up the matter with the chemist of the oil works which furnished this oil, he stated that through some error the acid had not been properly neutralized after the oil had been bleached.

The babbitted bearings of the engine did not show any ill effects and I do not think any such trouble would occur without this particular combination of zinc, acid and water, as this oil gave perfect satisfaction when used on Corliss engines with babbitted bearings.

Radiators Give Trouble

The accompanying illustration is of a heating system with which I have been having trouble because three radiators on the second floor fill up with water.

When I open the drain from the trap the water drains out and the system works all right for from 8 to 15 hours before it will fill up again. The radiators on the first floor give no trouble. The 1-inch line from the boiler to the first radiator is 80 feet long. Can any reader of Power tell me how to remedy the trouble?

Radiators and Piping

Slovenly Pumping Plant

Shortly after my arrival in this country I got a position as fireman in a pumping station not far from Philadelphia.

The plant contained five water-tube boilers, two 5,000,000-gallon pumps, two centrifugal pumps and a 15-kilowatt generator direct coupled to a high-speed engine. The working force was divided into three shifts, each being made up of an engineer, fireman and a man to look after the filters. Only two boilers were under steam and it was a hard job to keep up the pressure.

After a while I began looking around and I found that the whole outfit was in very bad condition. The pumps were running with the drip cocks wide open, and the centrifugal pump made a noise like a triphammer. To keep the boxes cool and save oil, a ½-inch water hose was supplying a stream of water to them.

The engineer in charge paid absolutely no attention to the temperature of the feed water. The blowoff cocks leaked so badly that the water ran out of the blowoff pipe in a small stream.

I kept the job until the end of the season and then I left. A year later I passed by this same plant and, looking in, I saw the same chief sitting in the same rocking chair. No change was apparent in the conduct of the station, except that it was more dirty and noisy.

The chief did not propose to kill himself for $55 a month, working seven days a week.

LAISSEZ FAIRE.

Paterson, N. J.

What Causes the Pipe to Wear?

On a hydraulic dredge used for harbor work, the first 60 feet of the discharge pipe from the hydraulic pump consists of cast-iron pipe 25 inches in diameter. This pipe runs along one side of the dredge in a horizontal position and connects with the pipe leading to the scows into which the material is discharged.

The pipe was originally 1½ inches thick, but after being in use for about 18 months it began to leak at several points along the top. On examination the pipe was found to have been worn to a thickness of but ¼ inch along the top for its entire length; the bottom, however, showed no signs of wear.

The material pumped through the pipe is a combination of mud and sand and the pump discharges against a pressure of approximately 30 pounds.

The engineers would like to know why the wear comes on the top of the pipe instead of on the bottom.

New York City.

Equalizing Pipe on Separator

Put a funnel into the neck of a bottle, as in Fig. 1, and pour water into it. The water will run freely into the bottle for

FIG. 1. ABSENCE OF AIR VENT PREVENTS WATER FROM FLOWING INTO BOTTLE

a time; but, if the joint at *A* is tight so that no air can escape, the air in the bottle will soon become compressed until its pressure equals the head of water in the funnel and then the flow will stop or

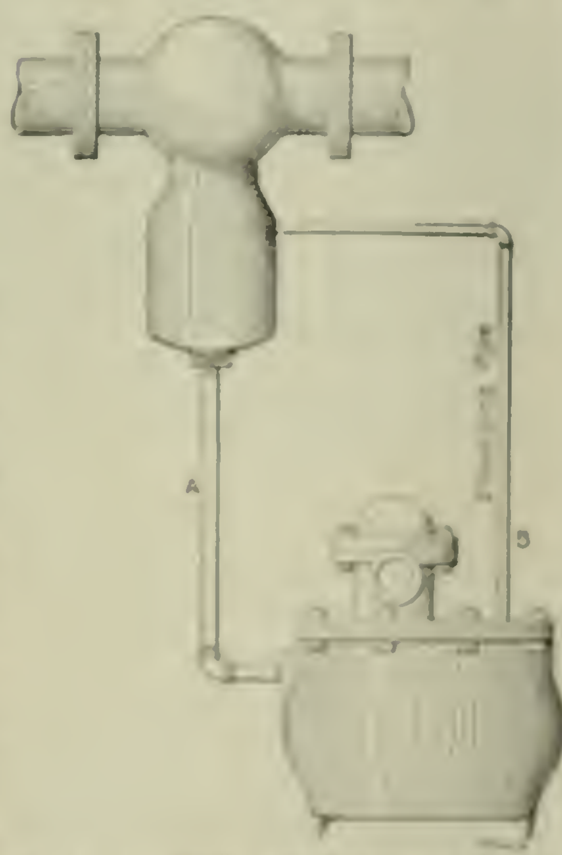

FIG. 2. SHOWING CONNECTIONS BETWEEN SEPARATOR AND TRAP

reduce to a dribble. If a sufficient vent is made at *A*, the flow will be as free as though the bottle were not there.

A similar condition is liable to arise in connecting a steam trap, as for instance in Fig. 2. When the flow of water is small the upper part of the trap is full of steam of the same pressure as that in the separator. If a slug of water comes over, the communication between the steam spaces of the trap and separator is shut off and the pipe *A* is like the neck of the funnel. Until the steam in the trap condenses (and it may have air in it which will not condense), the free flow of the water is impeded and the trap does not act as quickly as it should.

I have avoided trouble from this source in a number of instances by connecting the top of the trap to the steam space of the separator or whatever else is being trapped by an equalizing pipe *B*. This allows the water descending in *A* to push the steam or gaseous contents of the trap around through the pipe *B*, allowing the water to fall freely into the trap and the trap to work promptly and energetically to its full capacity. Furthermore, it takes care automatically of the venting of the trap, avoiding the necessity of getting down to it if it is in a pit, or of the trouble which may arise from neglecting it.

Deterioration of Boilers

Boiler explosions continue to occur daily, and the reasons and excuses for them are numerous and varied. I have been an advocate of clean boilers and clean water since the time I was personally concerned in an explosion caused by foul water, and have every reason to believe that many explosions are due to this cause. My theory is that more explosions are caused by foul water than from any other cause, not excluding overheated plates which come from filthy boilers.

Not long since, a tube was removed from a vertical water-tube boiler. This tube was coated with a hard scale formation ½ inch thick. It is evident that the water-cooling effect was of little or no value to the tube. Crystallization will take place under just such conditions as this. The tube will lose its strength and will yield possibly under one-fourth of the pressure that it will when the flue has been kept in contact with the water.

In shearing boiler heads from some steel and iron boilers recently it was found that the lower half of the steel head was of good, tough character, especially on the water side. The other half, away from the water side and above the water line, which was subjected to the heat of the steam, was like tempered steel and would snap before it would bend. This indicates that a steel boiler in aging may become very brittle. The life of a boiler depends upon working conditions and the abuse it receives.

In one instance a water-tube boiler was fed with water that formed a hard scale. Some small leaks appeared around the rivet holes, due to small cracks. It was found necessary to remove the heads and upon examination it was discovered that the cracks reached out from the tube holes. In the tube a hard, flint-like scale was found from $\frac{5}{16}$ to $\frac{3}{8}$ inch thick on the interior of this tube and the header was also badly coated.

Pitting is another element of deterioration. In one instance the top of a boiler was covered with asbestos. Upon uncovering the boiler in order to reset it in a new battery, it was discovered that pitting had occurred on two of the top sheets. The dome connection was also in the same shape. The original thickness of the plate was $\frac{7}{16}$ inch and some of the pits were $\frac{1}{4}$ inch deep.

A coat of graphite will form a surface under the outer covering which will prevent the metal from being attacked in this way.

Furnace Questions

Why is it that more letters are not written regarding the CO_2 question? There have been many articles on the theoretical side. Now let us hear from the men who plug up holes and crevices in the boiler setting, and who crawl around in furnaces studying grate areas and fire arches. They should know something about the question. Talking of furnaces, how much can the air spaces in the dumping plates of Roney stokers be reduced without danger of burning?

How can I stop or reduce the leakage of air through the joints of the big doors at the rear of a Babcock & Wilcox boiler?

If a return-tubular boiler has an air space in the setting, does not air leak into the furnace from the air space? Has anyone tried filling up the air space, and what was the result?

William E. Dixon.

Malden, Mass.

Cleanliness in the Power Plant

One of the most important details about a power plant is cleanliness. The chief engineer of a plant has much to do in this regard, because others connected with the plant will follow the example set before them.

A young man starting in as an oiler is quick to acquire the habit of smoking a pipe and chewing tobacco if his engineer does. He will spit on the engine-room floor if he sees the engineer do so. He will acquire the habit of sitting around reading newspapers just because the example is before him in the person of the engineer. He will go around the bearings regulating the oil without the sign of a piece of waste. He will fill his oil cups without paying attention to wastefulness, forgetting to wipe the can before setting it down. The result is a general smear just because the fellow has seen his engineer do so and probably because he belongs to the class of men who are not naturally clean.

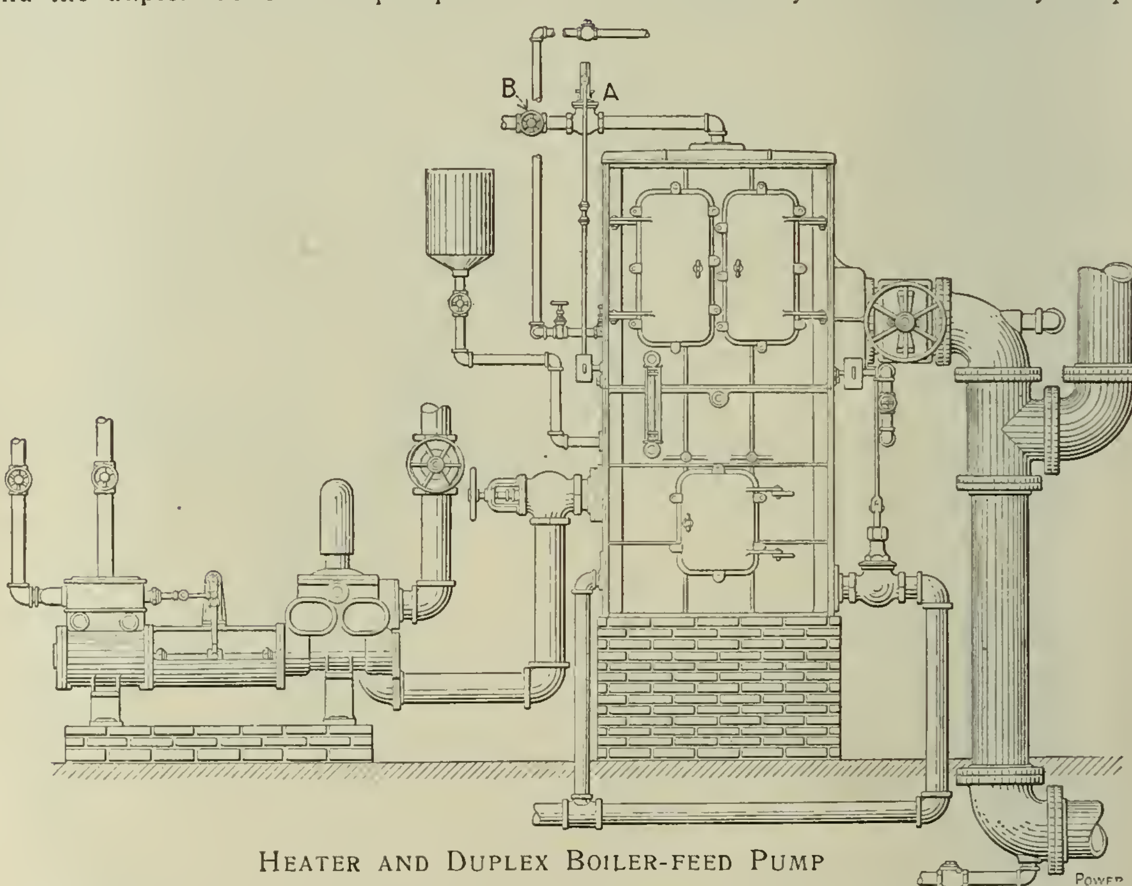
Some fellows learn by experience to keep clean, others do not. The slovenly have usually been brought up that way and never possessed any horse sense. No plant can be successfully operated without system, and the sooner the young engineer thoroughly comprehends its meaning and applies it to cleanliness, the better it will be for himself and all parties concerned.

Thomas M. Stirling.

Middlebranch, O.

Feed Water Regulation

In the power plant where I am employed there is a vacuum feed-water heater connected as shown in the accompanying illustration. The pump that supplies this heater also furnishes water for an outside line, on which it is necessary to carry as high as 80 pounds pressure per square inch. Since assuming charge of the plant, I have had some interesting experiences with the heater and the duplex boiler-feed pump.



Heater and Duplex Boiler-feed Pump

Originally, the heater was set so low in relation to the pump that there was not sufficient pressure to lift the intake valves. When the water was hot this condition caused steam pockets to form and the pump "kicked." The engineer or his assistant would have to step lively and close the throttle valve on the pump, and then admit some cold water to the heater to relieve the trouble. This was not pleasant for the fireman, for it kept him continually guessing as to the feed-water temperature and was also far from economical with the fuel supply. In addition to this the feed-water temperature fluctuated greatly as the demand of the boilers varied, this being due to the heavy rush of water into the heater as the regulator valve *A* opened, and the inability of the exhaust steam to properly heat this sudden supply of water.

Here were two difficulties to be overcome, but a third one appeared. Every time the regulating valve *A* was about to close or open it would chatter so fiercely that it could be heard some distance outside of the plant and also caused a commotion in the water pipes running to the office building some distance away. To remove the first difficulty, the heater was raised about 40 inches, and there has been no further trouble with the feed-water pump. In removing this trouble all complaints coming from the fireman were silenced and a saving in fuel was also made.

The 3-inch globe valve *B*, placed just beyond the regulating valve *A*, had always been kept wide open. This put the whole line pressure on the regulating valve and caused it to chatter, as mentioned. Then as the regulating valve opened there was such a rush of cold water into the heater that the temperature of the feed water to the boilers varied greatly.

This difficulty was removed by simply closing the 3-inch globe valve until it would admit only water enough to supply the heater with the regulating valve wide open. The globe valve had to be adjusted occasionally to meet the varying demand of the boilers, but this was very easily done. The chattering of the regulating valve is only a memory and it is now possible to maintain the feed-water temperature above 200 degrees Fahrenheit.

These were very simple remedies, but they may be of some service to the readers of Power in solving other difficulties that may arise.

Fairport Harbor, O.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Prevented Water Hammer

Under the above heading, A. Stevens tells on page 573 of April 11 POWER how he drained the water from an exhaust pipe under vacuum. The apparatus he employs is very crude and must require considerable attention. The same thing can be done automatically by means of a return trap such as is used for boiler feeding.

A check valve should be provided in the drain from the exhaust main to the trap and a second check valve in the connection to the feed tank. The former valve should open toward the trap and the latter away from it. In operation the condensation comes down to the trap through the drain pipe, equilibrium being established through a vent pipe connecting the trap with the exhaust main.

When the trap is full, the float rises, operating a trip valve which closes the vent and admits live steam at boiler pressure to the interior of the trap. The check valve in the drain closes and the other opens, so that the water in the trap is forced out until the lowering of the float moves the trip valve in the opposite direction and reëstablishes connections with the exhaust main.

W. T. MEINZER.

Brooklyn, N. Y.

Graphite as a Scale Preventive

I agree with E. G. Trumbo, in his article of April 4, when he praises the use of graphite in boilers to keep the scale from sticking to the metal.

From personal experience and application I know that graphite will prevent scale from sticking to the shell so hard. This property of graphite in itself is a great help to engineers in keeping their boilers clean.

In a power plant of six Babcock & Wilcox boilers, four were run 24 hours daily while the other two were out being cleaned. After being thoroughly cleaned, 10 pounds of graphite were equally divided between the two drums of each boiler, the boilers were scaled, and put into service and two others cut out. When drained out and opened up, considerable scale was found in the mud drum, and when the cleaner was run through the tubes every vestige was removed. On examining the scale the graphite could be seen clinging to the under side, showing that it prevented the scale from sticking.

FRED L. WAGNER.

Chicago, Ill.

The Giddings Engine Valve

Regarding Mr. Stuck's engine valve, I have noted the remarks of several writers who have had some experience with the Giddings balanced valve, and C. A. Cahill's letter in the May 2 number is quite clear, but there is no reason for the abrupt notch in the compression line.

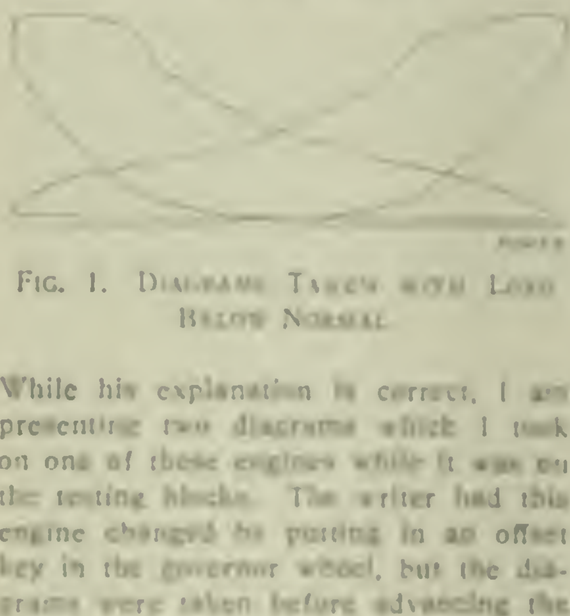

FIG. 1. DIAGRAMS TAKEN WITH LOAD BELOW NORMAL

While his explanation is correct, I am presenting two diagrams which I took on one of these engines while it was on the testing blocks. The writer had this engine changed by putting in an offset key in the governor wheel, but the diagrams were taken before advancing the eccentric. This change made the admission much sharper and better. In the diagrams the compression lines are good and also the release. The balancing of this valve was a difficult job, and the successful running of the valve depended upon this.

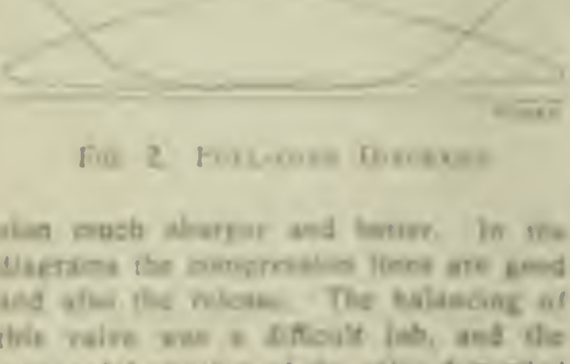

FIG. 2. FULL-LOAD DIAGRAMS

Mr. Stuck's suggestion of having a by-pass pipe for stopping and starting is good. I always found the new engines going out with this arrangement. For successful running, both springs in the governor must have the same tension. This can be determined by striking the springs with a light hammer and listening to the sound; the tighter spring will give a higher tone.

Baltimore, Md.

Asleep on the Job

The foreword in the March 14 issue regarding the engineers who fall asleep on their job hits the nail squarely on the head. How many would-be engineers are dozing? Then when caught by their employers or other persons on the watch, they will put the blame on someone else.

The time has passed when an engineer can afford to fall asleep on his job. The Edison or central-station interests are not to blame if some day the sleeper wakes up and finds them on his job.

Organizations and knocking are not the things needed. Employers are entitled to facts, figures and results. Work therefore should be done so that it will command as much respect as the work of professional men. It may be asked why do employers look at it in this way now any more than formerly? Well, because the general operating expenses are on the increase. Supply bills and wages are higher. The outside man is giving this as an argument. It is a catchy one. He makes it appear as if all trouble ends with the putting in of outside service. It sounds well when told by him, and, mind you, he has his piece well learned and can tell it. Then the "boss" comes after he has been posted and wants to know how much coal is burned per kilowatt-hour; how many B.t.u. are in the coal; perhaps, something of the CO_2, or how many pounds of water are evaporated per pound of coal used? What do you do? Have you any reports showing daily results, anything to fall back on? Can you produce facts which may send your "boss" back to his outside friend and shut him up for good? I am afraid not.

If you want to better your job, you should keep daily records. In this way you may be able to hold the coal man in plain and know just what you are doing. You will have a check on your firing and plant conditions.

The isolated plant is all right. But the isolated-plant engineer must keep awake.

This is an age of [illegible] tion. You must [illegible] abreast with the lead[illegible]

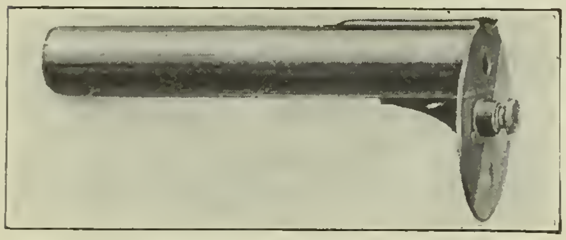
[illegible]

Binghamton, N. Y.

Measurement of Smoke Density

The construction of the smoke tintometer, as mentioned in the April 25 issue of POWER, is essentially the same as that of the smoke meter described by the writer in the London *Engineer* of January 31, 1908. I believe, however, that my instrument has superior qualities, one of which is that its simplicity permits it to be more readily made by anyone who may wish to possess a smoke meter.

As shown in the cut, the Kunze smoke meter consists of a metal tube 6 inches long and 1 inch in diameter, at the end of which is a disk similar to that of the smoke tintometer. I made the first disk of glass, but finding this expensive and easily broken, I used transparent celluloid. Only four tints were employed as the grades "clear" and "black," corresponding respectively to 0 and 5 of the Ringelmann chart, were unnecessary to operation. The grades 3 and 4 are most vital, as they constitute a violation of city ordinances as usually drafted. If the smoke appears darker than grade 4, it may be recorded as 5, and if no smoke is seen the record 0 may be used.



THE KUNZE SMOKE METER

At first I tinted my disks by painting them, but I found it difficult to get a flat tint without streaks or spots. A better way is to tint the disks by photography. The four segments of a large circle drawn on a sheet of bristol board are tinted corresponding to the grades 1, 2, 3 and 4 of the Ringelmann chart; this is then photographed and printed on a sensitized celluloid disk. By using an arc light for printing, one can time the exposure so accurately as to secure uniform grades of tints for any number of prints, and the tints after being fixed are not easily destroyed through use. Should it be desired to further protect the tinted surface, it can be done by having the celluloid disk turned out, leaving a small rim around the edge and, after sensitizing and printing the inner surface, covering it with a glass disk, in this way protecting the glass from breakage by the celluloid. In calibrating the different tints with the Ringelmann chart the instrument is used in its usual manner.

In employing any of the methods of tint comparison, including that in which the Lowdon instrument is used, a difficulty arises in that so many conditions may change the appearance of the smoke: the condition of the background, the color of the sky, the time of day, the position of the sun and many other conditions which will widely alter the effect of the observation. This trouble is mostly due to the fact that the eyes of the observer are not concentrated upon the smoke and the tint with which it is being compared, but are influenced by foreign conditions such as those named. This objection was overcome in the Kunze smoke meter through the use of small holes in the center of the tints as presented in front of the tube. In using the instrument the observer looks through the tube with one eye, and closes the other. The smoke will be seen by the naked eye through the small hole in the center of the tint and as all background is cut off there will be no disturbing influences and an exact comparison can be made. The disk is turned around its axis until the shade of smoke proper corresponds to the tint on the disk, or most nearly to it. If the smoke is darker than the surrounding tint, a dark spot will appear in the center. If the smoke is lighter, the spot will appear to be quite light in comparison. The contrast is great until the shades correspond to one another, at which time the contrast suddenly ceases to exist and the tint at the end of the tube is unbroken.

The use of this instrument need not be confined to smoke observations but may be used to compare color tints as readily as it does shades of grayness.

EDWARD J. KUNZE.

East Lansing, Mich.

Standpipe on Heating System

With reference to Alexander Dolphin's letter under the above title in the May 9 number, I do not think that the standpipe would give satisfaction. I think that the system would always be filled with water and that there would be violent water hammer. There could not be good circulation and the service would be poor. If it would be convenient to get below the return line a water seal in the shape of a U-bend would make a good form of trap. I have used a U-bend for a trap on low-pressure lines with success. It is bound to drain all the water out of the line, and it will not permit any steam to escape. There would be an objection to this trap for Mr. Dolphin's system which carries as high as eight pounds pressure, in that it would be necessary to extend the bend down about 18 feet below the return line in order to prevent the steam pressure from overcoming the weight of the water in the trap and thus allow steam to escape.

WILLIAM SWOPE.

Tiffin, O.

In the May 9 number of POWER Alexander Dolphin seeks information concerning a standpipe on a heating system. There is this objection to a standpipe. If he has a single-pipe system, every time the steam pressure goes off, the water in the standpipe will run into the radiators below the level of the water in the standpipe, and when the steam comes on again it will blow the remaining water out of the standpipe and cause severe pounding in the radiators. Then the water in the radiators must be removed, and this is no easy matter.

If he has a double-pipe system the steam pressure will clear the radiators of water but will cause much pounding and if there are any pockets he will find that the radiators behind the pockets will be flooded.

Then, too, with either system of piping, he will have a job to keep the proper head of water to balance the steam pressure. Five pounds on the steam mains will require 11.5 feet of water in the standpipe, measured above the lowest point in the steam mains; eight pounds will require 18.4 feet of water.

If the end of the pipe were in plain view it would be possible to put on a valve and throttle it, using it as a bleeder. Another way would be to use a water seal which can be made by taking two ¾-inch pipes about 20 feet long, laying them parallel and connecting them at one end with two elbows and a short nipple. Then place them upright and connect one end of the U-bend to the return main and let the other end discharge to the tank. This trap will keep the radiators clear of water and will prevent steam from blowing through.

ROY V. HOWARD.

Tacoma, Wash.

To Engineers Who Write

Much advice and exhortation have been devoted to those engineers who do not write. Just a word to those who do.

Many hesitate to write because they fail to see that what seems commonplace to them is just what some other fellow is aching to know. Others hesitate on account of lack of confidence. Then, too, a proposition reduced to black and white usually loses much of the force and luster it had while it was only an unexpressed thought. All these and more may account for the fact that some writers of letters stop right in the midst of their story.

For example, take the letter of C. B. Smith on page 646, April 25 number, on "Reduced Compression and Lead Saves Coal." Now, I happen to know the two engines of which he speaks. It also happens that I am running three engines of the same make. Naturally I am interested. Mr. Smith found it possible to save 3000 pounds of coal per day. If we could turn the same trick here, it would give us great pleasure. But here is the hitch. I know how my valves are set; but Mr. Smith has failed to show how his were set, either before or after adjustments. Possibly my compression is the same as his after adjusting, or my lead may be the same as his before adjusting. I do not know; he has left me in the dark.

A set of cards taken as the engines were originally and another set as they were when saving 1½ tons of coal per day would be relevant, or measurements of lap and lead and compression might be given. With such information the letter might be made very valuable to the many who are operating Rice & Sargent engines. Without it, all we know is that one man used a wrench and saved coal.

I have taken Mr. Smith's letter, not to cast any doubt or reflection upon it, but because it is easier to make one's meaning plain by using a concrete example. His fault is quite common. Let every writer try to put himself in the place of the "other fellow" for whom he is writing.

The admonition "Be brief," frequently given to writers, may be the reason for some of these letters which contain only half the story. We readers do not like to wade through a lot of verbiage to get at an idea. We want the ideas clearly set forth; but we want all of them. It may not be possible to do that and be brief; so I say, be concise. Get all the essential facts—and then prune.

Malden, Mass.

Coal Defined

In my letter under the above heading which appeared in the May 30 number I neglected to cross out the words "noncombustible elements" in the last equation of Table 2. The equation should read:

Pure Coal = Combustible Elements.

New York City.

Benefit of Organization

Under the above caption in POWER of April 11, there appeared an article signed by C. C. Harris, of Springfield, Mass., calling attention to an organization of firemen, oilers and engineers to be known as the Brotherhood of Power Workers. I assume it is a local benefit association organized for the purpose of caring for the sick and burying the dead. How this will benefit the power-plant worker as a worker I fail to see.

For some little time there has been a movement to organize the Institute of Operating Engineers. This organization is to be composed of all men associated with the power plant. Assuming that all power-plant employees from coal passer up will eventually become engineers, it is therefore an engineers' organization.

The purpose of the Institute of Operating Engineers has been explained at length in POWER and is the kind of organization the engineer sadly needs.

Through its system of lectures, grades and certificates, the apprentice may become in time an operating engineer and in turn receive his certificate of master operating engineer.

The present standing of the average engineer is due, in part at least, to his isolation and his short-sightedness. He has been left out of the general distribution of rewards and is therefore compelled to accept a lower wage than some of those over whom he has supervision.

When the standards set by the Institute of Operating Engineers are established, there will be a recognized distinction between the engineer in charge of a 25-horsepower plant and the chief of a large central station.

The man who will be able to obtain a certificate of master operating engineer, will have in his possession a paper of value and his services will be in demand. His compensation will be in accordance with his ability.

Chicago, Ill.

The Accident at Amoskeag Mills

In reading over the account in the April 11 issue of POWER of the accident at the Amoskeag mills, and the resulting death of three men, it seemed almost incredible that the two men on the engine-room floor were unable to get out of the building before being enveloped by the escaping steam. A little figuring, however, leads one to wonder how anyone was able to escape.

The only measurement given is the length of the basement, 151 feet. If the drawing is to scale, the width is 80 feet. The basement is probably not over 10 feet high and the engine room about 40 feet. These assumptions are sufficiently close for the information desired. This gives 600,000 cubic feet as the total cubical contents.

About one-fourth of the flange blew out, so that the area of the opening was 78.5 square inches. Using Napier's formula, the quantity of steam flowing through this opening in one minute, with a boiler pressure of 170 pounds, would be

$$\frac{185 \times 78.5 \times 60}{70} = 12{,}450 \text{ pounds}$$

One pound of steam at atmospheric pressure is equal to 26.8 cubic feet, so that in one minute 333,000 cubic feet of steam at atmospheric pressure would be blown into the basement and engine room. This would mean that in less than two minutes the entire building would be full of steam at a temperature of 212 degrees Fahrenheit, high enough to kill a man in a few seconds. Actually the engine room must have filled with steam to a hight of 10 or 15 feet inside of 15 seconds, and the men, unable to see, must have been caught before they could grope their way out.

W. L. DURAND.

Washington, D. C.

Triplex Pump Problem

In Mr. Potter's triplex-pump problem in the March 28 number, let us assume two different positions of the cranks as in Figs. 1 and 2. Let the connecting rod be four times the length of the crank, then when one of the cranks is on the bottom center the end of the plunger will be five crank lengths from the center of the crank shaft. The stroke of a plunger will equal two crank lengths and if for the sake of argument we call a crank length one volume, the stroke will equal two volumes.

The cranks, the connecting rods and the center lines of Figs. 1 and 2 will form a number of triangles. If the length of the center line forming one side of the triangles in Fig. 1 is determined and this distance measured from the center of the crank shaft, it may be determined how far up the end of the plunger has moved. By the use of the sine tables and the rule that the sides of any triangle are proportional to the sines of the opposite angles, I find that in Fig. 1 two plungers have displaced 0.5955 volume each, while the other plunger, being at the end of the stroke, has displaced two volumes, the sum of the three being 3.1909.

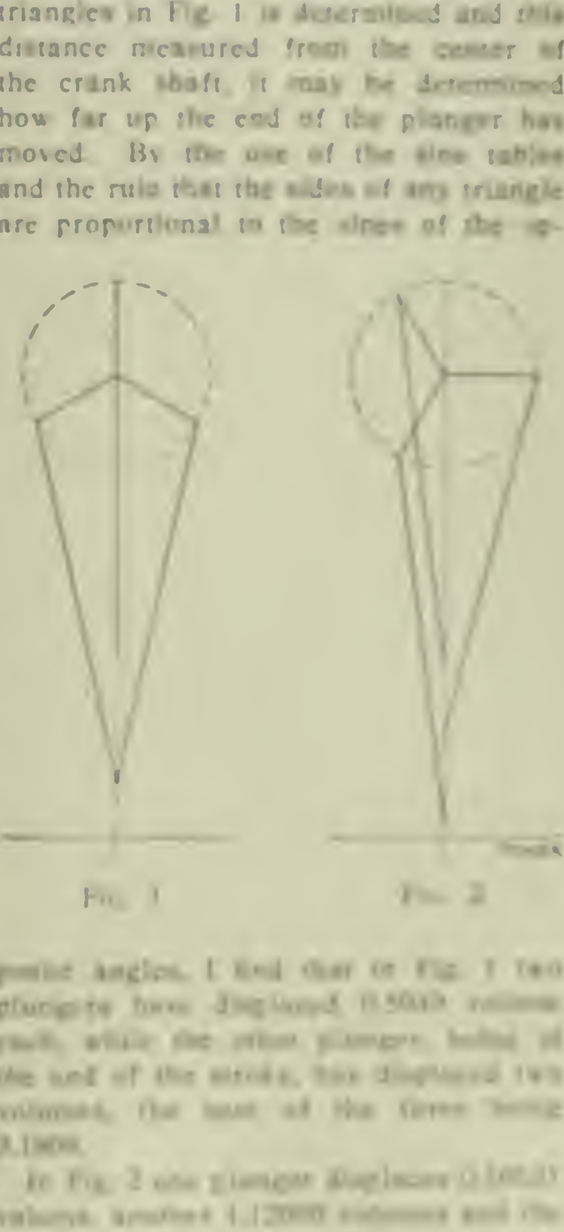

FIG. 1 FIG. 2

In Fig. 2 one plunger displaces 0.16033 volume, another 1.12000 volumes and the other 1.90545 volumes. The sum in this position is 3.15072. The shorter the connecting rod the greater becomes the effect of the angularity. With a connecting rod twice the length of the crank, I obtained 3.525 volumes for Fig. 1 and 4.32303 volumes for Fig. 2. While the difference in volume for the two positions is not large, when the cylinders are filled with water I think that something would have to be so.

LESTER PYLE.

West Fitchburg, Mass.

Value of CO_2 Recorder

In the issue of May 9, H. S. Vassar presents diagrammatically the results of a number of boiler tests for the purpose of confirming his disbelief in the value of flue-gas analyses in general, and automatic CO_2 recorders in particular. He starts out by placing these instruments in a class with pies and puddings—which are unnecessary, if not indeed harmful, luxuries—and clinches his arguments by citing a fable which represents all those who are spending time, effort and vocabulary in an earnest endeavor to show the true relation between CO_2 and efficient combustion, and to convince the power producer of the economic value of a continuous automatic record of CO_2, as "strangers glib of tongue" who are enticing the foolish managers of power plants into ordering these instruments "at a fabulous price" and all those who for many years have been spending time, money and patient, toilsome effort to perfect such instruments as "weavers of airy nothingness from nothing."

Mr. Vassar's presentation of experimental data is not without value.

First, because it shows how easy it is to draw false conclusions from insufficient data.

Second, it gives an opportunity to discuss the subject of CO_2 from a new viewpoint.

Third, and most important, it sets those who are, or should be, interested to thinking.

Valid conclusions cannot be drawn from the meager data presented. It is necessary to know the draft, rate of combustion, feed-water temperature, steam pressure, the percentage of superheat or moisture in the steam and, above all, the temperature of the flue gas and the percentage of coal left in the ash and clinker.

It is absurd to condemn the value of an automatic CO_2 recorder from the results of a series of tests in connection with which no such records were made. An average sample may be quite misleading because it cannot reveal what has happened during the sampling period. In an average sample showing 11 per cent. of CO_2 the flue gas may have varied between 5 and 17, 8 and 13 or 10 and 12 per cent., and unless these variations are known, valid conclusions cannot be drawn as to the economic value of CO_2.

Furthermore, the ordinary method of sampling by drawing the gas into a bottle filled with water and allowing the water to drain off gradually does not give a true average sample. The flow of gas varies inversely with the draft, and directly with the loss of head in the bottle, causing the flow to become less and less rapid as the bottle empties. Until Mr. Vassar gives assurance to the contrary, there is justification in doubting that he obtained true average samples.

Mr. Vassar says nothing about the temperature of the flue gas and, since the loss of heat up the chimney varies directly with the temperature of the escaping gas, no valid conclusion can be drawn without this knowledge.

The loss of coal through the grate bars is another factor which may vary between 1 and 5 per cent. and must therefore be taken into account. Without a knowledge of these factors it is absurd to draw a general conclusion. There are certain fundamental principles and natural laws with which experimental results must harmonize, and if they do not so harmonize, there is something wrong with the results or the manner in which they have been obtained.

To burn 1 pound of carbon to CO_2 requires 11.6 pounds of air, forming 12.6 pounds of combustion product composed of 21 per cent. CO_2 and 79 of nitrogen by volume. If 50 per cent. excess air is supplied the products of combustion will weigh 18.4 pounds and contain 14 per cent. of CO_2. With 100 per cent. excess air the products of combustion will contain 10½ per cent. CO_2 and weigh 24.4 pounds. With 200 per cent. excess there will be 7 per cent. CO_2 and 35.8 pounds of flue gas; and with 300 per cent. air, 5.25 per cent. CO_2 and 47.4 pounds of flue gas. Thus the weight of the flue gas increases as the percentage of CO_2 decreases.

In burning 1 pound of carbon 14,500 B.t.u. are liberated, and this quantity of heat remains the same whether the coal is burned to CO_2 with the theoretical minimum weight of air required or with an excess of 300 per cent. or more. There is therefore a definite quantity of heat available from every pound of carbon burned, irrespective of the excess of air supplied.

To raise 1 pound of dry flue gas 1 degree, requires 0.24 B.t.u. If the temperature of the escaping flue gas is assumed to be 500 degrees above atmospheric temperature, 1 pound of flue gas will carry away

$$0.24 \times 500 = 120 \text{ B.t.u.}$$

Therefore there must be loss of heat up the chimney. The following gives the losses for various percentages of CO_2 in the flue gas and also the percentage of these losses to the total heat produced:

CO_2, 21.0%	$12.6 \times 120 = 1512$ B.t.u.	or 10.4%
CO_2, 14.0%	$18.4 \times 120 = 2208$ B.t.u.	or 15.2%
CO_2, 10.5%	$24.4 \times 120 = 2928$ B.t.u.	or 20.0%
CO_2, 7.0%	$35.8 \times 120 = 4296$ B.t.u.	or 29.6%
CO_2, 5.25%	$47.4 \times 120 = 5688$ B.t.u.	or 39.2%

These are minimum figures for the stack temperature assumed, and can be reduced only by reducing the stack temperature.

The loss up the chimney may be and generally is greater than shown in the table, due to various causes: First, higher stack temperature; second, unconsumed combustible gases, and, third, water vapor.

Abnormally high stack temperature may be due to dirty and insufficient heating surfaces and excessive driving. With a properly constructed furnace and intelligent firing, appreciable quantities of unconsumed gases will not occur when 40 to 50 per cent. of excess air is used. Water vapor is always present, due to moisture in the coal and the air and to the combustion of hydrogen.

In all cases high or low CO_2 means high or low efficiency, and when, as some of the tests in Mr. Vassar's diagrams indicate, 5.25 per cent. CO_2 gives a higher efficiency than 8 per cent. (Fig. 1) and 8 per cent. is more efficient than 12½ (Fig. 2), there is something wrong either with the percentage of CO_2 given or the determination or computation of the other data.

While it would be preposterous to say that a CO_2 recorder is a sure cure for all sources of loss in the boiler room, it is none the less true that it is the most available and most reliable, and hence the best, guide to efficient firing, and in combination with a recording pyrometer gives a correct measure of the loss of sensible heat up the chimney. When it is considered that this constitutes from 60 to 90 per cent. of the total waste in generating steam, its importance must become evident to all concerned in boiler-house economy.

EDWARD A. UEHLING,
President Uehling Instrument Company.
Passaic, N. J.

The Line Shaft Breaks

In the issue of May 2, A. Rathman writes that the shafts break in the hub of the sheaves. That is the weakest place, as the keyseat is cut there.

An uptodate factory which had been installed but a short time was operated by a rope drive. The generator was driven by a Corliss engine of 1500 horsepower.

One night during a rain storm the wheel pit was flooded and the rope got wet and began to shrink. It was then slacked off all that was possible on the tightener. The stress was so great that a coupling on the generator shaft was sprung, cracking one bearing, and the rope drive had to be cut out to keep it from pulling the generator off its base.

Mr. Rathman does not say whether the plant was run 10 hours or 24 hours, but I infer that it is operated in the daytime. At night the drive is apt to get damp and contract, causing a heavy strain or even springing the shaft. The remedy I suggest is to keep the drive as dry as possible. A good belt dressing might be a help to prevent moisture, if applied when running slowly just before shutting down.

POWER

The National Electric Light Convention

Some of the features of the "electric light" convention recently held in New York City might be profitably adopted by the other national engineering bodies. The committee system is probably the most important of these. Of about thirty items on the program relating to engineering or closely allied branches of central-station work, nineteen consisted of committee reports and most of these were far and away more valuable than any of the papers constituting the remaining eleven "events." Just why this is so we do not presume to say in detail; it is sufficient that it is true, which is indubitable. Those of the reports that are of high merit are the results of a year's almost continuous effort by the several committees making them; this is a very obvious and excellent general reason why they are of more value than the average paper. Of course, there are other reasons and anyone interested can easily discover most of them.

The committee reports this year were of a much higher order of merit than those previously returned; this is but the natural result of continuing good, earnest workers on the committees from year to year instead of disorganizing things and handicapping the work by annual upheavals. The reports on meters, power, overhead line construction, underground construction and the preservation of poles and crossarms, for example, were masterly compilations of practical information, each worth its weight in gold to any central station within the class to which it applies.

It is by no means intended to intimate that the papers read at the convention were not meritorious. On the contrary, most of them were unusually so and this fact serves only to emphasize the demonstration which this year's program makes, that a committee report can be made of more practical value to the station operator or manager than a good individual paper.

However, the fact must not be ignored that some subjects cannot be treated as well in a committee report as in an individual paper. Hence, there will always be excellent work to be done in the way of preparing papers. No hard and fast line can be drawn, but in general it would seem that the best plan of apportionment is to have principles treated in individual papers and practice reflected and guided by committee reports—not forgetting that specialization pays in committee work as well as other kinds. This policy was reflected to a large extent in the convention under discussion, with the conspicuously beneficial results to which we have referred.

Progress or Something New?

As a people the Americans attempt to be progressive to a degree not reached by any other, but all of this progress is not in the right direction. Much of it is merely change which does not represent real progress.

When an idea is developed it is frequently adopted without sufficient investigation. New processes and methods of doing work and new products are daily creations which are adopted almost as a matter of course on the assumption that that which is new must be better than that which is old.

In the test of practical operation failure is more than often the ultimate result which investigation or even logical mental analysis would have predicted.

Some years ago improvements in rolling-mill practice made the rolling of large sheets possible. Immediately two-sheet boilers were put on the market with multitudinous unsupported statements of the advantages of a boiler construction devoid of circumferential seams. Short terms of service demonstrated the fallacy of the claims in a much more costly manner than would a reasonable amount of analytical research.

Concrete, both plain and reinforced, now supplants iron, wood, brick and stone in countless forms of construction, with little regard for its fitness in many instances. It is used in buildings, beams and bridges, in pavements, fences and conduits, aqueducts and for foundations and retaining walls, but careful engineers, while recognizing its many advantages for various purposes, are advising its employment only where it is manifestly advantageous.

In power-plant equipment the piping is a factor of prime importance and the necessity for reliability has led to the design of many types of pipe joints, among which the welded flange is not the least noticeable. Though it may be possible that a pipe line in which the flanges are integral with the pipe length is better than one with separate flanges, it is of paramount importance that the construction be safe beyond the possibility of suspicion.

When two pieces of iron or steel are to be welded together the surface must be clean so that the pasty metal may be rolled or hammered into perfect contact, and when the slag is not entirely removed from both surfaces this is impossible. There is always more or less difficulty in welding when one of the members is much thicker than the other, and this is aggravated when the surfaces to be joined are comparatively broad or long.

Between the pipe and the flange there is a considerable difference in thickness and the form of the joint is such that the removal of all of the slag and oxide is problematical. A joint of this kind though to all appearances perfect outwardly and may withstand a mild hydrostatic test, may be so imperfectly joined within that the stresses and flexures of even a short service will pull it apart.

The strength of a perfect weld may be approximately calculated, but the uncertainty of the continuity of the union between the pipe and the flange in a welded joint has led conservative engineers to discourage the use of the welded pipe flange, not because of the lack of strength and rigidity when sound, but because of the uncertainty of the nature of the union between the pipe and the flange.

Ignition in Gas Engines

It has been universally true ever since the early days of electrical engineering that electrical auxiliaries used with machines not themselves electrical are responsible for most of the troubles experienced in the operation of the machines, until the makers of them "wake up" and put the proper quality in their electrical auxiliaries. The gas engine is no exception to the rule—in fact, it is a shining example of its truth. It has been stated that more than two-thirds of gas-engine troubles are due directly to the ignition equipment; it is our opinion that the proportion is much nearer ninety per cent.

The remedy in all cases where the engine is small is to equip it with the best quality of ignition apparatus *and wiring* that money can buy. Large engines, however, suffer the unavoidable handicap of relatively slow complete ignition, no matter how good the equipment, because of the distance through which the flame must travel and the very small quantity of mixture in contact with the spark made by the igniter.

The Diesel engine has been perfected mechanically to such an extent, we are told, that it is operated in Europe by unskilled labor. Does anyone suppose this would be possible if the engine had to depend for ignition on the kind of apparatus commonly applied to gas engines? The fact that the air in the cylinder is hot enough to ignite the oil as it is injected undoubtedly accounts for the conspicuous operating success of the Diesel type of engine, now that the rubbing surfaces, crank shaft and nozzle have been made practically fool-proof.

Builders of gas engines will do well to take this lesson to heart. Ignition by means of a minute spark at one or even two points on the circumference of a large cylinder is inefficient, and attempted ignition, at one or forty points in any cylinder, by means of cheap apparatus is an insuperable obstacle to satisfactory operation.

Gathering Them In

"Twenty-nine steam plants in one town; twenty-seven of them are shut down and the other two are on the run." This is the substance of what the chief engineer of a central station in a prosperous Massachusetts manufacturing town told a Power representative recently.

Why have the owners of these twenty-seven steam plants found it to their advantage to close them, unless it is because electrical energy is sold to them at a lower cost than the steam plants can produce the same power?

This is not a proof that the isolated plant cannot produce power cheaper than it can be bought from the central station, but it indicates that some engineers are so operating their plants that they cannot compete with central-station rates.

There is not enough attention given by private-plant engineers to the undeniable fact that their positions are in peril. They do not seem to realize that their employers are going to get power where it will cost the least. There is no sentiment in business. The owner of a steam plant sees no poetry in the roaring furnace and revolving flywheel, and just as soon as it is determined that the central-station rate is cheaper than isolated-plant operation, out goes the small plant and with it the engineer.

When the operating conditions of some isolated steam plants are noted it is a wonder that they have not been superseded by the central station long ago. Some engineers are woefully ignorant about the machinery in their plants. Recently the man in charge of a four-valve engine could not tell his visitor the maker's name until he had looked at the nameplate. In another steam plant the engineer was operating a cross-compound engine. Each cylinder was provided with two exhaust valves and each steam valve was fitted with a riding cutoff valve. The engineer stated that each cylinder had but four valves.

With such men in the small steam plant it is no wonder that the central station is putting them out of business. An isolated plant, in order to withstand the competition of the central station, must be operated by an intelligent engineer.

Two steam plants in operation out of twenty-nine is a commendable record for the central station, but what a mighty poor showing on the part of the twenty-seven engineers! A fact worth noting is that the engineers of the two live steam plants are readers of power-plant journals.

Is it not about time to wake up?

High Voltage Transmission

At a meeting of the power-transmission section of the National Electric Light Association during the recent convention the question was raised as to what is the maximum voltage that can be carried economically on transmission lines. Although there were a number of prominent electrical engineers present and the question evoked considerable discussion, there appeared to be no definite opinions upon the subject.

At one time it was believed by many that distance was a factor dependent only upon the voltage; that is, power could be transmitted almost any distance providing a sufficiently high voltage could be employed to avoid excessive copper losses. The chief difficulty then lay in obtaining insulators which would withstand the high tension; but this now seems to have been overcome and with the introduction of the suspension type of insulator it is probable that this phase of the problem will be met for any voltages likely to be used. Another factor to contend with, however, is the breaking down of the dielectric strength of the air, resulting in objectionable leakage from wire to wire through the intervening air.

In Colorado, transmission lines carrying current at one hundred and ten thousand volts are in successful operation at altitudes of ten thousand feet above sea level, and a one hundred and forty thousand-volt line is being constructed in Michigan. This represents an increase in voltage about tenfold during the past fifteen years. What then appeared to be unsurmountable difficulties have been successfully overcome and it is probable that like progress will be made in the future. Nevertheless, definite data upon the subject of leakage through the air would be of great value to engineers engaged in power-transmission work.

It is expected that in twenty or thirty years all of the water power in Bavaria will have been developed. There is a total of some three million horsepower, about one-half of which is owned by the government. One of the first large projects to be undertaken under government auspices is that at Lake Walchensee.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Feed Water Entrance to Manning Boilers.

Why does not the feed water enter the water leg of a Manning boiler as in most vertical boilers?

M. B. H.

The feed water enters the Manning boiler as it should all vertical boilers, well up toward the top of the water, in order to give the contained air a short pass to the steam space. If the water enters the boiler anywhere in the comparatively cool water leg, the oxygen in the air leaves the water slowly and collects on the staybolts and sheets and injures them by corrosion; while if set free in the hot water near the top, it goes directly into the steam space and thence to the engine, where it can do no harm.

Soda Ash and Soda Crystals

What are the comparative values of soda ash and soda crystals for water softening?

F. W. S.

Soda ash and soda crystals are on the market in such degrees of impurity that a definite answer to your question is impossible.

Soda ash runs from 40 to 60 per cent. alkali, and soda crystals may contain anywhere from 20 to 30 per cent. of water. Ordinarily, the largest per cent. of alkali is obtained for the money when 48 per cent. soda ash is bought.

Sulphur for Hot Bearings

How is sulphur used for cooling hot bearings, and is it suitable for all sizes?

C. H. P.

Pulverized sulphur, commonly called flowers of sulphur, is mixed with a heavy oil, preferably cylinder oil, in proportions by measure of about 1 of sulphur to 6 of oil. The mixture is applied liberally and is suitable for all sized bearings.

Horsepower of an Engine

What would be the horsepower of an engine: mean effective pressure, 40 pounds; length of stroke, 12 inches; diameter of the cylinder, 14 inches; number of revolutions, 90?

W. G.

The horsepower of a steam engine is found by multiplying together the speed of the piston in feet per minute, the area of the piston in square inches and the mean effective pressure per square inch and dividing the product by 33,000.

Expressed as a formula the rule is:

$$Horsepower = \frac{PLAS}{33000}$$

Substituting the values given it becomes:

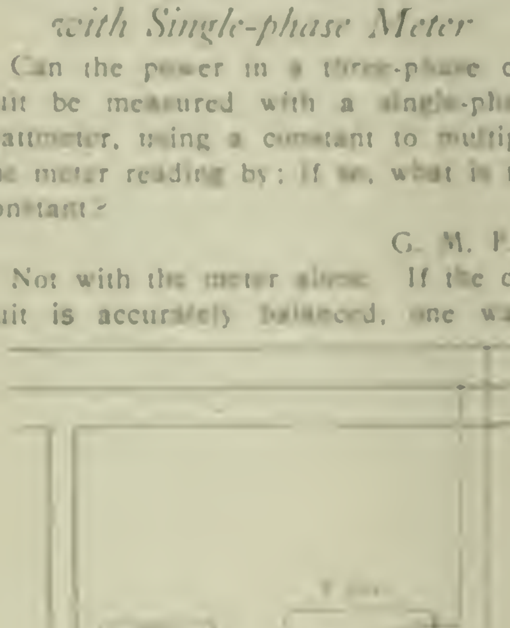
$$\frac{40 \times 153.94 \times 180}{33000} = 33.58 \text{ horsepower}$$

Measuring three-phase Power with Single-phase Meter

Can the power in a three-phase circuit be measured with a single-phase wattmeter, using a constant to multiply the meter reading by; if so, what is the constant?

G. M. F.

Not with the meter alone. If the circuit is accurately balanced, one wattmeter and a Y-box, connected as shown in the diagram, may be used. The wattmeter will indicate one-third of the total power in the circuit—that is, it measures the power in one phase only. The use of the Y-box is for the purpose of giving the potential coil of the wattmeter the true voltage between the main wire and the neutral point of the system. The resistance of each branch of the Y-box conductor must equal that of the potential coil.



MEASURING THREE-PHASE POWER WITH A SINGLE-PHASE WATTMETER

Alternating-current Frequency

What determines the number of cycles per second in an alternating-current circuit?

H. E.

The number of cycles per second is equal to the number of field-magnet poles on the alternator which supplies the circuit multiplied by one-half the number of revolutions per second. For example, a machine with eight poles running at 15 revolutions per second (900 revolutions per minute) will deliver current of 60 cycles per second, because

8 poles × 7½ r.p.s. = 60 cycles.

Same Speed at No Load and Full Load

A shunt-wound direct-current motor continues running at the same speed after the load is cut off that it showed with full load; what is probably the reason?

F. C. G.

It is probable that the brushes have a forward lead to such an extent that the armature reaction at full load weakens the field enough to keep the speed up to the no-load speed, but this would ordinarily cause bad sparking. Another possibility is that the field winding is differential instead of simple shunt. Examine the coils closely.

Removing Scale from Engine Jackets

How can I remove the scale from the water jacket of a gas engine that is so small that a scraper cannot be used in the jacket space effectively?

F. C. H.

Fill the jacket with a strong solution of washing soda and run the engine until the water becomes hot; empty the jacket and refill with pure water, not too cold, and run the engine until the water begins to evaporate (not boil vigorously); empty the jacket and refill again with pure water and run the engine as before. Repeat this until the water comes out reasonably clean. If it is rusty and dirty after the third or fourth dose of pure water, put a solution of washing soda through again and follow with the fillings of pure water as in the first effort.

Reversing a Direct-current Dynamo

What changes in connections are necessary when a direct-current dynamo is driven in the direction opposite to that for which it was built?

H. F.

Transpose the connections of the two cables leading to the brush holders and reset the brushes for the reversed direction of rotation.

Refrigeration Department

Principles and operation of ice making and refrigerating plant and machinery

The Westinghouse-Leblanc Water Refrigerating Machine*

This machine rests on the principle of producing cold by evaporation of an aqueous solution in a vacuum. But it differs essentially from the old machines of Leslie and Carré and from the vacuum machines now employed in America in that the water evaporated, instead of being absorbed by concentrated sulphuric acid, is removed by mechanically drawing off. This leads to a great simplification since there is no longer any need to trouble with reconcentrating by dilute sulphuric acid. If this expedient had not hitherto been devised, it was because it seemed impossible, practically, by mechanical means, to remove the enormous volumes of water vapor evaporated at low temperature (since the boiling point of water at atmospheric pressure is 212 degrees Fahrenheit, is much higher than that of other liquefied gases used in compression machines, viz., 14 degrees Fahrenheit for sulphurous acid, — 13 degrees for methyl chloride, — 31 degrees for ammonia, and — 108 degrees for carbonic acid). This was, in fact, quite impossible with piston pumps and could not be accomplished except by recourse to entirely different apparatus, such as ejectors, which, by reason of the enormous velocities attained by the liquid in them, allow a considerable flow of steam. Yet it has been necessary, in order to obtain the requisite high vacuum or low absolute pressure of 0.12 of an inch of mercury to get a refrigeration to 23 degrees Fahrenheit and less than 0.039 inch to reach 28 degrees, generally to combine with a steam ejector a special water ejector fed by a sort of reversed turbine. These two appliances, which separately would be insufficient, give the desired result when they are coupled in series.

The Westinghouse-Leblanc refrigerating machine permits the refrigerant to be employed more simply than in compression machines. While in the latter apparatus the evaporated refrigerant liquid, such as ammonia, cannot generally be employed directly and serves only to cool a brine, in the Leblanc machine it is the brine which is directly cooled and constitutes the refrigerant liquid. At the same time it is concentrated by the natural action of the vacuum machine. This peculiarity avoids the need of concentrating by heating the brine, which becomes quickly hydrated by contact with the moisture of the air and the substances that are being cooled. Here, on the contrary, it is always necessary to add a certain quantity of water to the heated brine before sending it to be cooled.

When the Leblanc machines were first built, the water vapor removed from the brine was condensed in the water ejector itself. This arrangement was applied only in one installation, in the Gillet Chemical Works, at Lyons, to cool a dye-works product to 46 degrees Fahrenheit only. In all subsequent installations the water vapor removed from the brine has been condensed in a separate mixing or surface condenser, the vacuum pump of which is formed by a liquid ejector. This new arrangement has rendered easily possible the design of powerful refrigerating machines for low temperatures, which would not have been practicable with the simple ejecto-condenser applicable only to small installations for quite high temperatures.

The accompanying illustration is a diagrammatic sketch of a Leblanc refrigerating machine, with a mixing countercurrent condenser, such as that installed at the Bethune mines. All the other installations are of nearly the same type, except that the condenser may be of the surface type. The heated brine coming out of the refrigerator *R* passes to a dilution tank *S D*, where a cock with a float brings fresh water when the level in the tank falls below a certain point. The brine, suitably diluted, is thence drawn up through the pipe *S C* to the top of the evaporator *A*, by reason of the vacuum existing therein. This evaporator is formed of a cylindrical body *B*, carrying at the top a finely perforated plate, through which the heated brine falls in slender jets. Under the influence of the vacuum which prevails in the evaporator, this brine in falling liberates water vapor, which escapes by the annular jacket surrounding the cylindrical body *B* and rises to pass through the short pipe *A E*. At the same time the brine, cooled by con-

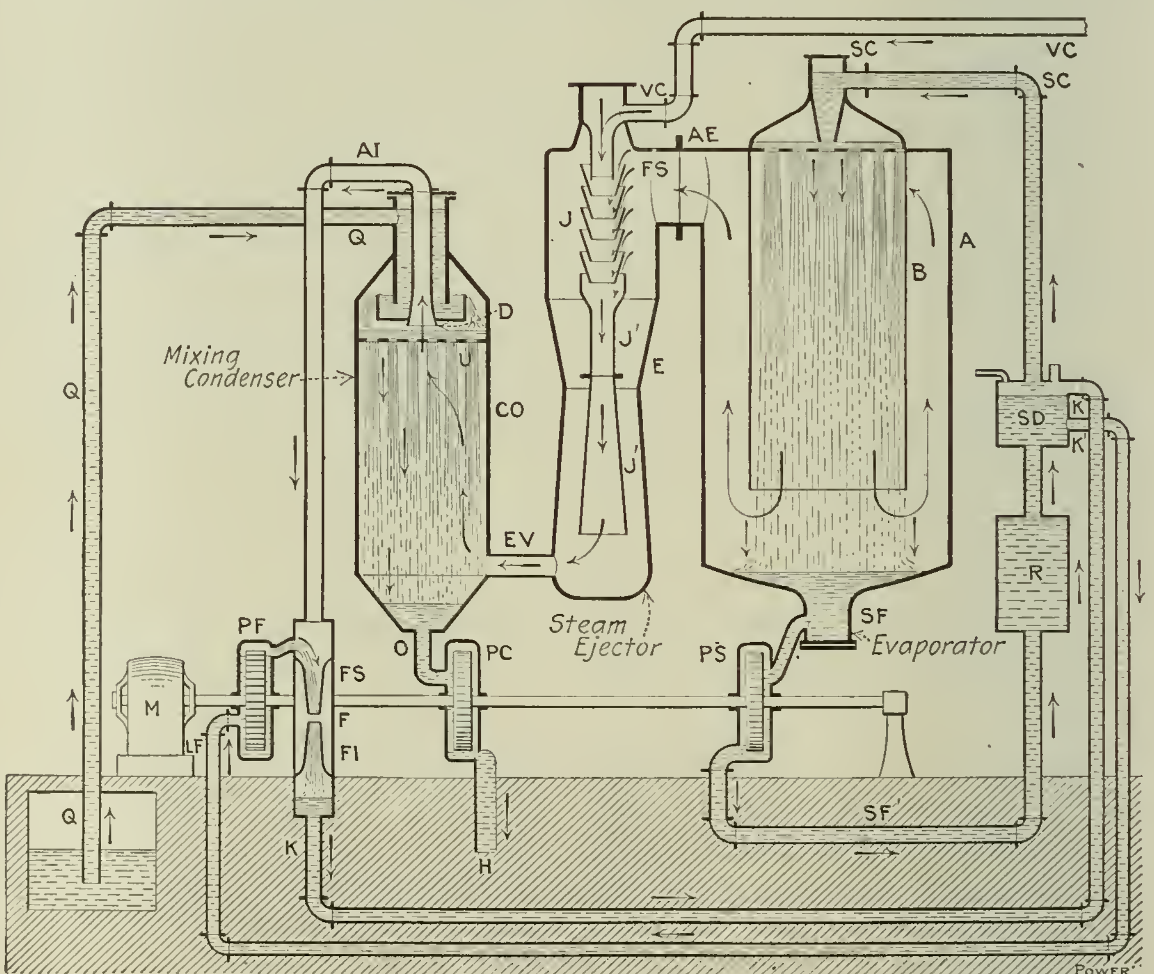


Diagram of Westinghouse-Leblanc Water Refrigerating System

*Translated from an article by Ch. Jacquin in *La Technique Moderne*.

centration, falls to the lower part *S F* of the evaporator *A*, where a centrifugal pump *P S* sends it to the refrigerator *K*.

The air and water vapor removed from the brine, at low pressure, enter at *A E* the periphery of the steam ejector *E*, which contains a series of nozzles *J* followed by a converging and diverging cone *J* into which comes a flow of hot steam from the pipe *V C*, which can be at atmospheric pressure only. The hot steam jet enters the nozzles *J* and draws along with it into the cone *J* the air and cold vapor coming from the brine. The mixture passes out at the lower part *E V* of the steam ejector and into the lower part of the condenser *C O*, where it is drawn upward by the vacuum exerted in the pipe *A I*. In rising, it meets slender jets of cold water coming from the tube *Q* and spraying through a finely perforated plate *U*. In contact with this water, the water vapor of the mixture condenses and falls with the sprayed water to the bottom *O* of the condenser, where the two combined waters are discharged at *H* by a centrifugal pump *P C*. The air which was contained in the rising gaseous mixture, with the water vapor from the brine, is sucked through the upper central orifice *D* into the pipe *A I*.

The suction is produced in *A I*, at the top of the condenser, by a water ejector *F*, containing a converging cone *F S*, into which is injected a liquid, generally water, at very high velocity, forced by the turbine pump *P F*. The liquid injected into *F S* carries with it, into the diverging cone *F I*, the air sucked from the condenser and falls into *K*.

In the ejecto-condenser machines (corresponding in the figure to a direct communication of the base *E V* of the steam ejector *E* with the top *A I* of the liquid ejector *F*) the ejecto-condenser is fed at *L F* by the water sucked from a well or tank, but it is then necessary to prime it with water under pressure. In the machines with a separate condenser, such as that shown, the turbine pump *P F* is fed with the brine itself coming through *K L F* from the dilution tank *S D*, and returning there at *K* whenever the level in this brine tank *S D* is to be raised. There is nothing further to consider but the priming of the liquid ejector, which starts work when the pipe *K* is open. Likewise there is no need of special water for the operation of this ejector, whose speed of circulation is such, and which requires so little liquid that it causes no trouble in the brine tank *S D*.

The liquid ejector *F* gives a constant vacuum, equal to the tension of the water vapor at the temperature of the liquid of condensation, some 15 to 20 millimeters. The steam ejectors *E* have their piping calculated to bring about the vacuum begun by the liquid ejector *F*, so as to obtain in the evaporator *A* a final absolute pressure, variable according to the temperature to which the brine should be cooled; for example, 0.12 inch of mercury when it is desired to reach 23 degrees Fahrenheit, and ¼ inch of mercury when 41 degrees suffices.

The three pumps, *P S* for circulating the brine, *P C* for discharging the condenser and *P F* the pump of the water ejector, all being of centrifugal type, are driven by a single small electric or steam motor *M*.

The Leblanc machine has the advantage of being built only of strong parts, with no valves, etc., subject to rapid wear. The absence of noise is also in certain cases a valuable quality; for example, on the "Suffren," and on the seven large warships of the "Danton" type now in construction, where there is an interesting application of this refrigerating machine for cooling ammunition magazines. The brine cooled in the refrigerating machine serves for cooling to a temperature of a few degrees above 32 degrees Fahrenheit, the air entering an air cooler and circulating in the magazine, thus preventing such rise of temperature of the powder as to cause an explosion.

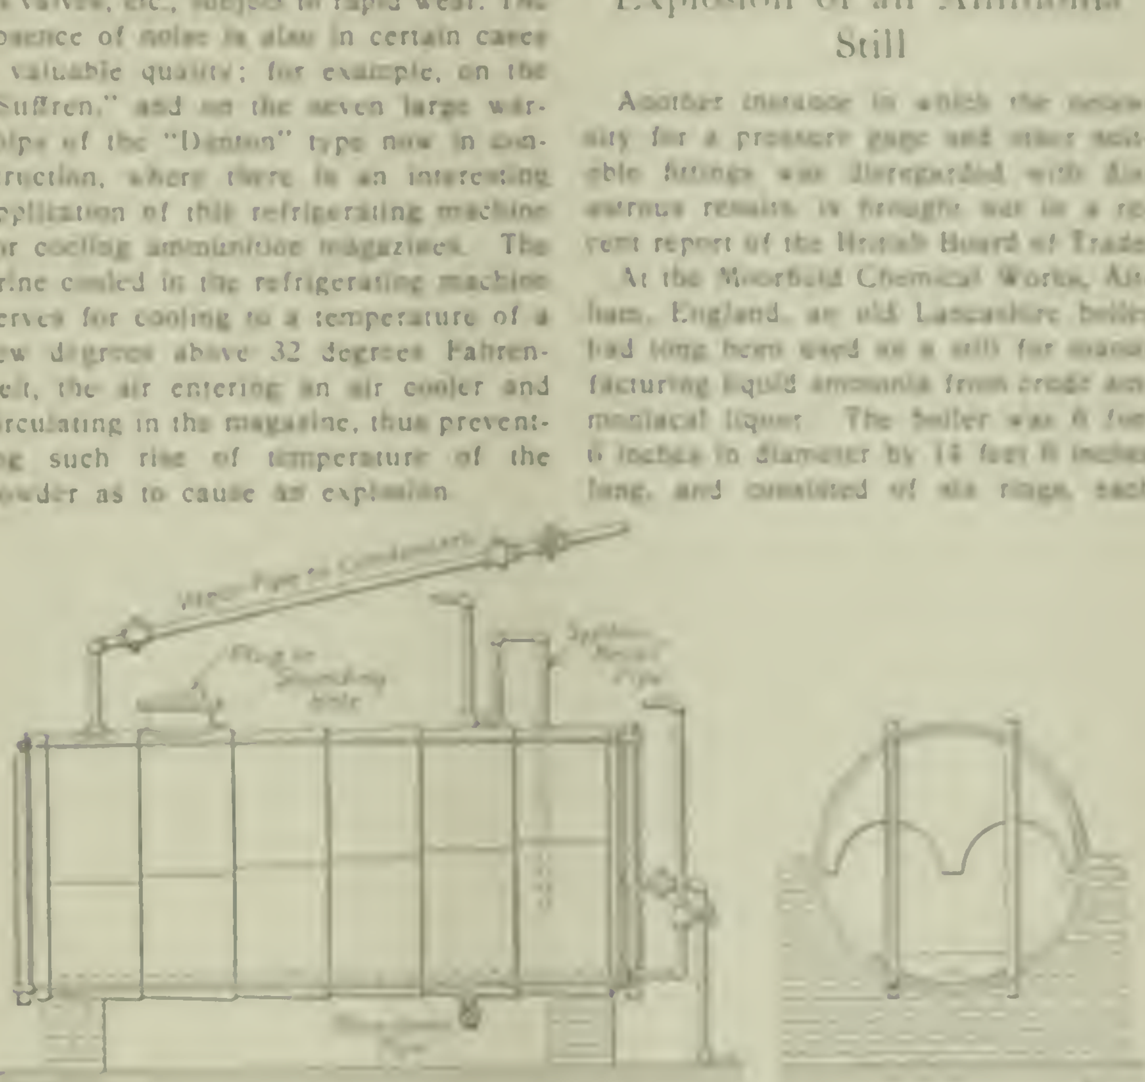
The Westinghouse-Leblanc machine is well adapted to chemical industries where there is no need to cool below the freezing point, its efficiency then being excellent, while for very low temperatures its power and efficiency notably decrease because of the extremely weak tensions which the water vapor then shows. It has recently been applied in the Nanterre factory of the French Glue and Gelatine Company to cool the air used to hasten the viscosity of the gelatine. In this installation, since the brine does not require to be cooled to a low temperature, the evaporation of the water does not need a high vacuum, and a steam ejector alone suffices to produce the vacuum required in the mixing condenser; the liquid ejector and its turbine pump are then unnecessary.

The Leblanc vacuum machine consumes in its condensers a little more water than compression machines require for their cooling, but, when the temperature of refrigeration is not very low, it takes, as motive power employed for driving its pumps, and as steam necessary for its ejectors, a total energy rather less than the mechanical power required for driving a compression machine; and this power is produced economically when the steam of the ejectors, which constitutes the greater part of it, may be derived from the exhaust of steam engines, as is often the case in large works.

Explosion of an Ammonia Still

Another instance in which the necessity for a pressure gage and other suitable fittings was disregarded with disastrous results is brought out in a recent report of the British Board of Trade.

At the Moorfield Chemical Works, Altham, England, an old Lancashire boiler had long been used as a still for manufacturing liquid ammonia from crude ammoniacal liquor. The boiler was 6 feet 6 inches in diameter by 14 feet 8 inches long, and consisted of six rings, each composed of two ¼-inch plates. The heads were ⅝ inch thick and were secured to the shell by means of internal angle irons. Double angle irons were also riveted to the front head and a pair of girders were placed vertically across the outside of each head, their ends being clamped to tie-rods running the entire length of the boiler, as shown in the illustration.



OLD BOILER USED AS AN AMMONIA STILL

A 1½-inch wrought-iron pipe for charging the boiler with ammoniacal liquor and milk of lime, entered the front head as did also a similar pipe for supplying the heating steam. A valve was fitted on each of these pipes and a 1½-inch vapor pipe led from the crown to two condensers. There was a siphon relief pipe, 1½ inches in diameter, which passed through the boiler crown and was connected to an internal pipe, the open end of the siphon being about 3 feet above the top of the boiler and the length of the internal pipe 4½ feet.

A blow-down cock was fitted to the bottom of the boiler and a manhole was provided at the top, through the cover of which was drilled a ¾-inch hole for sounding purposes; the latter was closed by a wooden plug. The vapor pipe also contained a ¼-inch hole for ascertaining the strength of the gas, and, like the other, this was closed by a wooden plug. No pressure gage or other mountings were fitted.

The method of working the distilling apparatus was as follows: When the boiler was to be charged, the cocks on both branches of the vapor pipe were closed. The ammoniacal liquor was then run in from the settling tank, up to within 3 feet of the top of the boiler, and then about 4 to 6 inches of milk of lime was introduced by means of an injector. The charging cock was then closed and the steam valve opened, admitting steam into the boiler and boiling the liquor.

The gas evolved was led to the condensers, where it was condensed to liquid ammonia. There were two condensers, it being the usual practice to pass the gas to one condenser for 20 hours, one cock being open and the other shut. The cocks were then changed and the gas led to the other condenser, which, after working for another 20 hours, exhausted the charge in the boiler. The spent liquor remaining in the boiler was run off by means of the cock at the bottom of the boiler, after which recharging took place. It required about one hour to run off the spent liquor, and another hour to charge the boiler. It was customary to open one of the outlet cocks on the vapor pipe at the same time as the steam was turned on to the boiler.

At about midnight on the night before the explosion the boiler was due for recharging and, according to custom, the man on duty should have opened the steam valve and the vapor cock, the latter of which he apparently neglected to do. For, about two hours later, a violent explosion occurred, blowing out the front head, the rivets connecting it with the angle-iron ring having been completely sheared off and the tie-rods ruptured. The rear head was also torn at its connection to the shell for about four-fifths of its circumference, and the boiler was projected backward about 2½ feet. The attendant was so severely injured that he died a few hours later.

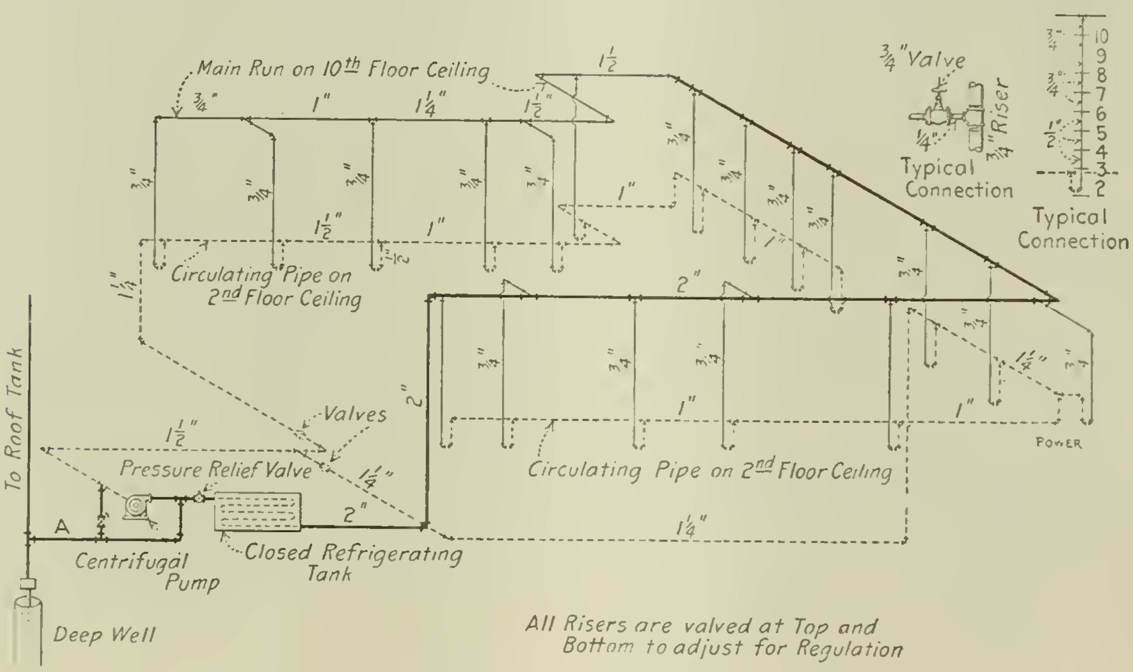
An investigation after the accident showed the relief pipe to be completely choked and as there was no pressure gage nor safety valve attached, an explosion was inevitable.

Air in Ice Water System

By Charles J. Johnson

I inclose herewith a blueprint of an ice-water system that is giving considerable trouble by mixing air with the water, causing it to become milky. As very few people know the real cause of this color, I am troubled with constant complaints.

I have thought out a remedy for this in the following manner. Put an air trap on the supply pipe A, or disconnect the line at this point and put in a direct line from the tank. Either one or both can be done, if necessary, but would like to hear from Power readers first.



Piping Diagram of System

Purging the Absorption System

By H. Westergaard

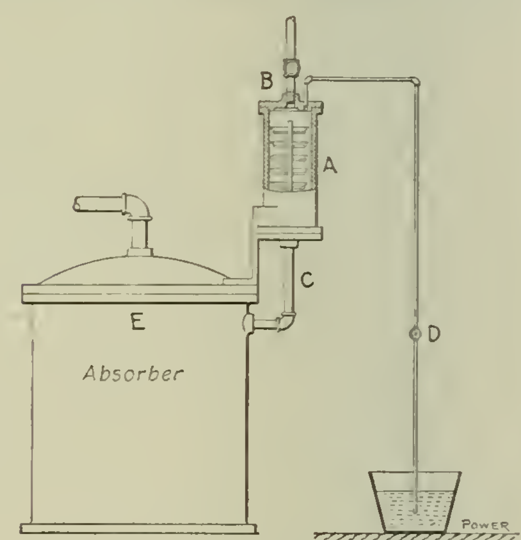
To get the best possible results from an ammonia-absorption system, the foul or permanent gases collecting in the top of the absorber must be drawn off at regular intervals. A purge connection with a shut-off valve is provided at the top of the absorber for this purpose in all installations of this kind, and the usual way to proceed when purging is to submerge the open end of this connection in a pail full of water. Then the purge valve is opened slightly and the gases are allowed to escape through the water.

The permanent gases will rise through the water and escape into the atmosphere, as they are not absorbed by the water. Most of the ammonia vapor which is mixed with these gases is absorbed by the water. This water is generally thrown away and the ammonia absorbed in it lost.

To avoid this loss of ammonia the writer employs the apparatus illustrated herewith.

The poor liquor from the exchanger enters an upright cylinder A at B and runs down over a number of perforated pans suspended at equal distance through the length of the cylinder. The lower end is connected with the top of the absorber by a pipe C. The purge pipe is connected to the top of the cylinder and is provided with a valve. The gases collecting in the space E of the absorber flow through pipe C and in the cylinder come in contact with weak and cool aqua ammonia, which presents a large surface and rapidly absorbs the ammonia gas present. The foul gases being insoluble under the existent pressure flow to the top of the cylinder and may be removed through the purge pipe.

The apparatus above described has so far proved successful, and it is my belief that it will not only save ammonia but will furnish a lower absorber pressure than would be possible without it. Whether I am right the operation of the plant this summer will show.



Scheme to Avoid Loss of Ammonia

One of the few points of advantage of the absorption system over the other refrigerating systems is that it is better adapted to maintain low temperatures, but it can only accomplish this result if the absorber and other parts of the system are kept free from permanent gases.

Analyses have shown that the foul and permanent gases purged from an absorption system contain besides air some gases which have been formed by the decomposition of ammonia, and practical experience seems to indicate that this decomposition increases with the temperature in the generator or still. It is, therefore, of great importance to provide that part of the plant with an abundance of heating surface, properly distributed so that the temperature of the liquor in the generator can be maintained at a fairly low point when the machine is operating at its maximum capacity.

Spring Meeting Mechanical Engineers

It has been 27 years since the American Society of Mechanical Engineers last met at Pittsburg before the spring meeting of this year, which was held there from May 30 to June 2. The extensive mechanical interests attaching to Pittsburg and the large membership of the society in and about that city justified expectations of an especially profitable gathering which were fulfilled by the event. The attendance was large and the program replete with interest, excellently arranged and admirably carried out.

Those who arrived on Tuesday had an opportunity to inspect the Foundry and Machine Company exhibit installed in connection with the convention of the National Foundrymen's Association, which had taken place the previous week. In the evening an informal reception was held at the Hotel Schenley, during which President E. D. Meier was presented with an engrossed testimonial in commemoration of his seventieth birthday, the presentation being made by J. H. Woodbury, as follows:

"The flight of time is so noiseless that it requires anniversaries to mark its progress, and at a meeting of engineers in Boston a few weeks ago, it was remarked that you would have a notable anniversary on this occasion which ought to be recognized in a manner similar to that of the seventieth birthday of several of your associates and predecessors, and the matter was placed in the hands of a committee of your fellow members from various parts of this country.

"Your career has been indeed a notable one in its facility of doing many things and doing them well.

"In the service of your country in both cavalry and artillery, you became a part of movements of national history. In the reorganization of the militia of your State, you became a force in the maintenance of law and order.

"It is, however, in the greater victories of peace that we have come more closely in touch with your career as an engineer.

"You have been connected with the great cotton industry in making improvements in baling the raw material, in mill construction, and also that of the textile machinery which produces the finished product.

"In the great problems of transportation you have been connected with locomotive practice and railway management.

"The functions of the engineer as an economist have been wrought by yourself in the generation of steam and in the more radical innovations of the internal-combustion engine.

"But this recital of deeds well done is trite in comparison with that of the respectful tribute which we give to your sterling manhood which has endeared yourself to those with whom you have been associated.

"Accept, then, this engrossed testimonial briefly stating our felicitations; and this will be followed in due time by a folio containing the names of those taking part in this testimonial, and we ask you to give sittings to an artist whose portraiture will, I trust, be worthy of the subject."

The sessions were held in the auditorium of the Carnegie Institute, that of Wednesday morning being devoted to the subject of cement.

The Committee on Standardization of the society working in conjunction with a similar committee of the National Association of Master Steam and Hot Water Fitters, presented a schedule of standard-weight flanged fittings and extra-heavy flanged fittings. This schedule will be presented in an early issue.

In the afternoon the visitors were taken to the works of the Universal Portland Cement Company at Universal, and returning a visit was paid to the Westinghouse shops at East Pittsburg.

On Wednesday evening the session at Carnegie Institute was devoted to the machine shop, while the gas-power section held a simultaneous session in one of the halls of the Carnegie Technical Schools. The meeting took the form of a discussion of "Large Gas Power Plants," introduced by descriptions of their plants and relations of their experiences with them by F. A. Maccomb, superintendent of furnaces of the Edgar Thomson Steel Works; R. H. Stevens, mechanical engineer, Homestead Steel Works; A. N. Diehl, superintendent of furnaces, Duquesne Steel Works, and A. L. Hoerr, steam and hydraulic engineer, National Tube Works. Most of the speakers thought that a pause, if not a reaction, had been reached in the rapid development of the large gas engine, and that, even in industries where gas is available as a byproduct, its economic application will be found more limited than has been thought, although H. K. J. Freyn ardently championed the internal-combustion motor and maintained that its present superiority would be emphasized by the increasing cost of fuel. The proceedings of the gas-power section and the discussion will appear in detail in an early issue.

There was also presented at this session a paper describing some of the recent work of the Bureau of Mines, by S. B. Flagg and C. D. Smith. This was illustrated by lantern slides, and described the experiments made with a long combustion chamber having a Murphy stoker at one end, and from which gases are withdrawn each 5 feet of its length for analysis. This furnace and the experiments upon it have been made the subject of a recent bulletin by the Bureau of Mines and will be treated further in an early issue. Reference was also made to experiments now in progress wherein a producer is run at such a high temperature that its capacity is very much increased and by the use of proper fluxes the ash and clinker are melted and drawn off continuously as slag. The temperatures necessary for the formation of liquid slag are very favorable for the production of producer gas and in the tests already made the CO has generally been above 30 per cent. while the CO_2 has been well under 2 per cent. These percentages were obtained, however, with air alone, no steam being used. Frequently 2000 to 2500 cubic feet of gas per square foot of fuel bed have been produced per hour having a heat value of about 115 B.t.u. per cubic foot, thus giving an output of approximately 25 horsepower per square foot of fuel-bed area, and no attempt has been made to operate the producer at its maximum rate.

The local committee had prepared a special pamphlet dealing with the important large gas-engine installations in the vicinity and containing illustrations of those at Carrie Furnaces, the Edgar Thomson Steel Works, the Duquesne Works, the Mesta Manufacturing Company, the Cambria Steel Works at Johnstown, and the National Tube Works, opportunities to visit which were open to the visitors.

The first paper considered Thursday morning was that of Prof. Reid T. Stewart upon "Stresses in Tubes." The author gave the results of some investigations tending to show that the stresses in the wall of a tube exposed to external fluid pressure are of the same character as those in a column having ends fixed in direction.

Using the experimental results obtained in some previous tests upon the collapsing pressures of commercial steel tubing, he derived equivalent column formulas upon the assumption that the circumferential stress in a tubular annulus subjected to external fluid pressure is theoretically the same as that in a straight column with fixed ends, whose length is one-half the mean circumference of the tubular annulus. These formulas are

$$[illegible] \quad (1)$$

$$[illegible] \quad (2)$$

where S is the axial load on the column in pounds per square inch, l the length of the column, and r the least radius of gyration of the section. Formula (1) is applicable only to cases where the ratio $\frac{l}{r}$ is less than 221 and formula (2) to cases where this ratio is greater than 221.

Next came "The Purchase of Coal," by D. T. Randall. This paper is presented in the columns following this report.

"Energy and Pressure Drop in Compound Steam Turbines," by Prof. F. E. Cardullo gives a graphic method of taking into account the transfer of heat which occurs from the higher to the lower stages by friction, eddy, etc., causing a departure from the condition of constant entropy ordinarily assumed. Professor Peabody submitted a table for the same purpose.

In the "Pressure-Temperature Relations of Saturated Steam," Prof. Lionel S. Marks explains the recent work of Holborn and Bauman and deduces a modification of the Van der Waal formula which expresses the pressure-temperature relations very satisfactorily from 32 degrees to the critical temperature. The values of the pressures derived from this equation have a maximum difference from the best experimental values of about one-tenth of 1 per cent. in the range from 212 to the critical temperature (706.1 degrees Fahrenheit). Below 212 degrees the maximum difference is 0.196 per cent. at 50 degrees corresponding to a pressure of 0.00035 pounds per square inch.

The formula is

$$\log. p = 10.515354 - 4873.71\ T^{-1} - 0.00405096\ T + 0.000001392964\ T^2.$$

"A Pressure Recording Indicator for Punching Machinery" was a description by Prof. G. C. Anthony, of the application of the steam-engine indicator to the punch, obtaining diagrams showing the variation of pressure during the stroke, the maximum pressure for which punches should be designed, the point of maximum stress in the punching of plates, the advantage to be derived from the use of shearing punches, the effect of clearance between punch and die, etc. The lower die rests upon a piston, the pressure of which is communicated to that of the indicator hydraulically. One of the discutants thought that the stress could be taken upon a spring beam which would weigh it more directly.

On Thursday afternoon a portion of the members visited the National Tube Company's works at McKeesport, while the rest were taken by boat up the Monongahela river, calling at McKeesport on the return trip for the others. This excursion proved to be a grateful interim in a rather strenuous program, affording at the same time an opportunity for physical rest and social intercourse.

On Thursday evening a reception and dance was given by the local members in the new ball room of the Hotel Schenley which was hurried to completion for this occasion.

The session of Friday morning, although designated upon the program as a "steel works session," developed considerable interest from the power standpoint through a debate upon the comparative merits of gas engines and turbines for blowing purposes which occurred in the discussion of R. H. Rice's paper upon the "Commercial Application of the Turbo-Compressor, and Reciprocating Blast Furnace Blowing Engines," by Professor W. Trinks. We shall have more to say of this in a subsequent issue. Mr. Rice's paper is presented in this issue.

The concluding paper of the meeting was by Bathold Gerdan, of Düsseldorf, Germany, and George Mesta, and was presented by Herr Gerdan in person. It dealt with steam-hydraulic forging presses of which he is the inventor and which are manufactured in America by the Mesta Machine Works.

On Friday afternoon the visitors had the option of a visit to the Duquesne works of the Carnegie Steel Company or a trip to the Mesta Machine Company's works at West Homestead, both of which excursions were well attended.

A new feature in an American Society of Mechanical Engineers' program was a smoker, given in honor of the visiting societies by the Engineers Society of Western Pennsylvania in the Union Club. George H. Neilson, the orator of the evening, found no difficulty in making light of the rather heavy subject of crucible steel, and numerous speakers, including a local monologuist, together with an excellent quartet, brought out the funny side of engineers and engineering, and wrought the audience up to a condition of good fellowship which made an effective closure of the week's program.

Too much cannot be said of the work of the local committee. Every facility was placed at the command of the visitors for access to the many industrial and engineering attractions of which Pittsburg is the center, and every attention paid to their comfort and convenience. The ladies were kept busy with special receptions, luncheons, drives and visits, and for each of the principal trips an illustrated pamphlet had been prepared with details of the program for that event and descriptions of the principal things to be seen.

Although the selection requires conformation by the council, the expression in favor of Cleveland as the place for the next spring meeting was so unanimous that it is practically certain that the next year's meeting will be held in the "Forest City."

The total output of all the air-compressor plants employed on the Panama Canal work during the year ending June 30, 1910, was 7,227,203,513 cubic feet of free air and the average cost was 4.03 cents per 1000 cubic feet.

The Purchase of Coal*

By D. T. Randall

Large savings may be made in the boiler room along two distinct lines: First, by burning the fuel at the highest practicable efficiency; and, second, by choosing fuel of a character suited to the plant conditions.

The coals of the United States vary widely in character, some being high in fixed carbon and low in moisture, volatile matter and ash, while others are low in fixed carbon and high in other constituents. An analysis reported "as received" represents the composition of the coal just as it is delivered at the laboratory. An analysis reported on the "dry basis" represents the composition of the coal after having been dried for one hour at 105 degrees Centigrade in a special oven. Moisture is an inherent constituent of the coal and an increase in its percentage decreases the heating capacity of a given coal proportionately. This constituent is weighed and paid for on an equal basis with the combustible portion of the coal, and therefore its determination is of importance in ascertaining the value of coal.

The ash in coal is, like moisture, an inert constituent. It may be distributed in small particles in such a way as to make separation from the coal impossible, or some of it may be present in larger pieces, owing to carelessness in mining and preparation. An increased percentage of ash decreases the heating value proportionately and causes additional expense and loss in efficiency due to extra labor required to handle it. The fusibility of the ash governs the amount of clinker that will be formed and consequently some attention should be given to this feature.

The B.t.u. or heating value of coal determines its value as a fuel. When coals of the same character are under consideration the heating value may be taken into account as a correct measure of the value of the coal, but when coals of different character are to be compared, the character of the coal as well as the heating value must be considered.

There is often considerable variation in the quality of coals from the same district; this is due principally to impurities. On account of economy in mining and in marketing coal, it is common practice for one company to operate a number of mines and to ship coal from all of these mines to its customers. It is only rarely that coal is equally good in all the mines and, therefore, the customer will receive some good coal and some inferior coal.

The influence of volatile matter upon the efficiency depends on the design of the furnace. With a poor furnace and indifferent firing, coals containing about

*Abstract of paper read before the American Society of Mechanical Engineers.

18 per cent. volatile matter may give results 10 or 12 per cent. higher than coals containing 30 per cent. or more volatile matter. With furnaces adapted to the kind of coal burned, however, there is little loss of combustible gas.

The size of coal is important in many cases. If it does not coke and is fine, there may be considerable leakage through the grates when burned on stokers with inclined grates or on hand-fired grates at rates that require frequent breaking up of the fuel bed. The size of the coal also affects the economy with which it may be fired. If the coal is too large, more air is admitted than is necessary, and if the fuel bed cannot be increased in thickness to overcome this difficulty, there will be a loss of heat. If the coal is fine and the draft is very strong, some of it will be carried off the grate before it is completely burned. Fine coal which cakes and forms a porous coke may be burned with good efficiency. If the coal does not coke but packs closely on the fuel bed, it is difficult, if not impossible, to secure a uniform air supply at all parts of the bed and the combustion is poor, owing to an excess of air at some points and a lack of air at others.

Fuels considered without reference to any particular equipment may be valued on the basis of their available heating value. It has been found possible to design furnaces to burn almost any fuel with reasonably good efficiency when based upon the available heat of the fuel. This has been accomplished with tan bark, sawdust, lignite and low-grade coals. As a rule, inferior coals can be bought much more cheaply on their heating value than the higher grades of coal and it is to the interest of every consumer to select the coal which will give the greatest amount of heat for a unit cost, provided it can be burned successfully. In many cases it will be profitable to change the equipment so as to burn slack or coals which are below the average quality. It is fully as important to take into account the size and character of coal when automatic stokers are used as when the coal is hand fired.

The methods employed in burning coal are of equal importance with the quality and should be given careful attention. The coal dealer should not be held responsible for results in boiler plants except as influenced by changes in the quality of the coal delivered.

The manner in which a sample of coal is obtained is fully as important as the manner in which it shall be analyzed. It is only fair to both parties concerned that the sample should be obtained in the manner which will secure a small portion which is thoroughly representative of the entire lot.*

Selection of Coal

The problem of purchasing a supply of fuel for any given plant, so as to obtain coal that is suitable for the equipment in use and one that will deliver the greatest amount of heat to the boiler for each dollar expended, is one which requires experience and an intimate knowledge of the various kinds of equipment for burning coal, and also of the different characteristics of the coals available at reasonable freight rates. The following information should be considered by the engineer in deciding on the best coal for a plant:

a Kind and size of boilers and furnaces;

b Load conditions, average and maximum loads;

c Draft available and how controlled;

d Character of the coals offered or available;

- (1) Moisture and its effect on the weight of combustible matter delivered;
- (2) Volatile matter and its relation to kind of furnace;
- (3) The amount of ash, its fusibility and tendency to clinker;
- (4) The amount of sulphur and how combined;
- (5) Heating value in B.t.u.;
- (6) Coking qualities of the coal;

e Size of the coal;

- (1) Relation of the size of coal to the equipment.

Specifications for Coal

After it has been decided what kind of coals may be burned successfully in any given plant, it is important that the specifications be so drawn that it will be to the interest of the dealer to deliver the kind of coal which has been established as standard in his proposal and prevent the substitution of lower grades which might be difficult to burn with good results. It is evident that specifications based on the heating value alone will not do this and that there should be some clause making it possible to reject the coal, or to burn it and pay for it at a reduced price if the coal should fall below the requirements.

There has been much said for and against purchasing coal on a guaranteed analysis and, as is often the case, both sides are right but they are really discussing different things. A properly drawn specification protects the dealer who is prepared to furnish good coal in competition with dealers handling inferior coals at the same price. Where these specifications require the coal contractor to state the analysis of his coal which on acceptance of the bid becomes the standard for the contract, there need be but little variation in the price if the dealer is familiar with the analyses of the coal offered, and if the standard is based on average values the premiums and penalties for the year should practically balance each other. Many dealers have bid on impossible analyses and then blamed the specification plan for their losses.

A properly drawn specification providing for premiums for better coal than that specified, encourages the coal operators to exercise greater care in mining and in picking the coal before shipping, and enables them to secure a return on the cost of such preparation. Most consumers have found that it is not profitable to pay freight on an unnecessary amount of slate and ash in the coal.

The important items in a specification are as follows:

- *a* The amount and character of the coal desired;
- *b* Conditions for delivering the coal;
- *c* A statement regarding the disposition which will be made of the coal if it is outside the limits specified;
- *d* The corrections in price for variations in heating value, ash and sulphur, provided it is advisable to limit the percentages of ash and sulphur in the coal to be delivered;
- *e* A blank form on which the dealer may submit the price and the kind and quality of coal which he proposes to furnish.

This method of purchasing coal has already been adopted by many of the larger and more progressive consumers of coal. Its advantages are so clearly demonstrated to engineers thoroughly experienced in power-house practice that few who are in a position to purchase large quantities of coal are willing to do so without a guarantee as to the quality. With information as to the coal bed, the district and the mine from which the coal will be furnished and the guaranteed analysis, an experienced engineer can make a suitable selection of coal.

A contract based on a guaranteed analysis provides for a definite procedure in settling for variations in the quality of the coal delivered and avoids the necessity of devoting much time to personal arguments and correspondence regarding poor coal. If both the consumer and the seller are familiar with the technical points involved in the sale of coal on a guaranteed analysis, it will prove a fair method by which the purchaser pays according to the value of the coal delivered to him, and the dealer is reimbursed for any expense due to better preparation of the coal.

Th' other day I took a walk out near th' dynamo room an' knocked a bottle of belt dressin' offen th' gallery. It must have hit my pipe but I didn't notice it then. When I got back t' th' engine room I could smell it [illegible] all over th' place, but I couldn't find it an' began t' get scared. [illegible] got up [illegible] an' I knew [illegible] what th' trouble was.

---

*Mr. Randall cited a method of obtaining a sample identical with that published in the May 23 issue of Power.

Commercial Application of the Turbine Turbo-Compressor*

By Richard H. Rice

The General Electric Company recently put in operation at the Oxford Furnace, N. J., plant of the Empire Iron and Steel Company, a turbine-driven air compressor for blowing the blast furnace.

The unit consists of a six-stage compressor operating at a normal speed of 1650 revolutions per minute and driven by a direct-connected four-stage Curtis steam turbine. The design is such that this normal speed produces a blast pressure of 15 pounds per square inch. The unit, however, is designed to regulate the volume of air delivered per minute so as to keep the rate of discharge constant at any value, determined by the furnace superintendent, within its capacity. The construction of this unit, as well as the method of regulation, was given attention in a description of the plant which appeared in the March 7, 1911, issue of Power so that the operation of the unit will be considered only.

Both turbine and compressor attain their best efficiency under similar conditions as regards rotating speed, making the combination a logical and efficient one. Under conditions usually met with in blast-furnace operation involving pressures of blast of 10 to 20 pounds per square inch, the efficiency remains sensibly the same. A curve of efficiency at varying volumes is shown in Fig. 1 and above this has been drawn a curve of speeds and pressures which, taken in connection with the first named curve, shows the variations of efficiency with pressure, at rated volume.

This latter curve shows graphically the variation of pressure with change of speed, which follows the law of squares; that is, doubling the speed gives four times the pressure, etc., from which it will be seen that only moderate changes in speed are necessary to give considerable changes in pressure. It is these changes in speed, increasing or decreasing the blast pressure, which are utilized to maintain a constant rate of flow of air into the furnace, against the varying resistances set up in the tuyeres and furnace by varying furnace conditions; as, for instance, clogging of tuyeres and changes in the size and composition of the charge, temperatures, etc.

The means by which these changes of speed are produced in the manner necessary to keep up a constant rate of influx of air per minute was fully described in the previous article.

At the time this blowing unit was put in operation, it was not expected that the volume of air required by the furnace would be at such a low figure as turned out to be the case, the machine having been designed for a normal volume of 22,500 cubic feet per minute. On putting the machine on the furnace, it was found the volume required was only about 15,000 cubic feet per minute and the pressure corresponding to this volume under furnace conditions ranged from 10 to 12 pounds. Under these conditions, it was found that pulsations were met with in the pressure

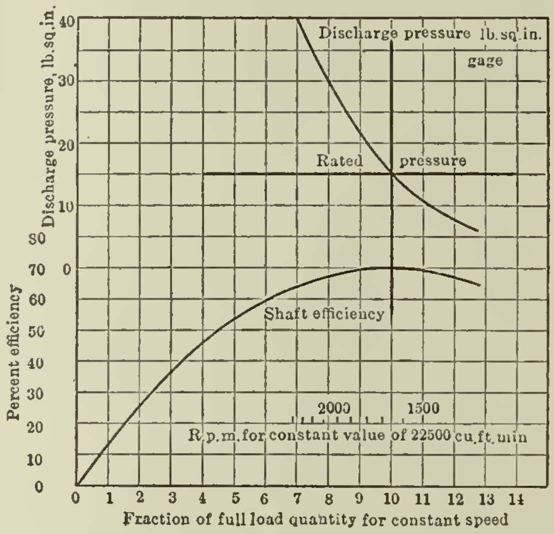


Fig. 1. Efficiency and Pressure Curve with Constant-volume Governor

line, this pressure fluctuating about 2 pounds, and in order to overcome this pulsation it was found necessary to throttle the inlet opening. Since this time, a convenient butterfly valve-throttling mechanism has been designed and applied, which is found to eliminate these pulsations without appreciable loss of efficiency.

The pulsations in pressure above noted are an inherent characteristic of all centrifugal blowing apparatus of similar construction, and they occur when the apparatus is operated at loads and pressures widely differing from those for which the apparatus is designed; that is, from normal full volume and pressure. At any given volume they occur at a certain critical pressure and at all higher pressures, but do not occur at lower pressures than the critical. As volume is increased, critical pressure increases also. The critical pressure is slightly affected by the density and the humidity of the air.

Fig. 2 gives the characteristic critical pressure-volume curve of this compressor.

Fig. 3 is the curve of pressure and volumes for this compressor at constant speed.

At the time this was written the blast pressure at Oxford Furnace varied from 10 to 14 pounds during the day with volume constant at 16,000 cubic feet per minute. The speed varied from 1500 to 1600 revolutions per minute. The average steam pressure was 135 pounds.

The figures in Table 1 are taken from a typical station log, showing the variation of pressure and volume during the 24-hour period of operation.

The apparatus used for blowing the furnace before putting this machine into operation consisted of two vertical reciprocating blowing engines built by the I. P. Morris Company, each of the following dimensions: Steam-cylinder diameter, 54 inches; blowing-cylinder diameter, 72 inches; stroke, 72 inches. Blowing-cylinder displacement, 339 cubic feet per revolution each. Maximum speed rating, 30 revolutions per minute each, giving 20,300 cubic feet per minute total displacement. Actual maximum speed, 23 revolutions per minute each, giving 15,000 cubic feet per minute total displacement. The average blast pressure was 8 pounds.

Judging from the revolutions of this engine, it was thought that the volume used was about 14,500 cubic feet. On putting the centrifugal compressor into action, an immediate increase in the

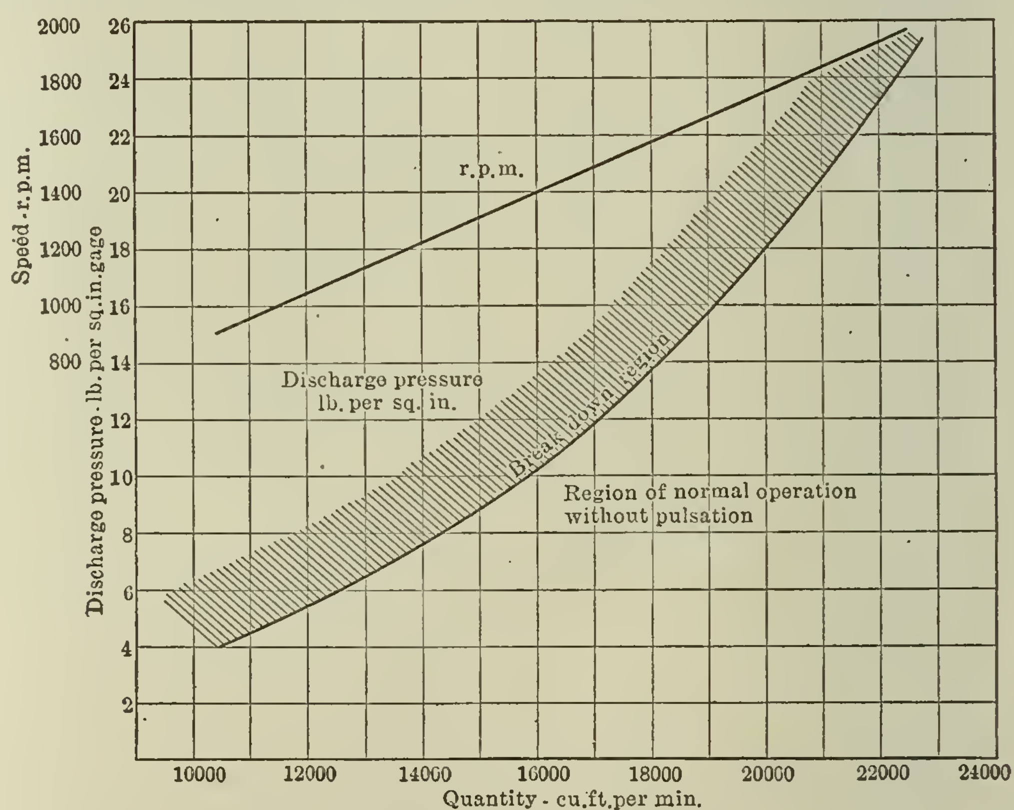

Fig. 2. Curve of Breakdown Points from Factory Tests

*Abstract of paper presented before the American Society of Mechanical Engineers.

amount of iron melted by the furnace was experienced. The output went up from an average of 139 tons per 24 hours in February, 1910, to 176 tons in April, 1910, and the iron was found to be of a more uniform character and the operation of the furnace was improved. A gradual increase in the amount of air has since taken place and the corresponding increase in pressure required to force the air through the furnace has been necessary as was to be expected. This increase of air has resulted in an increase in the production of the furnace from 176 tons on starting to the present average of about 190 tons. The machine is now operating with 16,000 cubic feet of air and the production of ore is 185 tons per 24 hours average. It is proposed to continue this increase to 200 tons per 24 hours, the limit of the charging apparatus.

The dimensions of the furnace are as follows: Diameter at bosh, 17 feet 6 inches; at hearth, 11 feet; at top throat, 12 feet; hight from hearth to dumping ring, 80 feet.

The condensing apparatus is of the barometric type. This was described, however, in the March 7 number.

Made [illegible] tons of iron in 24 hours.

Owing to the fact that the condensing apparatus is of the barometric type, the further fact that the machine is operating far below its designed capacity and the difficulties involved in making an accurate boiler test to determine the amount of feed water under present conditions, no tests have been made to determine the actual efficiency of the machine. It is, however, furnishing considerably more air than the old machines, as is evidenced by the greatly increased product of the furnace, and is at the same time operating with fewer boilers. Also these boilers are more easily worked than when operating with the engine.

There is great difficulty in making comparisons of the performance of this type of blowing unit with reciprocating types, either steam or gas driven, owing to the absence of actual test figures, since none have been published which permit of accurate and satisfactory comparison. With the results which have been obtained from all sources as to the actual performance of such machines and from actual experience with this machine and its sister machine installed at the Northern Iron Company, in line with tests which have been made in the factory, it seems that the following conclusions are correct in reference to this apparatus as compared with reciprocating engines for blowing blast furnaces:

That the output of the furnace is increased on account of the greater steadiness of operation and more uniform conditions obtaining in the furnace.

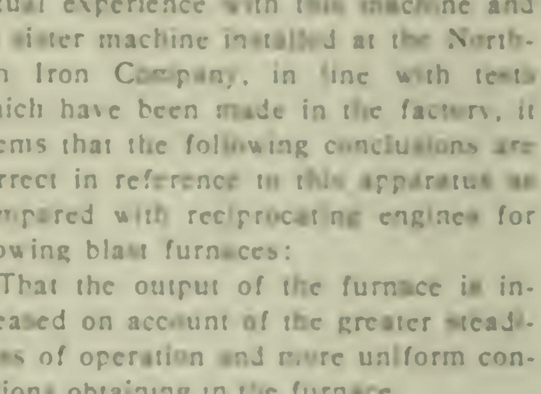

Fig. 3. Factory Test, Showing Pressure Plotted against Quantity of Air

That the quality of the product is improved.

That the steam consumption is equal to, or less than, that of the best compound engines blowing similar furnaces.

That the engine-room space occupied is only a fraction of that needed by reciprocating engines, either steam or gas.

Considering all factors, including consumption of fuel; cost of operation, including oil and supplies, attendance, etc.; cost of buildings and foundations, interest on the investment, and cost of maintenance of plant; that the centrifugal compressor is a blowing apparatus which can be operated for a lower net cost than any other means of blowing furnaces.

A power-transmission plant is being erected at Lauchhammer, Germany, designed to generate current for transmission at a pressure of 110,000 volts, which is stated to be the highest voltage used for power transmission in Europe. The current transmitted is three-phase; the generator pressure is 5000 volts, which is transformed up to the transmission voltage by four transformers, each of 5000 kilowatts capacity.

Milwaukee's License Law

That persistent agitation on the part of progressive engineers in all parts of the country for the enactment of license laws and ordinances is not fruitless is proved by the action of the Common Council of Milwaukee, Wis., which recently passed an ordinance making it unlawful for an unlicensed person to have charge of any portion of any steam-power plant exceeding 10 horsepower except locomotives, engines and boilers in the civil service of the city, State or Federal Government and boilers used for heating in which the pressure is less than 15 pounds per square inch.

It is provided that the mayor shall appoint a chief examiner who may select an assistant, the two constituting a board of examiners all of the time of which shall be spent in examining applicants for license, inspecting boilers and engines and in discharge of such other duties as may be prescribed by the ordinance.

To be eligible for examination an applicant must be 21 years of age; of good moral character; temperate habits; be vouched for in writing by two citizens of Milwaukee and have had not less than two years' experience as a machinist, oiler or fireman in the construction or operation of steam engines or boilers.

Licenses are of three grades and are based on a rating of 12 square feet of heating surface per boiler horsepower. First-class licenses are unlimited as to horsepower; second-class licenses permit the operation of plants up to a capacity of 300 horsepower, while the holder of a third-class license is limited to the operation of 75 horsepower. But one engineer may act as assistant to another holding the next higher grade of license. Special licenses without examination may be issued to engineers operating the plants in which they are employed provided that they have been in charge for the six months next prior to the passing of the ordinance. Transfers of special licenses from one plant to another may be made at the discretion of the board.

All engines, boilers and auxiliary apparatus are directly under the jurisdiction of the board, are subject to periodical inspection, whether insured or not, and all engineers are required to notify the board of any defect in any and every detail. Appeal may be taken from any decision made by the board to a board of arbitration [illegible] whose shall consist of three practical engineers of at least 10 years' experience.

Provision is made for the operation of steam plants by unlicensed men in cases of emergency and many details are left to the discretion of the board of examiners. When not engaged in the actual work of inspection, the board will hold daily sessions from 8 a.m. to 10 a.m. for the purpose of examining applicants for license.

It was the intention of the Common Council to give the city a rational license and inspection ordinance which, administered in the spirit if not in the exact letter, will benefit the engineer, the owner and the public by eliminating the incompetent engine runner and the unsafe boiler.

In one particular the board of examiners is allowed no discretion. It is mandatory that the board see that each and every boiler plant in the city is at all times during its operation in charge of a duly licensed engineer.

Ohio Board of Boiler Rules

Following the example set by Massachusetts the legislature of Ohio has passed a bill creating a Board of Boiler Rules, consisting of the chief examiner of steam engineers, as chairman, and four members appointed by the governor. Of these four it is intended that one shall be an employee of the boiler-using interests, one from the boilermaking interests, one from the boiler-insurance interests and one an operating engineer, but the governor may at his discretion make these four appointments from any class of citizens.

With the exception of boilers of railroad locomotives, portable boilers used in pumping, heating, steaming and drilling in the open field, for water, gas and oil, and portable boilers used for agricultural purposes, and in construction of and repairs to public roads, railroads and bridges, boilers on automobiles, boilers of steam fire engines brought into the State for temporary use in time of emergency, boilers carrying pressures of less than 15 pounds per square inch, which are equipped with safety devices approved by the Board of Boiler Rules and boilers under the jurisdiction of the United States, all boilers in operation in the State must be inspected at intervals not exceeding one year.

Rules for the construction, installation, inspection and operation of boilers, for ascertaining the safe working pressure, for the construction and sizes of safety valves, locations for fusible plugs, and other appurtenances are to be formulated by the board.

Public hearings on complaints, recommendations and for the examinations of inspectors will be held quarterly and at such other times as may be necessary. Changes in the rules may be made after any hearing, such changes being subject to a further hearing which shall have been duly advertised. All changes in the rules which affect the construction of boilers become operative six months after being approved by the governor.

Boilers of special design may be installed by permission of the board if after an examination of the drawings and specifications such boilers are deemed safe. The chief examiner of steam engineers is *ex-officio* chief inspector of steam boilers and is authorized to appoint, with the approval of the governor, an assistant inspector and ten general inspectors for service in the different districts into which the State is divided. He may also appoint as special inspectors employees of any company authorized to conduct boiler insurance and inspection business in the State, provided such employees have passed the examination required by the Board of Boiler Rules.

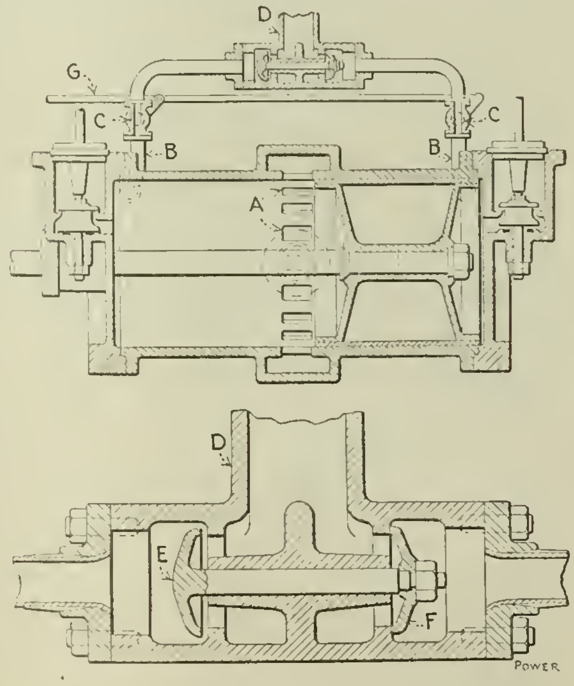
By a system of fees for boiler inspections and for the examinations of applicants for certificates of general boiler inspectors the department will be partially self-supporting.

Punishment by fine or imprisonment or both for the violation of any of the rules of the board by the owner, user or operator of boilers is provided for in the bill which makes the rules of the board operative on January 1, 1912.

In creating the Board of Boiler Rules the legislature of Ohio has closely followed the Massachusetts precedent and it is confidently expected that the same salutary effects will result that have obtained in the latter State in the elevation of the standard in boilermaking.

Stumpf Auxiliary Exhaust Port

In the operation of the uni-directional-flow steam engine of Prof. Johann Stumpf it has been found that the compression at starting and during overload periods is sometimes excessive and to remedy the effect of which an auxiliary exhaust valve has been designed.



Stumpf Auxiliary Exhaust Valve

To each end of the cylinder there is attached a pipe *B* leading to the valve box *D* and controlled by a cock *C*. In the valve box there are two valves, *E* and *F*, mounted on a common spindle.

Under ordinary working conditions the cocks *C C* are closed, but if for any reason it is desired to reduce the compression they may be opened by means of the rod *G*.

With the cocks open and the piston traveling toward the left, steam will be admitted to the valve box and the pressure will close the valve *F* and open *E*. This allows the steam to escape until the compression is high enough to close it or until admission takes place and it is closed by the pressure of steam from the boiler. When the other valve opens the process is repeated at the other end.

PERSONAL

H. J. K. Freyn has resigned his position with the Illinois Steel Company to take charge of the gas-engine department of the Allis-Chalmers Company.

Tom Oakes, who has been identified with the valve interests for the past thirty years, is now connected with the New York office of the Nelson Valve Company.

Reinhard Kunz, who is well and favorably known among the engineers of Wisconsin, has been appointed by the mayor as chief of the board of examiners of engineers for the city of Milwaukee.

SOCIETY NOTES

The Engineers Blue Club of Jersey City will hold its annual outing at Eitners park, Staten Island, on July 9.

On May 26, the American Institute of Steam Boiler Inspectors held a meeting at the United Engineering Societies building in New York City. The major part of the evening was devoted to mechanical topics. J. S. Lane, of the Engineer Company, read a paper on "Combustion and Balanced Draft," which was followed by a lively discussion. F. L. Johnson spoke forcibly on the value of thorough inspections to the engineer in particular and to the public generally. James Winters read a paper on the physical and mental qualifications required to make a successful inspector and pointed out that this field was no place for weaklings. The next meeting of the society will be held at the same place on the last Friday of September, when the regular monthly meetings will begin and be continued throughout the season.

That there is considerable water power in Iceland is denoted by the following announcement: Two English experts have recently visited Iceland in order to survey the large Dettifoss fall, on the river Iökulsa, which is calculated to have a capacity of 60,000 horsepower. Another less known fall, the Vigaberg fall, is estimated to have a capacity of 50,000 horsepower.

New Jersey State N. A. S. E. Convention

The twentieth annual convention of the New Jersey State Association of the National Association of Stationary Engineers took place at Newark, May 2, 3 and 4. There was an exceptionally large attendance of delegates, and at the many sessions considerable important business was transacted. The meetings were all held in the new auditorium.

On Friday at twelve o'clock the exhibition hall in the new auditorium was opened with a short address by Mayor Jacob Haussling. He welcomed the engineers and their guests to Newark and congratulated the convention upon the splendid exhibit of the supplymen. More than seventy booths occupied the main hall, which was neatly decorated, and the display was by far the largest in the history of the New Jersey State Association.

The first session of the delegates was called to order on Friday afternoon, at half past two, by Past State President J. C. Savage, who welcomed the delegates and their friends to the city. Mr. Savage then introduced Harry D. Cozens, one of the organizers of the national association and its first national president, who spoke interestingly of his past experience in the National Association of Stationary Engineers, and concluded his remarks by congratulating the New Jersey State Association upon its progress. It was in the engine room of Mr. Cozens, in the court house at Providence, R. I., in the year 1879, that the National Association of Stationary Engineers was organized. He is now chief engineer of the court house at Newark, N. J. After the appointment of the necessary committees, the several reports were read and adopted, the secretary's report showing the organization to be in a healthy financial condition.

Exhibit Hall at New Jersey State Convention

On Friday evening a most enjoyable entertainment was given in the exhibition hall, in which the "Bunch" participated. The program was arranged by Frank Martin.

On Saturday evening a banquet was given at the Continental hotel, which was largely attended by the ladies. F. L. Johnson officiated as toastmaster and introduced the following gentlemen, who made brief and instructive addresses: John H. Donnelly, president of the common council; W. J. Reynolds, past national president; Edward H. Kearney, national vice-president; E. W. Sears, State president; Assemblyman Michael J. McGowan; Joseph F. Carney, past national president; A. L. Case, State deputy; John J. Callahan, past State president. The speeches were interspersed with vocal and instrumental music.

At the Sunday morning session the delegates listened to an able address by National Vice-President Edward H. Kearney, after which the officers for the ensuing year were elected as follows: Edward W. Sears, Newark No. 3, past president; William Krouse, Passaic No. 11, president; Martin J. Hickey, Jersey No. 1, vice-president; Charles Sievers, Hoboken No. 5, treasurer; Thomas A. Brown, Newark No. 3, secretary; Thomas J. MacMeran, Paterson No. 2, doorkeeper; Thomas Heath, Elizabeth No. 14, conductor; A. L. Case, Plainfield No. 12, chairman of license committee.

The New Jersey Delegation to the State Convention

Newark was again chosen as the place for holding the next annual meeting.

The following firms had exhibits:

Acheson Graphite Company, American Steam Gauge and Valve Manufacturing Company, V. D. Anderson Company, Ashton Valve Company, Cling-Surface Company, Couse & Bolten, Crandall Packing Company, James W. Crane, Crane Company, Cryer Return Line System Company, M. T. Davidson Company, Dearborn Drug and Chemical Works, R. & J. Dick, Dixon Cascade Pump Company, Engineers Blue Club of Jersey City, Garlock Packing Company; Greene, Tweed & Co., Greenpoint Fire Brick Manufacturing Company, Griscom-Spencer Company, Hampson & Marks (American Engine Company), Harrison Safety Boiler Works, Hewes & Phillips Iron Works, Home Rubber Company, Homestead Valve Manufacturing Company, Iron Works Company, Jefferson Union Company, Jenkins Brothers, The Henry Johnson Company, E. Keeler Company, Kennedy Valve Manufacturing Company, Keystone Lubricating Company, Lagonda Manufacturing Company, Jacob Levi Company, Lippincott Steam Specialty and Supply Company, Ludlow & Squier, Lunkenheimer Company, McLeod & Henry Company, W. B. McVicker Company, Macknet & Doremus Company, Morehead Manufacturing Company, Mutual Supply Company, Nathan Manufacturing Company, National Oil and Supply Company, Nelson Valve Company, Newark Brush and Scraper Company, New York Lubricating Oil Company, New York Belting and Packing Company, Norben Oil and Supply Company, Ohio Blower Company, Otis Elevator Company, Peerless Rubber Manufacturing Company, Philadelphia Grease Manufacturing Company, William S. Pitts Company, William Powell Company, POWER, Clement Restein Company, John A. Roebling's Sons Company, David C. Seymour, W. S. Sheppard, Simmons Pipe Bending Works, Millard F. Smith, C. E. Squires Company, Standard Oil Company, Standard Regulator Company, Strong, Carlisle & Hammond Company, Under-Feed Stoker Company of America, H. B. Underwood & Co., C. Yingling & Son.

Kentucky State N. A. S. E. Convention

After opening the ninth annual convention of the Kentucky State National Association of Stationary Engineers with prayer by the Rev. J. H. Young, C. E. Fertig, chairman of the convention committee, introduced Mayor W. O. Head, of Louisville, who delivered a warm address of welcome. Frederick L. Ray, State president, followed with the president's annual address, after which R. W. Brown, secretary of the Louisville Convention and Publicity League, spoke, his subject being "Our City." He enlarged upon the beauties and advantages of Louisville as a commercial, residence and convention center and greatly impressed the visitors with the hospitable words of welcome so characteristic of the native Kentuckian. Response was made by Osborn Monnett, of POWER.

F. W. Raven, national secretary, then spoke on "Our Order," outlining its aims and purposes and explaining to the mayor and visitors the high ideals which actuate the association in all its affairs. At the close of the morning session, W. L. Osborne, of Chicago, formally opened the exhibit with a few words of greeting to the delegates.

GROUP OF KENTUCKY ENGINEERS AT THE N. A. S. E. STATE CONVENTION

Owensboro was chosen as the place of next meeting, the new officers being as follows: John H. Oelze, of Owensboro, president; J. L. Shrode, of Hopkinsville, vice-president; J. L. Harpole, of Hopkinsville, secretary; Edward Kockenrath, of Louisville, treasurer; C. Carroll, of Louisville, conductor, and William Cummings, of Henderson, doorkeeper.

A smoker, tendered by the Central States Exhibitors' Association, was a social feature of the meeting, while on Saturday afternoon, after lunch at the Willard hotel, as guests of the Louisville Convention and Publicity League, the delegates and visitors were taken for an automobile ride, visiting the Louisville Lighting Company, the Louisville Railway Company power house and Cherokee park, this also being through the courtesy of the public-spirited citizens.

The meeting came to a close with the annual moonlight excursion on the Ohio river, given by Louisville National Association of Stationary Engineers association No. 1, a special invitation being extended to the visitors.

Exhibitors at the convention were as follows: Ahrens & Ott, Louisville, Ky.; V. D. Anderson & Co., Cleveland, O.; Andrew Cowan & Co., Louisville, Ky.; James Clark, Jr., Electric Company, Louisville, Ky.; Crandall Packing Company, Palmyra, N. Y.; Dearborn Drug and Chemical Works, Chicago, Ill.; Garlock Packing Company, Palmyra, N. Y.; United States Graphite Company, Saginaw, Mich.; Greene, Tweed & Co., New York City; Hawk-Eye Compound Company, Chicago, Ill.; Hills-McCanna Company, Chicago, Ill.; Home Rubber Company, Trenton, N. J.; Jenkins Brothers, New York City; H. W. Johns-Manville Company, Milwaukee, Wis.; Kentucky Consumer's Oil Company, Louisville, Ky.; Laile Company, Louisville, Ky.; Lunkenheimer Company, Cincinnati, O.; Lyons Boiler Works, De Pere, Wis.; Moran Flexible Steam Joint Company, Louisville, Ky.; E. D. Morton & Co., Louisville, Ky.; *National Engineer*, Chicago, Ill.; National Smoke Prevention Company, Louisville, Ky.; W. H. Neil Company, Louisville, Ky.; Osborne High-Pressure Joint and Valve Company, Chicago, Ill.; William Powell Company, Cincinnati, O.; POWER, New York City; *Practical Engineer*, Chicago, Ill.; J. J. Reilly Manufacturing Company, Louisville, Ky.; Standard Oil Company, Louisville, Ky.; Sterling Boiler Compound Company, Louisville, Ky.; Charles C. Stoll Oil Company, Louisville, Ky.; Henry Vogt Machine Company, Louisville, Ky.; Wickes Boiler Company, Saginaw, Mich.

The installation of a large electric-power station at Vemark, in the province of Telemarken, Norway, was started during the early part of May, the Rjukanfos, or Foaming, falls supplying the power for the machinery. This fall, which is one of the magnificent sights of Norway, has been changed so that now there is a straight drop of about 400 feet, where previously the drop was 800 feet. By this means 145,000 horsepower was made available.

POWER

Vol. 33 NEW YORK, JUNE 20, 1911 No. 25

THE engineer is prone to think that after he has once established an operating routine in his plant nothing special remains to be done in the way of increasing economy. That if he keeps his plant in good commercial shape and the bills run along about on an average it is evident the original economy is being maintained. Record keeping is irksome and as long as the plant expenses are about the same, month in and month out, he is satisfied.

But if he would dig deeper into his local conditions, know more about factors which surround him, he would probably find that there are circumstances in connection with his case of which advantage could be taken for obtaining an increase in efficiency.

Perhaps two engines are carrying the load when one will do the work more efficiently; an air leak in the setting may offset all efforts toward economical combustion; scale may coat the boilers sufficiently to prevent rapid transmission of heat, and there may be several other possibilities reducing the over-all efficiency of the plant—but why continue?

Record keeping will show up the fifty-seven varieties of little wastes, will absolve the furnaces from the sin of gluttony, and allow them to enjoy a normal, healthy, coal appetite—in fact, it will show how much money is being saved and what improvements or changes in the arrangement of the plant have been responsible.

It is in making a detailed study of the operating conditions that the greatest advantage of complete operating data is seen. Without them, if a change is made, how can it be known except in a general way what the effect has been?

Knowing things in a general way in this day and age does not get a man much in the engineering line. He must have specific information to show what he is doing and with records available, advantageous changes are frequently indicated which otherwise would remain in obscurity.

In other columns of this number is told the story of how a large saving was made by the simple expedient of shutting down the air compressor which controlled the thermostatic valves on the radiators of an office building.

This was not in a new plant where the routine was just being arranged, but in a plant which had operated for years at excellent economy and where a system of record keeping is in vogue that for completeness of detail probably cannot be surpassed in this country.

The saving realized here came about through the desire to take advantage of every opportunity for decreasing the coal bill.

Naturally, the light-load period is the time when energy costs most per kilowatt-hour and concentration of thought on the light-load period proved most productive, while with the operating records available it was possible to show just what the conditions were before, just what they were afterward, and just how much money could be placed on the credit side of the ledger.

This is a sample of the keen commercial instinct, the reducing of technical affairs to the dollar and cents standpoint, which mark the difference between the stopper and starter and the real engineer.

Pennsylvania Terminal Service Plant

By A. D. Blake

A plant of over 2500 boiler horsepower supplying the new Pennsylvania railroad terminal in New York city with light, power, compressed air, refrigeration and heat through an indirect system. During periods of no heating demand, electricity is taken from the Long Island power house.

One of the most important problems connected with the layout of the new Pennsylvania terminal station in New York City, was that of supplying service power, light, heat, etc.

The main power plant for the entire system is located at Long Island City, where the facilities for handling coal and the abundant supply of condensing water make it possible to generate electricity at a minimum cost.

While it would have been feasible to have supplied the passenger station with power and light from this source, there were other factors which had to be considered. Refrigeration was required in connection with the restaurant service; compressed air was necessary for the switching equipment and for the ejection of sewage; a high-pressure water system for fire protection was desirable; and most important of all, was the necessity of providing an adequate heating system. These, together with several other features, proved to be governing factors; hence it was decided to build and equip a service plant to meet the needs of the great terminal. The building also contains one of the railway substations supplying motive power to the trains.

According to the general scheme adopted, electricity for service light and power is generated during the winter months by noncondensing turbo-generators, the exhaust from which, together with that from the air compressors, pumps and other auxiliaries, is used for heating the station. During the summer months, however, when there is no heating demand, or at times when the exhaust from the compressors and pumps is sufficient to meet the demand, the turbines are shut down and electricity is taken from one of the 60-cycle machines at the Long Island power house. This arrangement also serves to guard against the terminal being without light and power should anything happen to the machines at either plant.

The service plant is located on Thirty-first street, opposite the station, with which it is connected by underground passages. The building is of steel and brick, faced at the front with granite to match the exterior of the station. It extends four floors above the street and three below. The street level is occupied by the boilers, the railway rotary converters and transformers and the various switchboards. The first level below the street contains the pump room and the direct-current switches; the second level the turbo-generators, air compressors, hydraulic-elevator pumps, ice machine and ash conveyer; and in the basement are located the sewage ejectors, ventilating fans for the service plant, part of the coal-handling apparatus, the storage battery and the refuse destructor. There is also an intermediate gallery containing part of the switch and bus structure. The floors above the street level are occupied by the economizers, the coal-storage bin, offices and store rooms.

Fig. 1. Service Switchboard, Alarm Switchboard and Exciters

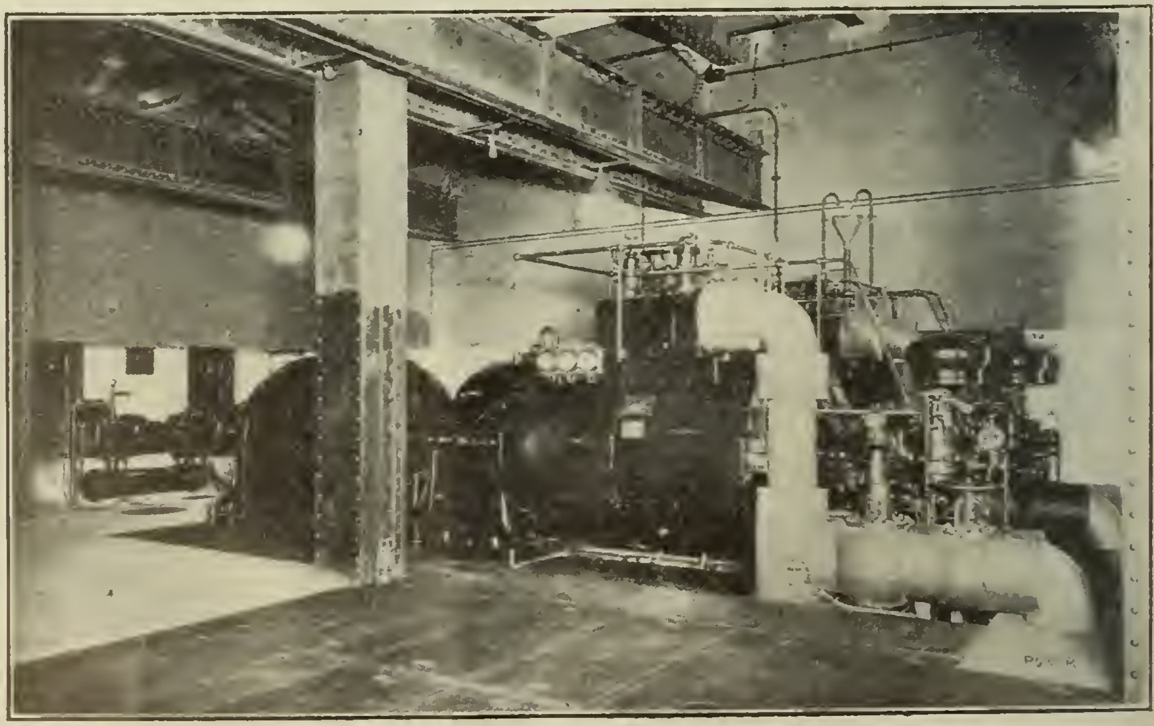

Fig. 2. Turbogenerators

Fig. 4 Direct-current Switchboard

Fig. 5. Main Heating and Circulating Pumps

Boiler Plant

Steam is furnished by five 525-horsepower Babcock & Wilcox boilers equipped with shaking grates and designed to carry a steam pressure of 200 pounds, although they are usually run at about 160 pounds. Space is provided for five additional boilers of the same size to be installed as the demand for steam increases. Owing to the plant being in the heart of the city and therefore subject to the smoke ordinance, it was found inexpedient to burn bituminous coal; hence No. 1 buckwheat coal was selected and hand firing employed.

A radial-brick stack, carried on steel framing, rises 50 feet above the roof and the supports were made strong enough to carry an additional 50 feet of stack should the erection of adjoining buildings make this necessary. At present the top of the stack is 127 feet above the grates and the natural draft is supplemented with forced draft furnished

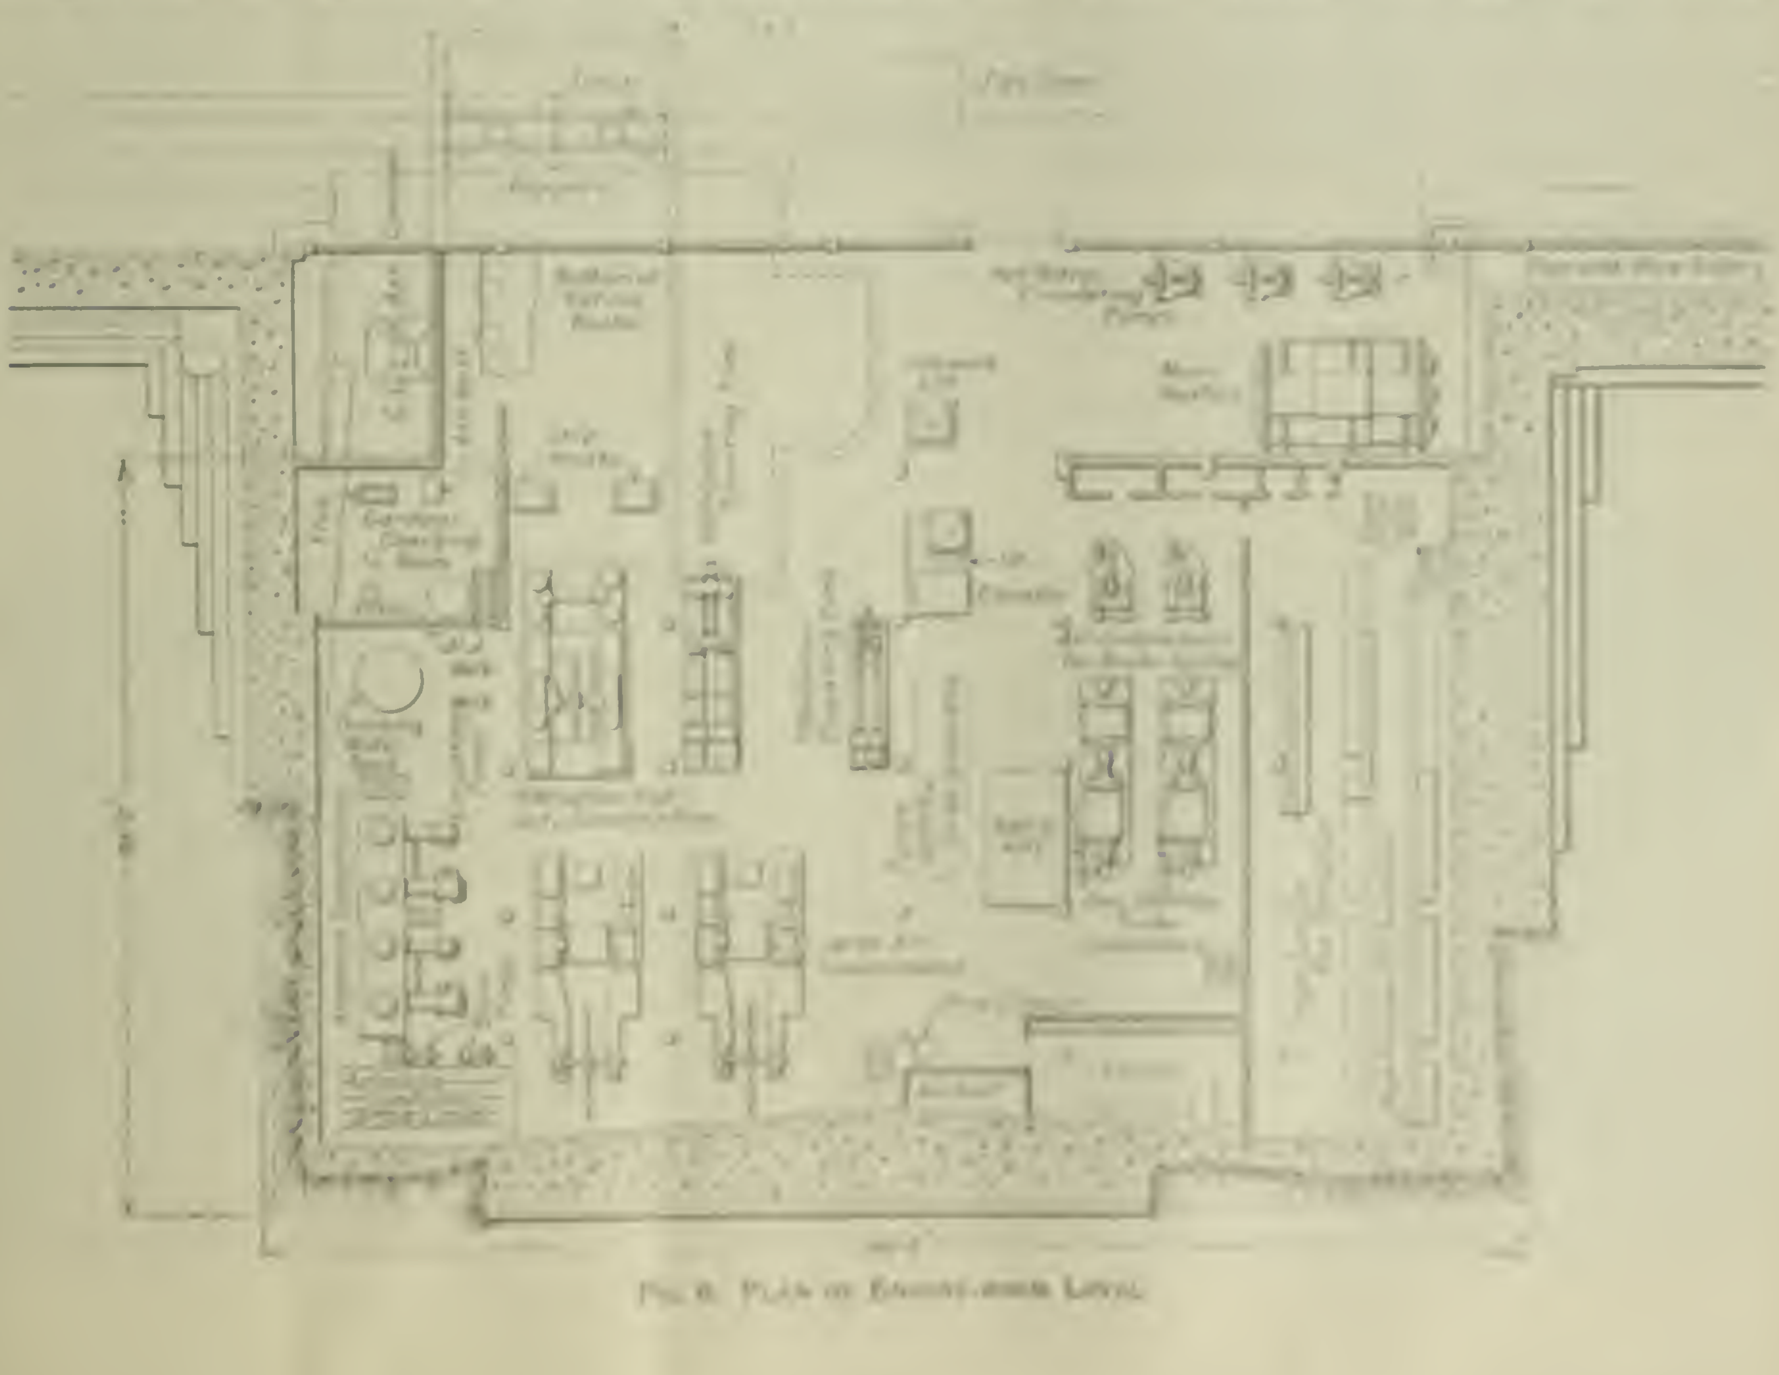

Fig. 6. Plan of Engine-room Level

by two Sirocco blowers direct connected to high-speed engines and capable of maintaining a pressure of 2½ inches of water in the ashpits.

The gases before reaching the stack pass through Green economizers, of which there are two, each containing 32 sections of 10 tubes.

The feed water is pumped from the hotwell to a feed-water storage tank of about 25,000 gallons capacity; from whence it is taken by the boiler-feed pumps and delivered to the feed-water heater, thence to the economizers where its temperature is raised to over 200 degrees Fahrenheit.

The heater is of the induction type and is located on a branch of the 18-inch line into which the auxiliaries exhaust.

The Holly system is employed to return the drips to the boilers.

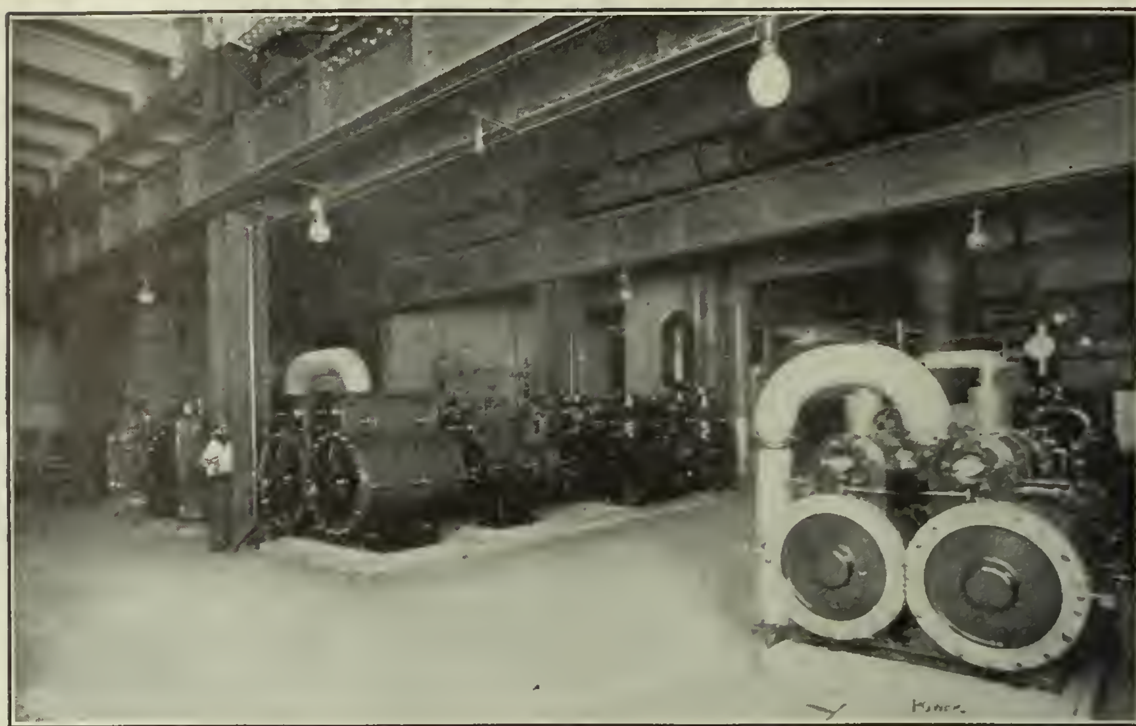

Fig. 7. Hydraulic Elevator Pumps

Coal and Ash Handling

Coal is brought to the service plant in cars over the Pennsylvania railroad and dumped from the track level, which is one level above the basement, into a hopper from which it is carried by a belt conveyer to two skip hoists. These lift the coal to the top of the building and discharge onto a motor-driven belt conveyer which distributes it along a storage bin of 1000 tons capacity located over the boilers. From here the coal is delivered through hoppers and automatic weighing scales to the floor in front of the boilers. A significant feature of the coal-handling apparatus is that, from the

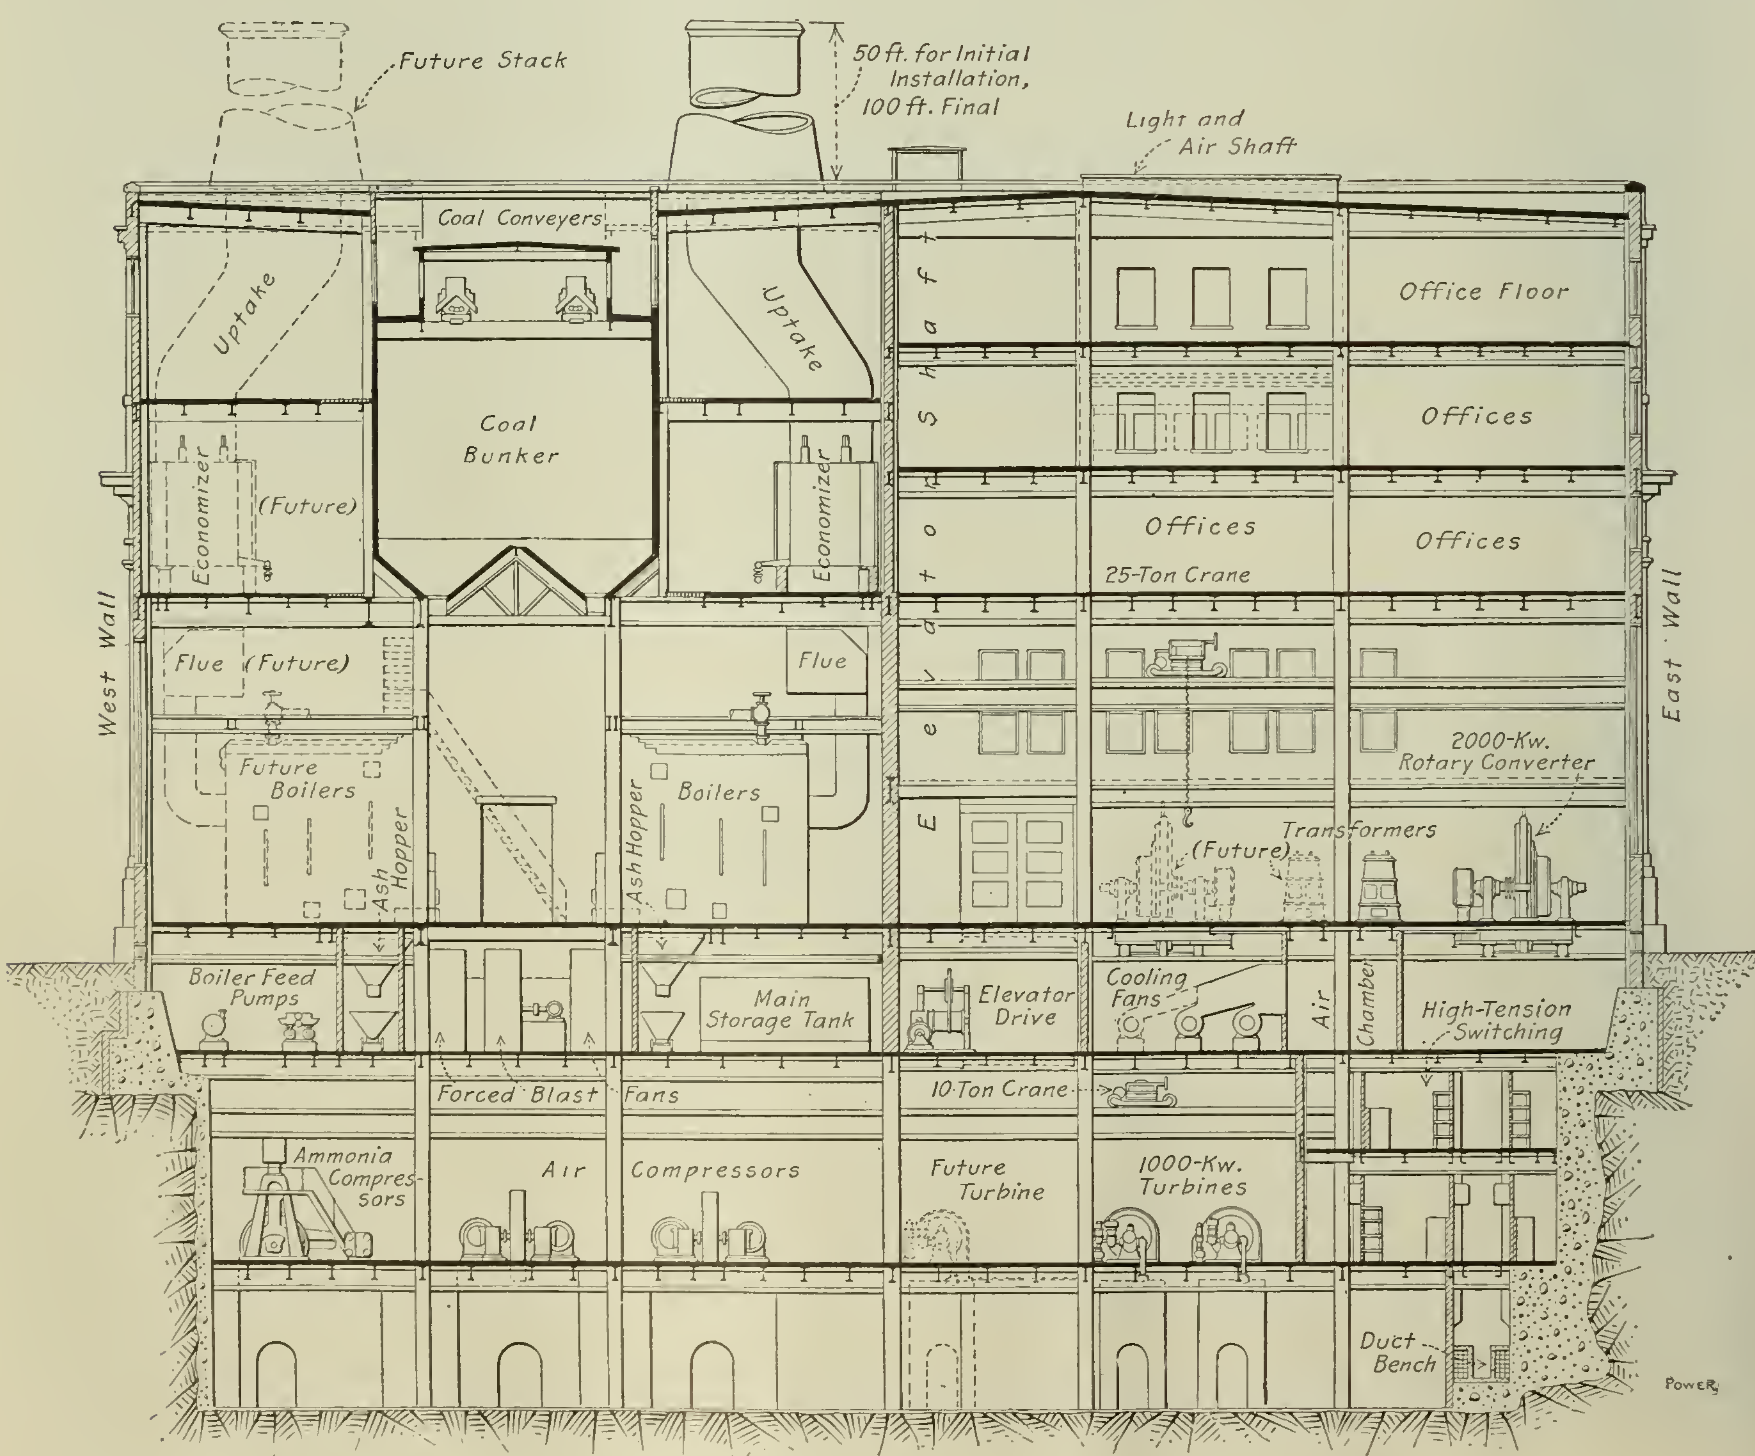

Fig. 8. Sectional Elevation Looking toward Front of Service Plant

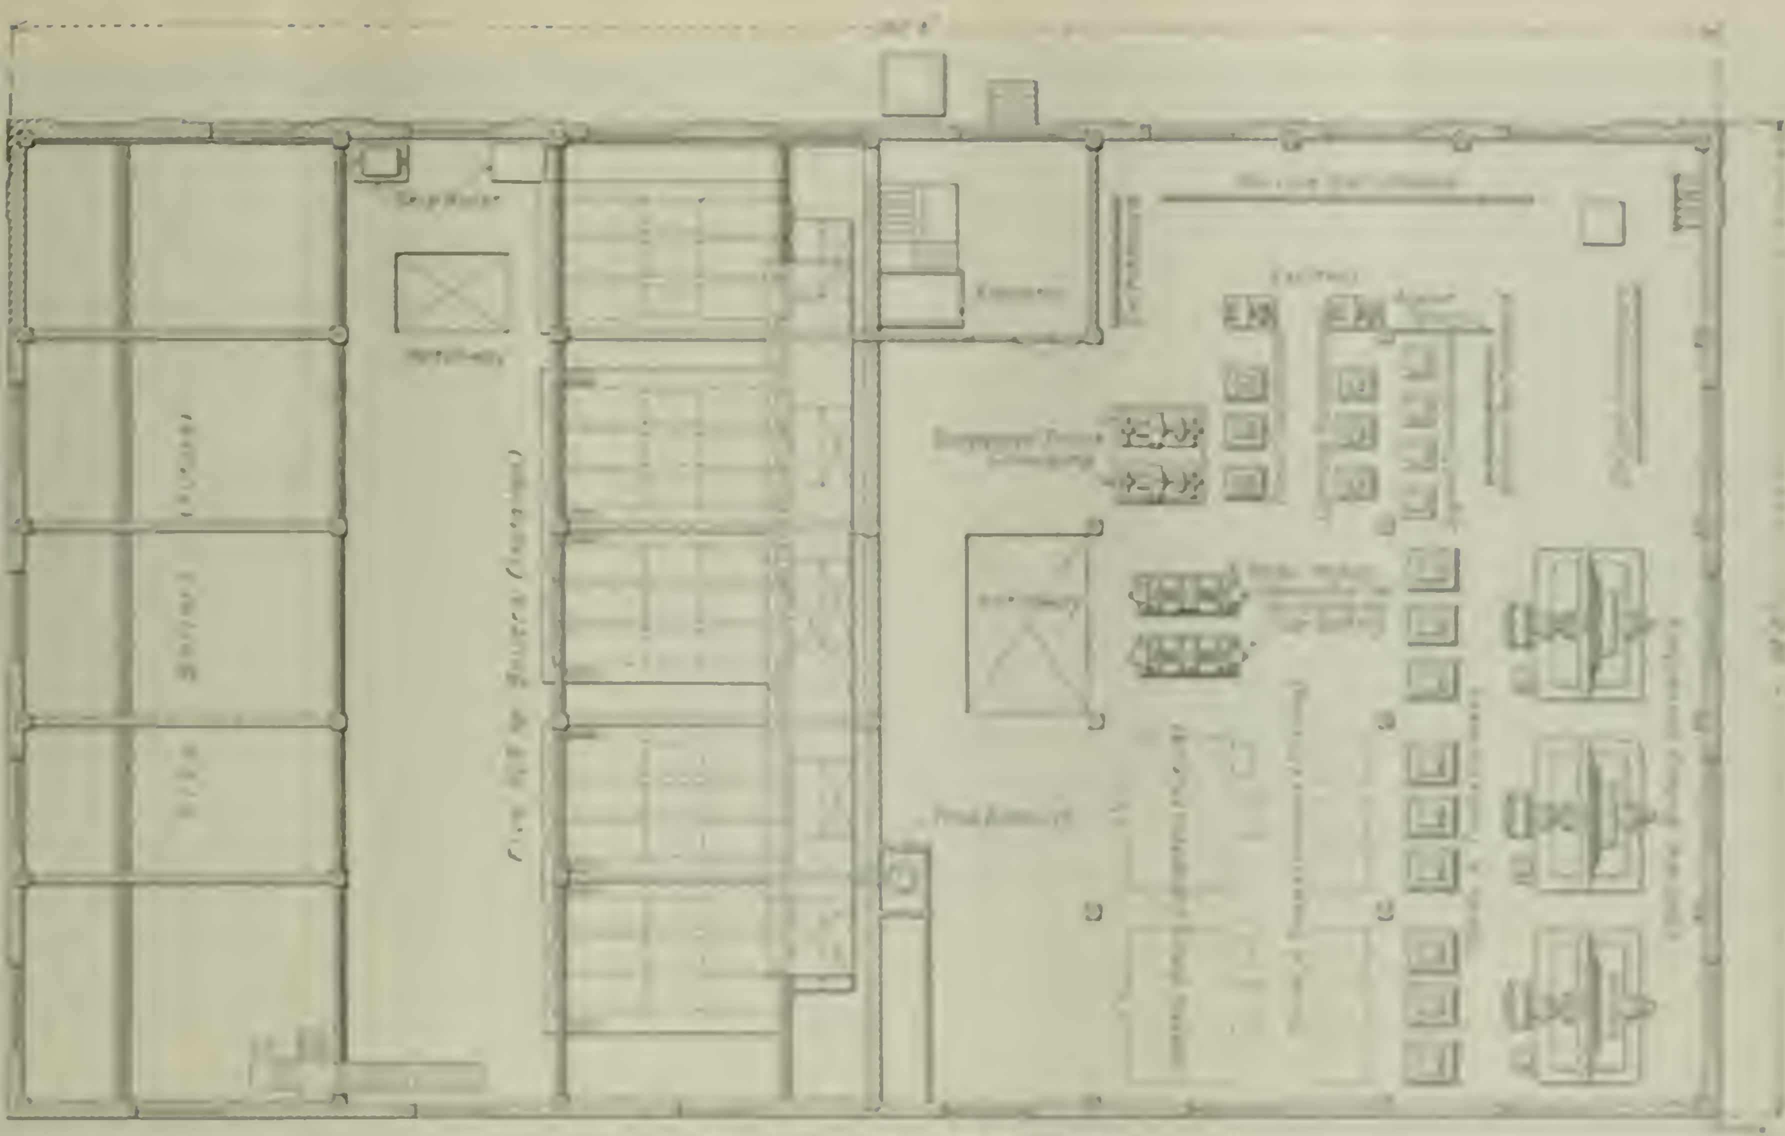

Fig. 11. Plan of Street Level

time the coal leaves the cars till it is in the bin, it is under the control of one man.

Under each ashpit there is a hopper through which the ashes are discharged into hand cars and wheeled out over a large reinforced-concrete storage hopper located under the sidewalk. This empties onto a belt conveyer which, in turn, discharges into gondola cars and the ashes are carried away over the same tracks upon which the coal is brought in.

Light and Power

Electricity for light and power in the passenger station, as well as the service plant itself (when not supplied from the Long Island power house) is furnished by two 1000-kilowatt Westinghouse-Parsons turbo-generators running at 1800 revolutions per minute and generating three-phase currents at 240 volts. The leads from these generators are carried to solenoid-operated switches, thence direct to the 240-volt busbars on the service switchboard. These connect with the lighting panels of the switchboard from which three-conductor cables lead to a number of subswitchboards located in various sections of the terminal. These, in turn, supply numerous panel boards from which the circuits are so arranged as to balance the load between the three phases. With the exception of a few tungsten lamps in the main waiting room and office hallways, the light is furnished by Nernst lamps. As a matter of general interest, it may be stated that there are over 100 miles of electrical conduit in the passenger station alone.

Power for the various motor circuits is at 420 volts. This is supplied through two banks of transformers (see Fig. 13). The circuit leads from the 240-volt busbars to one of the transformer panels, through a disconnecting switch to the primary side of one bank of transformers where the voltage is stepped up to 11,-

Fig. 9. Barriers of High-tension Switch Structure

Fig. 10. Coal Conveyer

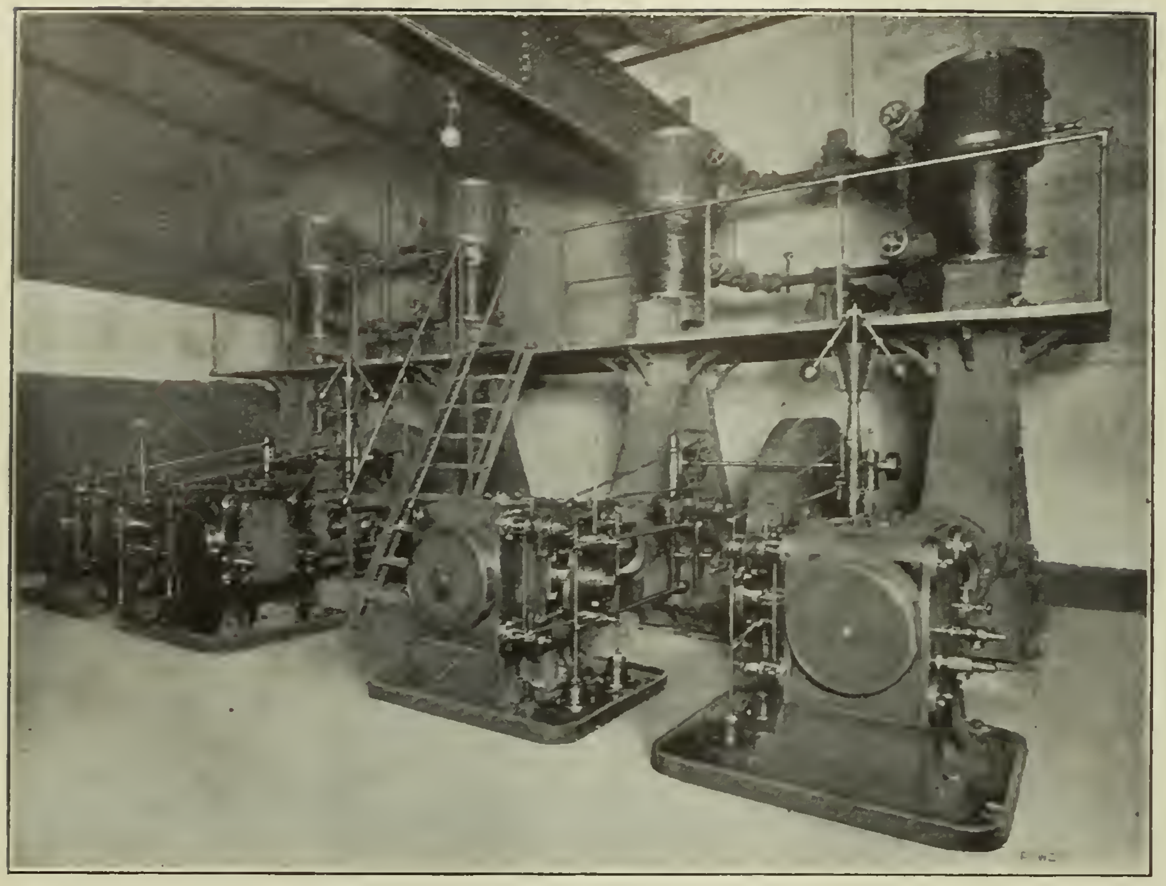

Fig. 12. Refrigerating Machines

000. It then passes over to the other bank of transformers where it is stepped down to 420 volts, and from here passes through another disconnecting switch to the 420-volt busbars; these supply the power circuits.

Although this arrangement may at first seem cumbersome, its flexibility becomes apparent when it is considered that during part of the year current is taken from the Long Island power house. This is brought over at 11,000 volts and after passing through the high-tension switching structure, the circuit ties in between the two banks of transformers; here it divides, part being stepped down to 240 volts for lighting and the remainder to 420 volts for power.

There are two motor-generator sets for furnishing excitation to the generators. A 60-cell 400-ampere-hour storage battery supplies excitation when starting the turbo-generators and also supplies emergency lighting circuits around the plant as well as the fire-alarm circuits.

Direct current for charging the motor-driven baggage trucks and automobiles is supplied by two motor-generator sets. The electric elevators and dumbwaiters are operated with direct current at 650 volts, taken from the rotary converters supplying the train motive power.

Air Compressors

There are three principal uses for compressed air about the terminal: the electropneumatic switching and signal system, sewage ejection and brake testing. Compressed air for the first two services is supplied by two cross-compound, two-stage Nordberg compressors, each having a capacity of 2000 cubic feet of free air per minute and compressing up to 90 pounds per square inch. There is an intercooler between the air cylinders and an atmospheric aftercooler located on the roof.

For testing the brakes on cars, however, a higher pressure is required and for this purpose two motor-driven compressors are provided. These have a capacity of 100 cubic feet of free air per minute and compress to 125 pounds per square inch. Their operation is entirely automatic;

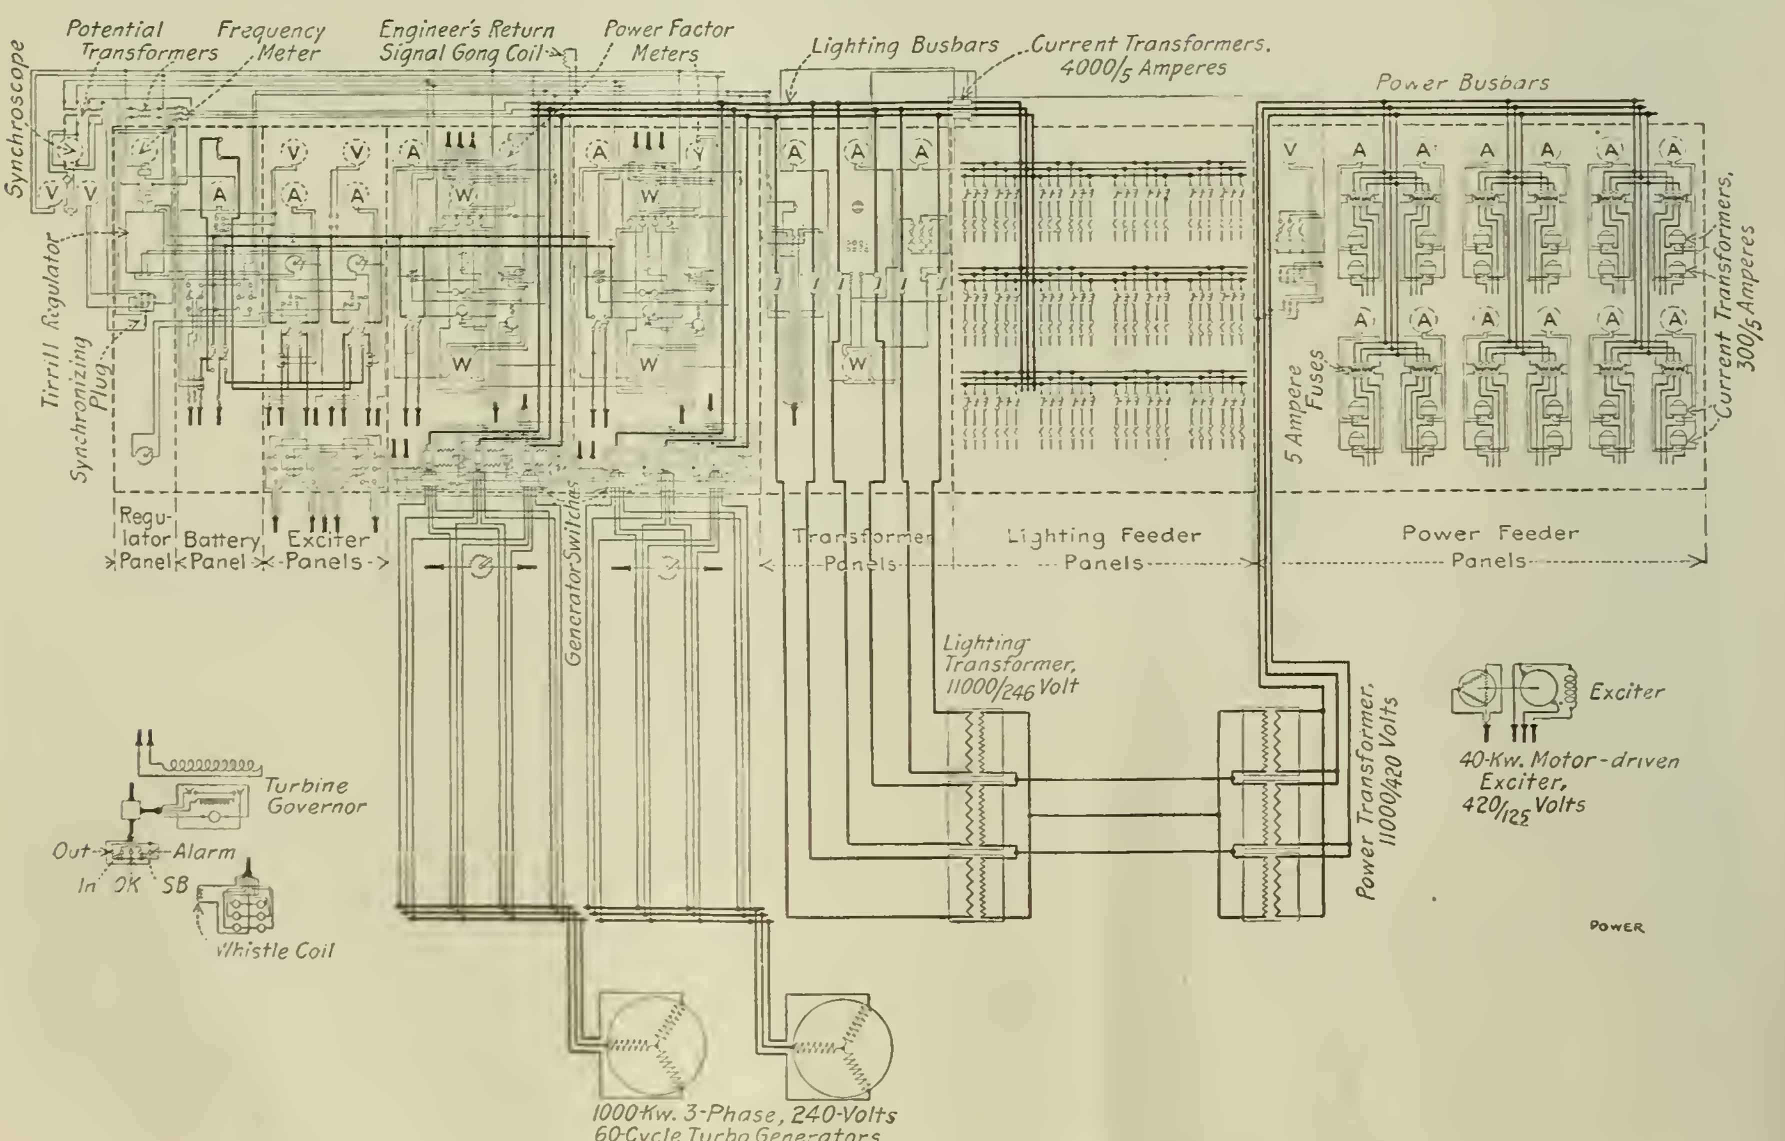

Fig. 13. Wiring Diagram of Service Switchboard

FIG. 14. MAIN AIR COMPRESSORS

If this compressor is unable to supply enough air to maintain the required pressure, the other is automatically started and continues until the upper limit of pressure is reached.

Air for the hydraulic elevator tanks is taken from the Nordberg compressors at 90 pounds and stepped up to 300 pounds by two railway air-brake compressors mounted on the wall just behind the large compressors.

HYDRAULIC ELEVATOR SERVICE

All the baggage lifts, twenty-one in number, and eleven of the passenger elevators are of the direct-acting plunger type, working at a water pressure of 300 pounds per square inch. These are supplied by three compound steam pumps, one a Heisler high-duty flywheel pumping engine having a capacity of 1500 gallons per minute; the second is a direct-acting pump of 1500 gallons capacity, and the third is of similar design but having a capacity of only 800 gallons per minute. The maximum load can be handled by operating one of the large pumps in connection with the small one. A 3000-gallon pressure tank, a 3000-gallon suction tank and a 5000-gallon surge tank form part of the hydraulic-elevator system.

REFRIGERATING SYSTEM

The refrigerating plant consists of two eighty-ton vertical single-acting York ammonia compressors, each having two ammonia cylinders and direct connected to a horizontal cross-compound Corliss engine. Calcium brine is circulated by centrifugal pumps through the cooling boxes in the kitchens of the station. The temperatures required in these boxes vary from 10 to 28 degrees Fahrenheit according to their contents.

Drinking water for the station is filtered and cooled in the service plant, before being circulated through the system.

HEATING SYSTEM

The station is heated by an indirect system. The exhaust steam from the compressor engines, elevator pumps, fire pumps, etc., is delivered through an 18-inch main to three closed tubular heaters having a total heating surface of about 17,500 square feet. A 30-inch exhaust-steam main also leads from the turbines to the heaters and provision is made for using live steam when the supply of exhaust steam is inadequate. The condensed steam from the heaters flows to the hotwell.

The heating water after passing through the heaters is circulated by motor-driven centrifugal pumps through a closed system of heating coils in the passenger station, over which fresh air is drawn by fans and circulated through the various rooms. The heating is regulated by varying the supply of steam to the main heaters, and any temperature of water up to 200 degrees may be obtained. The maximum air temperature obtainable is about 130 degrees.

In addition to the station heating considerable live steam is required for heating the switch cabins and the cars while they are in the station yard.

The total steam required during the month of March, 1911, was over twenty million pounds.

Every room in the terminal is ventilated by mechanically exhausting the air from it, there being in all 21 ventilating fans.

WATER SUPPLY

Water for fire protection is furnished by two steam-driven pumps, each having a capacity of 1200 gallons per minute. They are automatically controlled, taking water from the city mains and discharging at 150 pounds pressure. In order that they shall at all times be ready for service, they are kept running continuously at a slow rate, a small quantity of water being utilized for other purposes from the fire mains.

The water used in the kitchens of the restaurant is taken direct from the city mains while that supplying the drinking fountains throughout the station is first filtered and cooled in the service plant and then forced through the system by motor-driven centrifugal pumps. Water from the cooling jackets and coils of the air compressors and the refrigerating system is used for flushing the toilets.

A storage tank of 50,000 gallons capacity in the service plant is kept constantly filled to furnish an emergency supply, should the city supply fail.

All sewage is led to ejector tanks located in the basement and in the pipe tunnels; these are automatically emptied by means of compressed air into the street sewers.

All drainage in the service plant below the sewer level and the drips are led to a sump in the basement. This is periodically emptied by automatic float-controlled motor-driven pumps. Similar

FIG. 15. ROTARY CONVERTERS AND TRANSFORMERS

sumps are located in the pipe tunnels under the station and yard.

Substation

The substation, which is located in the service-plant building, furnishes motive power to that section of the electrified system which is within the vicinity of the terminal. Twenty-five-cycle, three-phase currents at 11,000 volts are generated at the Long Island power house; these are stepped down at the substation, converted to direct current at 650 volts and delivered to the third rail. Sixty-cycle, three-phase currents at 11,000 volts are also supplied and are stepped down to 420 and 240 volts for (alternative) service power and lighting and to 2300 volts for the primary circuit of the signal system. The substation equipment consists of nine single-phase 750-kilovolt-ampere air-cooled transformers, delta connected and supplying three 2000-kilowatt rotary converters. The latter are started by induction motors mounted on the same shaft with the rotor. These starting motors are supplied with power through a set of three transformers connected to the 11,000-volt line.

There are also three 11,000-2300-volt transformers which supply current for the train-signal system.

The high-tension switch and bus structure is of selected buff brick with soapstone barriers and cement slabs. All the oil switches are solenoid operated and are controlled from two switchboards on the main floor. There are two sets of busbars and the arrangement of switches is such that any feeder or section may be cut out for repairs without interfering with the rest of the equipment or interrupting the service.

The direct-current switches for the train feeders are all motor-operated and are located on the floor below the converters, although they are controlled from the same switchboard as are the high-tension oil switches.

In all, there are five switchboards, but these are arranged so that one operator can attend to them all.

At present the load is such that only two rotary converters are required to be in service at a time, the third being used as a spare; but space has been provided for three additional machines.

The entire plant was designed, built and equipped by Westinghouse, Church, Kerr & Co., of New York.

Analysis of Industrial Power Costs

By M. Oswald Jenkins *

The items chargeable to the cost of producing power in an isolated plant from the central-station viewpoint.

*New York Edison Company.

The cost of producing a unit quantity of power from small steam plants, such as are usually found in city manufacturing buildings, ranging from 100 to 400 horsepower in capacity, presents a subject which, although by no means new, is ever interesting owing principally to the widely varying results which may be obtained for a given case, depending largely upon the object for which the calculation is being made, and also upon the skill of the investigator.

If the unit cost of producing a given quantity of power is being sought for the purpose of making a direct comparison with the cost of purchasing the same amount of power, as a finished product, from an outside source, such as a central station, the character of the investigation and the cost items concerned would be quite different than if comparison were being made with similar power-producing plants.

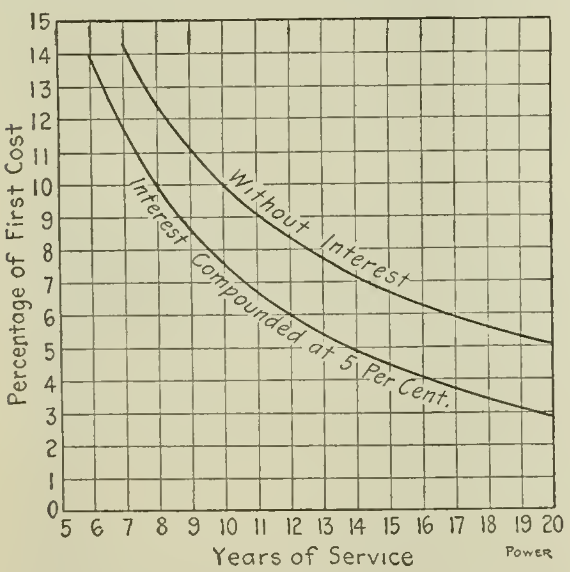

Fig. 1. Per Cent. to Be Set Aside as a Sinking Fund

Operating and designing engineers associated with power-plant work in general, and those identified with the smaller plants in particular, are interested in the efficiency of operation, and consequently in the cost of operating a power plant only as affected by its inherent efficiency, which includes only the actual cost of operation, such as fuel, labor, water and repairs. These constitute what might be termed factory costs as distinguished from total-production costs and the selling price of the manufactured article. They are quite sufficient for purposes of comparison with similar plants, revealing as they do the exact and complete results from the viewpoint of economy in design and operation. They are also sufficient for determining the selling price of power where the purchaser is a tenant in the building and as such is obliged to pay his *pro rata* share of the plant investment and other fixed expenses in the form of rent, irrespective of the power requirements.

Such an indirect power charge is usually of necessity in proportion to the floor space occupied by the purchaser, rather than in proportion to the demand on the power plant; the latter being a more just method of fixing the price. Thus, the cost of power as expressed in terms of cents per horsepower-hour or kilowatt-hour, or dollars per horsepower per year, and considered to be the total cost of producing power, may represent only that portion of the total cost known as operating expenses of the plant, and may be misleading. The total power cost includes other items of expense to which particular attention is herein directed.

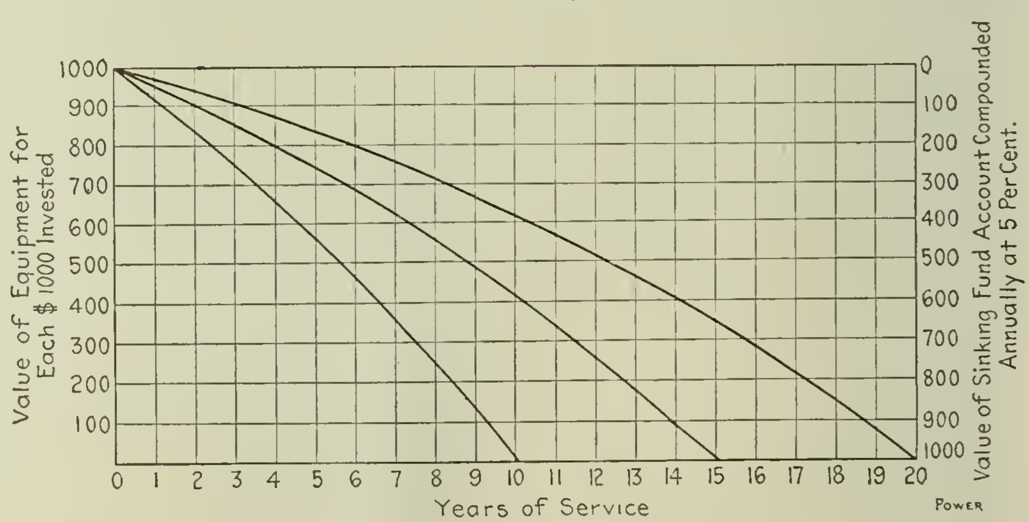

Fig. 2. Chart Showing Present Value of Plant

Since the general introduction of electric power from a public supply for manufacturing purposes, comparison between the cost of purchasing electric power delivered to the premises, and of producing power by a steam plant on the premises, requires a more comprehensive view of the plant costs and a better understanding of a correct and proper method of determining them; failure to do so often leads to erroneous conclusions, with results likely to be unfair to both producer and consumer of the public supply.

The power-costs account should rightly include every item pertaining to the plant presence and operation. Both items and accounts are to be determined on the basis that the power-plant operation is an entirely independent business than that primarily engaged in by the owner, and as such is to be dealt with accordingly. As any essential department of a well organized business (which a power plant is not if public power is available) must be able to stand on its own account, so should a power plant, and even more so, for it must provide adequately for power requirements for the entire factory, including any and all emergencies. It must continue to do efficient service for as many years as the factory will require, and above all must show a return on the capital invested in it equal to that of the average manufacturing business, where money invested is not free from risk, say, 15 per cent. over and above all other items of expense.

In order to arrive properly at the various costs generally known as fixed charges on a plant, some method of accounting must be employed. In every case where money is invested in manufacturing a commodity which is incidental to the general business, and which may be purchased from a public supply, the important thing is to be able to quickly determine the ability or inability of the manufacturing costs to compete with the cost of the public supply, and the method of accounting that will best show which is the one to employ. The principle is to buy whatever can be purchased cheaper than it can be manufactured, it being presumed that those who make a specialty are better equipped to turn it out cheaply than one would be who turns it out simply as a byproduct.

The original cost of a power plant may be represented by two accounts at all times; namely, the present value, and the value of the sinking-fund reserve established for depreciation. The sum of these two accounts should at all times be equal to the original investment. Each of these may again be divided as in the following schedule. The amount indicating the plant value would consist of two items, the salvage or market value, and that chargeable to obsolescence, the latter being the difference between the present and the salvage values:

Original cost	Depreciation and amortization sinking fund.	Increment, compounded. Portions of plant outstanding.
	Present value	Salvage value. Loss owing to obsolescence.

27	Gas for lighting	
28	Gas for heating	
	Total cost for all light, heat and power	

The original capital investment of successful operations must be returned from the earnings. This may be accomplished by means of a sinking-fund reserve, established solely for amortization, in which case depreciation is taken care of separately, or both depreciation and amortization may be represented by a single sinking-fund reserve. For small plants the depreciation account for obvious reasons usually serves both purposes and will be so considered here. The process consists of setting aside a certain percentage of the earnings each year to be invested in a safe security which at compound interest will equal the original investment in a given number of years according to the life of the plant.

Fig. 1 shows the amount in per cent. of the original investment to be set aside each year as a sinking fund in order to return the principal in (from 5 to 20) years, according to the life of the plant. The upper curve provides for a return without interest and the lower one with interest compounded annually at 5 per cent. The account thus established is wholly for depreciation and amortization and is not intended to provide for maintenance or repairs, which come under operating expenses, or for additions or renewals which are capital charges and should be treated as original costs.

In connection with this it may be well to remember that the life of a power plant is not determined solely by its physical ability to operate satisfactorily. Circumstances bearing on business growth, location, management and cost of power from a public supply may render it useless long before old age makes itself felt. It is the general experience that from 12 to 17 years constitute the life of the average plant and many have been abandoned at a much earlier age.

From the curves in Fig. 2 can be determined the present plant value for a useful life of 10, 15 and 20 years. These curves show that a $10,000 plant estimated to have a useful life of 15 years will be worth a trifle over $4000 after 10 years' operation. Any number of curves might be constructed in a similar way corresponding to different lengths of plant life. Having in this manner fixed the present value, other values may readily be determined when the question of abandoning the plant is being considered. If, as cited, after 10 years' operation the plant were to be abandoned, the new power account should assume responsibility for the difference between $4000 and the salvage obtainable. In other words, the amount due to obsolescence would be chargeable to the new power account as an investment charge, when by the operation of a new sinking-ing-fund reserve it will be returned as original capital. In fact, it could not be otherwise, for, partly due to the ability of the new account to carry the obsolescence charge, it proves its claim to the right to replace or supersede an existing plant. In the many cases where large power companies replace comparatively new machinery with larger, more efficient and more expensive machinery, and where large, beautiful buildings are being replaced with larger and more modern ones, a like method of determining the amount chargeable to obsolescence is employed with good effect.

Table 1 will serve to show the items of expense involved in operating a plant, and is arranged for the purpose of showing the exact average yearly cost at any time during the life of the plant. The average yearly cost is important to consider, and it is absurd for one to say that the plant has paid for itself, and now costs nothing except the operating expenses of labor, coal, water and repairs. The fact is that the former yearly average cost may have been slightly reduced or increased by reason of continuous operation, but could never be reduced to nothing even if the plant were to operate indefinitely.

There is perhaps little need of calling special attention to all of the items appearing under the heading of "Annual Cost of Steam Power" since each appears to be a proper charge. However, items Nos. 6 and 22 may require further consideration. Item 6 provides for, first, the time and thought given to the plant affairs by the head of the establishment and the superintendent of the factory, who must assume the responsibility of keeping all things going, directing the buying of coal, lamps, oil and supplies, engaging engineers and firemen, and seeing that repairs are made; second, a power plant is not an essential part of the business but an independent business and should be able to show a profit on the money invested in it over and above bare interest. The profit to be expected should be at least equal to the profit of the principal business engaged in; otherwise the owner would be much better off if the plant investment were in the form of a safe security paying only 5 per cent. and the factory were purchasing power from the public supply.

Item 22 refers to the loss of output due to a variation of speed at the driven machines, thereby affecting the output. It is plain to be seen that if the average speed of a productive machine were 5 per cent. below the maximum, due to such variation, the output would suffer; or, in other words, by the use of purchased power—presuming that its amount would be constant—nearly 5 per cent. increased output could be obtained with the same factory equipment and labor.

Table 2 shows an electric-power cost form corresponding to the steam-power form. As inspection will show, it provides for every item of expense likely to be incurred for light, heat and power supply.

It is believed that such a method of accounting for power costs will produce results which are fair to all parties concerned.

Compression

Steam is let into the cylinder of a steam engine for the sole purpose of turning the crank shaft at a predetermined speed against resistance. When the legitimate resistance is augmented by avoidable friction the possible efficiency of the machine is not reached.

To turn the shaft, pressure is applied to one side of the crank pin and whatever reduces the pressure upon this side of the pin or adds to that upon the other reduces the total output of energy at the flywheel and decreases the efficiency of the engine.

Compression of steam on one side of the piston reduces the effective pressure of the steam on the other side and decreases to this extent the pressure available for turning the crank shaft of the engine.

When the pressure of compression exceeds the pressure of the expanding steam the energy required for the work must be taken from the flywheel, reducing the amount of energy available for useful work.

Compression reduces the area of the indicator diagram, showing that for any given point of cutoff less work will be done in the cylinder when compression is used.

Though compression fills the clearance space with steam taken from the exhaust pipe instead of from the boiler, it takes steam from the boiler to run the engine to do the compressing, and if there is no other loss the friction of the engine during the period of compression is the price that must be paid.

Flexible Operation with Oil Fuel*

By Herbert A. Wagner

At the Westport station of the Consolidated Gas, Electric Light and Power Company of Baltimore, oil fuel is used for banking and in conjunction with coal for handling peak loads. With this arrangement the boilers have been forced to four times their rated capacity.

It is well known that the capacity of the modern water-tube boiler depends, within fairly wide limits, upon the amount of fuel burned per hour. Several plans have been proposed and used to increase the grate area so that more fuel can be burned, but the only practical plan for doing this necessitates firing from both ends; this requires increased space and additional devices for coal handling, etc.

The load on the Westport station of the Consolidated Gas, Electric Light and Power Company of Baltimore has well defined peaks of comparatively short duration, and these considerations led to experiments with fuel oil for supplementing the coal fires and obtaining the desired increase in boiler output.

After trying several settings the furnace arrangement shown in Fig. 1 was finally adopted, and proved so satisfactory that it was decided to equip the entire boiler plant in this way. The boilers are of the standard Babcock & Wilcox type and are rated at 650 horsepower. The space back of the usual coal grate is made into a large combustion chamber with the oil burners at the extreme rear end. This combustion chamber is separated from the boiler tubes above it by tiling and from the coal grate by a low bridgewall. The hot gases from the burning oil pass over the coal grate and upward through the first pass in the usual three-pass Babcock & Wilcox setting. Ample air inlets are provided around the burners and also in the side of the combustion chamber. Each furnace is provided with four oil burners.

The oil is delivered to the burners under 70 pounds pressure and is atomized in each burner by a steam jet, the steam required for this purpose being less than 1 per cent. of the amount generated by the boiler. By this arrangement either oil or coal or both together may be used to fire the boiler. Furthermore, the changes from the ordinary boiler setting are very slight and require no additional space. One of the four burners in each furnace is used as a pilot and for the equivalent of a banked coal fire for keeping the boiler ready for steam. These pilot or banking burners are operated from a separate oil line, so that a single valve in the main oil line may be used to turn oil into any number of furnaces desired, thus putting any number of banked boilers into commission instantly. The general arrangement of piping is shown diagrammatically in Fig. 2. The master valves 1 and 2 each control the pilot or banking burners for a group of five boilers, and in like manner the valves 3 and 4 control the remaining burners in each group. For illustration, assume that group A is being fired with coal for the usual load, and that group B is banked with oil; valves 1, 3 and 4 will then be closed and valve 2 will be open. If a sudden increase of load occurs the opening of valve 4 upon signal from the switchboard will instantly put group B into service. Still greater capacity could be obtained by opening the valves 3 and 1 to operate boilers A with both coal and oil. In addition to the master valves shown there are, of course, valves for controlling each burner and the group of burners for each boiler.

*Abstract of a paper read before the National Electric Light Association at New York City, June 2, 1911.

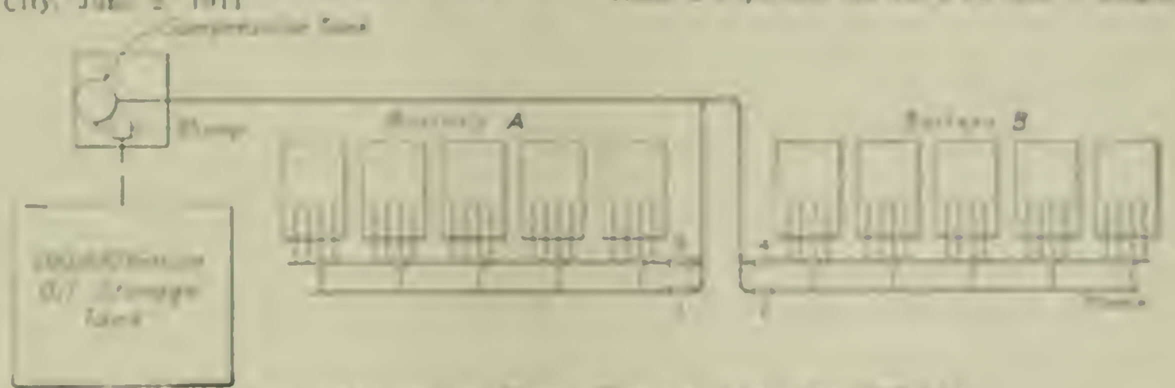

Fig. 2. Arrangement of Piping Shown Diagrammatically

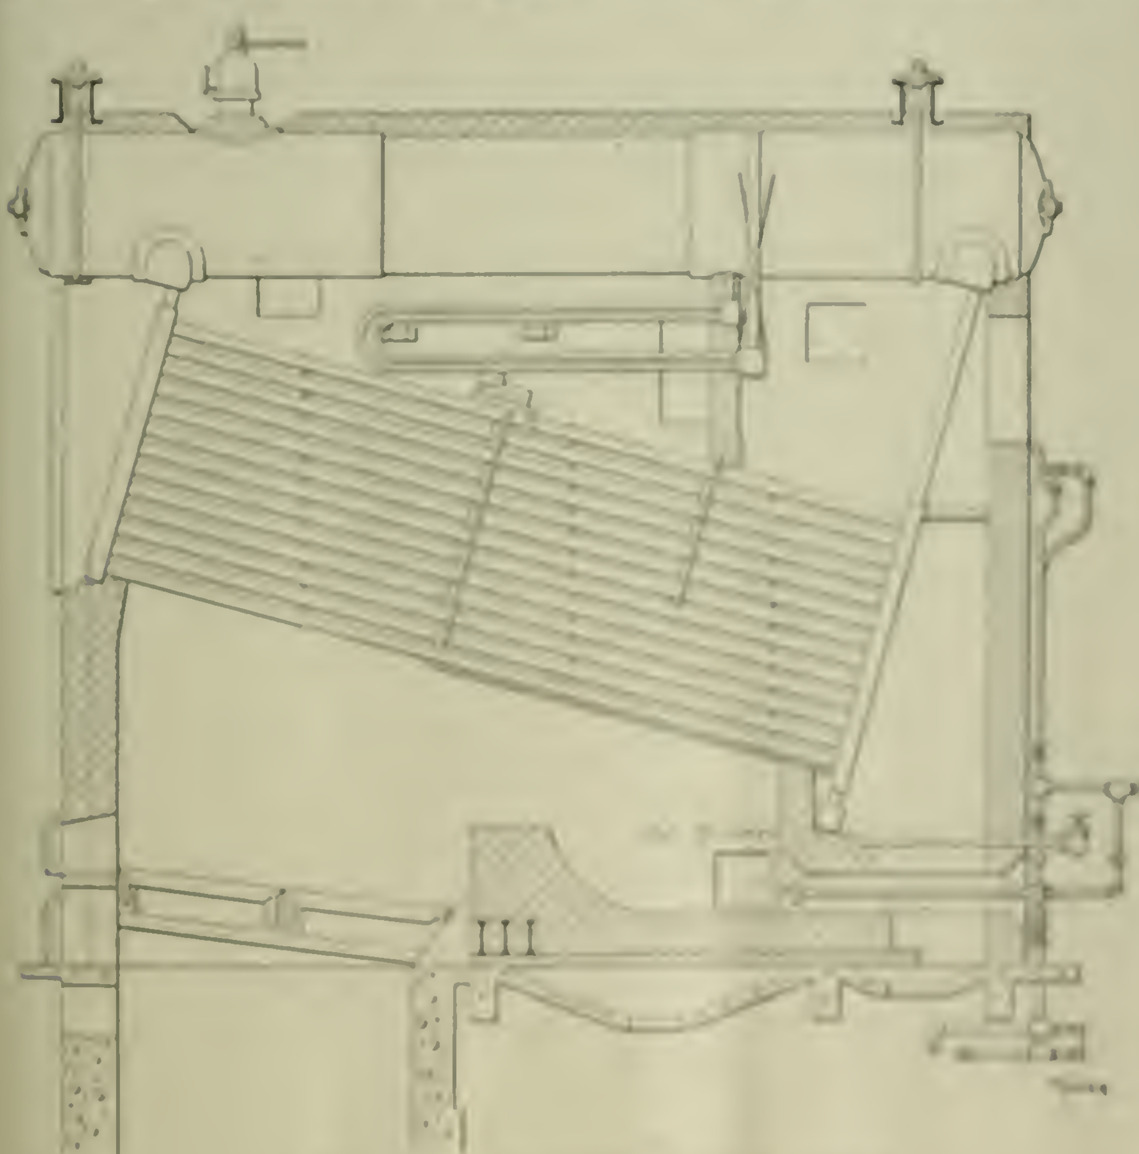

Fig. 1. Furnace Design Finally Adopted

Ordinary boiler tests with this arrangement have shown approximately the following results for maximum boiler output during eleven-hour runs:

Coal alone	[illegible]
Oil alone	[illegible]
Coal and oil together	[illegible]
Coal and oil [illegible]	[illegible]

Under actual operating conditions, however, the gain by the use of oil is more marked. It has been found that 2000 kilowatts of station load can be carried by each boiler when using coal and oil together, with as much ease and certainty as 1200 kilowatts per boiler can be carried by coal alone. This shows, under operating conditions, a gain in capacity of 66⅔ per cent. by the use of oil, or a saving of 40 per cent. in the cost of the boiler plant for a given capacity.

It is under emergency or peak-load condition, however, that the advantages of fuel oil must be considered, and the durations of load under such conditions are usually too short for any comparisons by the usual boiler-test methods. Tests were made, therefore, under regular operating conditions to determine the minimum number of boilers which could be used to carry actual peak loads. The best record obtained in past operation at the Westport station with coal was 16,888 kilowatts carried on eleven boilers; this is equivalent to 1535 kilowatts per boiler.

The same station operating in conjunction with a hydroelectric-power transmission line recently carried a load of 11,100 kilowatts for two hours with four boilers fired with coal and oil. This represents a load of 2775 kilowatts per boiler of 650 horsepower rating.

Tests have shown that a cold furnace, with water in the boiler at 142 degrees Fahrenheit, could be made to steam at 175 pounds pressure in 25 minutes with oil fuel as compared with 42 minutes with coal.

The cost of fuel oil at Baltimore is 43 per cent. more than coal, per heat unit, but in spite of this difference the actual cost of "banking" is less with oil than with coal, for the reason that the oil is burned efficiently while the coal is necessarily burned very inefficiently.

Fuel oil shows its advantages as compared with coal most markedly when used as fuel for operating steam plants in connection with long power-transmission lines from water-power plants. Owing to conditions which, up to the present time, are inseparable from high-tension transmission lines, steam auxiliary or standby plants are a necessary adjunct to such lines where power is used to supply the various needs of a large community. Such steam plants may be required merely to supply power during brief interruptions due to transmission-line troubles, or to supply part of the power for peak loads, or to make up for deficiencies in the water flow during dry seasons.

In Baltimore the local company purchases at present about 15,000 kilowatts from the Pennsylvania Water and Power Company. This is transmitted over 40 miles of transmission line at a pressure of 70,000 volts. The local company generates by steam all power for peaks over the 15,000 kilowatts purchased. The steam plant is operated in parallel with the water-power plant, and normally carries a constant load of about 2000 kilowatts, and as much over that amount as peaks may demand. In addition to this the steam plant stands prepared at all times to take the entire load should the transmission-line power fail.

So far during six months of operation there have been few interruptions on the transmission line. With but one exception these have been due to the failure of relays to operate properly. Such failures as have occurred, however, have thoroughly tested the value of fuel oil for quick steam generation. A few of these severe tests will be mentioned.

December 4, 1910: The transmission-line service was suddenly interrupted, throwing a load of 10,500 kilowatts on five 650-horsepower boilers. Oil was turned on under these boilers, which were at the time operating with coal, and steam pressure was held until the transmission-line service was restored. Moreover, the primary voltage at the substations was held within 1 per cent.

January 28, 1911: With the steam station carrying 2000 kilowatts on three 650-horsepower boilers, using coal, with three firemen on watch, the transmission-line service was suddenly interrupted and the load on the steam plant was increased to 8500 kilowatts. Oil was turned into eight additional boilers, and, although the steam pressure dropped from 175 to 165 pounds, it gradually came up to 175 pounds during the next 15 minutes. This drop in steam pressure was well within the range of automatic voltage regulators to maintain the primary voltage at the substation within 1 per cent.

May 12, 1911: The steam station was carrying 2000 kilowatts with four coal-fired boilers in service, and four additional boilers banked by means of one oil burner under each. The transmission service was suddenly interrupted and a load of 7600 kilowatts thrown on the steam plant. Oil was turned onto the four boilers in service and the four banked boilers; the steam pressure was maintained and in four minutes the boilers were blowing off.

Lignite Deposits in the United States

In an address on lignite, delivered before the American Philosophical Society, at Philadelphia, Penn., on May 5, by Joseph A. Holmes, director of the Bureau of Mines, the extent of the lignite deposits in the United States was shown by the accompanying figures, giving the areas in several of the States.

In several of the States in the Rocky Mountain region there are large areas of coal that represent a transition between typical lignite and bituminous coals. For these the name "subbituminous coals" has been suggested, and is tentatively used by the United States Geological Survey.

While the lignite beds in Alabama, Mississippi and Tennessee represent a transition between peat and the more typical lignites of the Dakotas and Texas, little or no use has been made of the lignite beds in these three States.

The lignites in Texas and Arkansas have been used to a limited extent, as have also the lignites of the Dakotas and eastern Montana. In this latter field the lignites contain 20, and in some cases more than 40, per cent. moisture. They slack badly and rapidly on exposure to the atmosphere, and this quality seriously interferes with their use and value for fuel purposes.

"The outlook for the utilization of lignites," said Mr. Holmes, "is favorable along three lines: First, in gas producers,

LIGNITE DEPOSITS IN UNITED STATES

	Lignite, square miles	Subbituminous, square miles
Alabama	6,000	....
Tennessee	1,000	....
Louisiana	8,800	....
Arkansas	5,900	....
Texas	53,000	....
South Dakota	4,000	....
North Dakota	31,000	....
Montana	7,000	8,800
Wyoming	....	21,360
Washington	....	1,100
New Mexico	....	5,000
Colorado	....	5,910
Idaho	....	1,200
Total	116,700	43,370

without either drying or other treatment; second, in boilers of special construction, such, for example, as that installed more than a year ago at Williston, N. D., by the United States Reclamation Service, where lignite is used in its natural condition almost immediately after being brought from the mine, and, third, made into briquets. In this case the lignite should be thoroughly and finely crushed and dried to a moisture content of from 5 to 10 per cent., and then compressed while still warm into briquets."

Limited quantities of lignite from California, North Dakota and Texas have been made into satisfactory briquets at the Government mine-experiment station at Pittsburg, using the full-sized German briquetting press, which develops a pressure of from 20,000 to 25,000 pounds per square inch. In the cases just mentioned the briquets were made without the use of any binding material, a sufficient amount of tarry material remaining in the crushed and dried lignite to serve as a bond to hold the particles together in the briquet.

"It is believed," said the speaker, "that the investigations of the Bureau of Mines along this line will demonstrate that the lignite in Texas, the Dakotas and Montana can be made into briquets on a commercial scale, and that in this form the lignite can be used as a substitute for other domestic fuel in these regions." There is sufficient raw material in these States to last for some time.

Especially conducted to be of interest and service to the men in charge of the electrical equipment

Electrification of Textile Mills*

By George P. Gilmore

The application of the electric drive to textile machines has reached the stage where many manufacturers, superintendents, engineers and mechanics are giving it much time and attention and I expect to see in the near future a large increase in its use. One result of the mill men's study of the question will probably be that textile and power-machinery manufacturers will make many alterations in the design and construction of their machines with a view to making them as a unit more adaptable one to the other and both to the requirements of textile manufacturing.

In my opinion, too much that is not true has been said about the cost of installation of electric power, its maintenance and economy, as compared with mechanical power, for the best interests of electric power, and too little regarding its real advantage.

Prime Movers

The steam turbine as a prime mover for the generation of electric power has no rival. It has none of the irregularities of the reciprocating engine, is more economical than a reciprocating engine, except possibly when the engine is new and operating at its most economical point of cutoff, and requires less floor space, oil and attention. Because of its high speed, the generator is smaller and consequently costs less and the exhaust steam from the turbine can be used for any purpose requiring low-pressure steam, as it contains no oil.

On test a 1500-kilowatt turbine has shown an economy of 17.22 pounds of water per kilowatt-hour at full load and 17.68 pounds at 25 per cent. overload, equivalent to 12.80 pounds per horsepower at full load and 13.2 pounds at 25 per cent. overload. Immediately after this test the turbine was run 2½ hours at 50 per cent. overload; then temperatures of the generator were taken and the windings showed a rise of 20 degrees Centigrade.

Safety

Thanks largely to the insurance companies, who have established a code of rules for the proper installation of electrical equipment, it is practicable to supply current from the generators to motors and lamps so that there is no danger of fire or of shock to operatives. In fact, there is much less danger from a well installed electric drive than from a mechanical drive.

The Motors

Modern motors are efficient, rugged and reliable and require very little care; they can stand heavy overloads for long periods without injury—in fact, I ran twelve 5-horsepower motors 58 hours per week for five months, developing 9½ horsepower each, and not one of them was injured or caused a shutdown. They may be placed in any position or location and arranged to drive shafts either horizontal or vertical or at any angle.

Of course, it is necessary to use different types of motors for various machines and locations. For motors up to and including 10 horsepower, simple oil switches are used for starting. For card rooms or other places where there is lint, fly or dust in the air, the squirrel-cage induction motor, which has no resistance coils in the rotor but has its starting resistance in a stationary closed case, is best suited; for other purposes or places an induction motor with an internal resistance may be used.

Some attention is now being given to variable-speed motors direct connected to cylinder shafts. In view of results obtained from one large installation where the motors were directly coupled to the cylinder shafts I am of the opinion that it is not necessary to change the cylinder speed with this drive as often as has been the practice with belted drives.

Table 1 herewith shows the results of spinning yarn at a constant spindle speed on frames having the same size rings in counts varying from 10 to 120 as compared with the production previously received from belted machines, using varying speeds and size of rings. The great increase shown in the production of 10s was largely due to the fact that the mechanically driven frames were not properly equipped or fitted to spin this count.

Installation and Operating Costs

The following figures cover the costs of an installation using turbine-driven generators, individual motors on pickers, ring spinning and some twisting frames and group drives for cards, combers, sliver and ribbon laps, drawings, fly frames, reels and spoolers. The prime movers are two 1500-kilowatt units. The total cost, including buildings, chimney, boilers, prime movers, all auxiliaries, motors, wiring, shafting, belting and all equipment, was $345,150. The cost per kilowatt of rated capacity, therefore, was $115.05, divided as follows:

TABLE 1. COMPARISON OF PRODUCTION RATES

Yarn	Twist per Inch	R.P.M. Front Roll	Pounds per Spindle in 58 Hours: Motor Drive	Belt Drive	Per Cent. Increase
10 C. P.	11.0	[illegible]	7.45	[illegible]	[illegible]
24 Card. P.	17.2	[illegible]	[illegible]	[illegible]	[illegible]

45 P. Card	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
46 P. Card	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
60 C. P.	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
70 C. P.	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
100 Comb. S. I	[illegible]	[illegible]	[illegible]		
120 Comb. S. I	[illegible]	[illegible]	[illegible]		

	Cost per Kilowatt
Buildings, chimney and foundations	[illegible]
Power-house equipment	[illegible]
Motors installed	[illegible]
Wiring	[illegible]
Shafting	[illegible]
Belting	[illegible]

This was an expensive installation, owing to the fact that the power house was built in water, requiring concrete foundations under walls, boilers and machinery as deep as 9 feet in many places, and it was necessary to construct water-

*Extracts from a paper read before the Master Mechanics Association of America at Fall River, Mass., May 18, 1911.

ways to and from the power house, costing $10,343.

It was originally intended to group-drive the ring spinning frames, but after the purchase of the frames it was decided to use individual motors and as it was impossible to get motors of the correct size for the number of spindles per frame, the nearest standard size, which was 25 per cent. larger than necessary, was used, thus increasing the cost per spindle for installation and decreasing the efficiency of the motor.

The costs of installation for frame drives were:

	Per Spindle
Ring spinning, individual drive	$0.53
Ring spinning, group drive	0.35
Ring twisting, group drive	0 60
Ring twisting, individual drive	0.89

TABLE 2. COMPARISON OF INSTALLATION AND OPERATING COSTS FOR RECIPROCATING ENGINE AND MECHANICAL DRIVE AND TURBO-ELECTRIC PLANT

INSTALLATION

	Engine and Mechanical Drive	Turbines and Electric Drive
Plant capacity	4,000 Hp.	3,000 Kw.
Installation investment	$258,860	$345,150

OPERATION

Cost per pound	0 0508	0.0456
Saving, per cent		10 23

Mules are a group-drive proposition as the great variations in power required during each cycle of their operation would require a very large motor, making the cost and efficiency prohibitive. In one case I applied an ammeter to a 200-horsepower motor driving 22,288 mule spindles and found the load varying from 125 to 250 horsepower.

For comparison of power costs between plants driven by reciprocating engines through mechanical transmission and those driven by turbines through electrical transmission, I have used the actual cost of the 3000-kilowatt plant previously referred to for the electric drive and carefully estimated the cost of an engine and belt drive of equal capacity, using figures submitted as prices by power-machinery manufacturers at the time this proposition was under consideration.

The fuel, repairs and supplies for the electrical plant and all figures for the mechanical drive are estimated. The efficiencies of the two types of drive are assumed to be equal. (See Table 2.)

From these figures it would seem to be necessary to find some material benefits to be derived from the electric drive over the mechanical to warrant the extra expenditures necessary for its installation and operation. In these figures I have tried to be conservative and, if either, favor the mechanical drive.

It is generally understood that the power costs amount to about 6 per cent. of the cost of production; therefore, if the production were increased two-thirds of 1 per cent., the 11.2 per cent. excess in power costs would be balanced.

In Table 1 I have shown the increased production of various counts obtained in one plant where the electric drive has been installed. Taking the results obtained on the count for which this mill was laid out as a basis for the comparison of a mechanical and electrical driven spinning room, the figures in Table 3 are obtained.

It was found that an operative attended the same number of spindles at their increased production as before, that there was less breakage of ends, because of the constant speed and absence of belt slip; consequently better yarn was produced with less labor. The breaking of ends is not caused by the creeping of belts but mostly by short jerky slips such as occur when dry or hard spots in the belt get on the small driving pulleys.

Table 4 gives the results of tests made to determine the power required for dif-

TABLE 4. RESULTS OF TESTS MADE TO DETERMINE THE POWER REQUIRED TO DRIVE VARIOUS MACHINES AND PER CENT. SPEED LOST IN TRANSMISSION

NOTE.—In mule spinning, average counts 12 hank, combed Egyptian—76 silk.
NOTE.—Peeler cotton was being opened during test on bale-breaker, opener and lappers.

ferent machines, as shown by electrical instruments, and the loss due to slippage of belts, bands, etc., between the drive and the spindle. It was found that the ⅛ inch added to whorl and cylinder fully compensated for the band slip on the individually driven spinning frames.

As spinning requires about 60 per cent. of the power used in a mill it is not strange that it has received more attention than other processes and therefore is in a more advanced state of development than the other drives.

Advantages and Disadvantages of Electric Power

Advantages—The advantages of electric power have been discussed by electrical engineers and power-machinery manufacturers in many papers on the subject, but are more fully understood and appreciated by mill agents, superintendents and mechanics who have daily experience with it and have a better chance of studying and because of their knowledge of the work required of it are better qualified to judge its merits.

Among the advantages and possibilities of the electric drives may be mentioned the following: Smaller power house and foundations; separation of power house and mill; economy of prime movers over a wide range of load; steady and even speed; no chance of wrecking the prime mover by a charge of water from the boiler; maximum use of the expansive power of steam; utilization of exhaust steam, because it is clean; more reliable power; more accurate knowledge of the power developed and used; information supplied by switchboard; absence of belt race and large belt troubles; less floor space required for a given output because of increased production; lower ceilings and lighter roof construction because of the absence of heavy shafting; better lighting because of the absence of belts; increased production; better machinery arrangement; more operating flexibility; lower operating costs; cleanliness; ease of determining machine troubles by applying electrical instruments; ability to stop all transmission by any employee in the room, and the ability to make use of purchased power as an auxiliary for overtime work, in case of accident, or to build a mill without a power plant.

Disadvantages—The principal drawbacks to electric power are the cost of installation and, in some cases, whether real or fancied, the cost of operation.

Cost of Engine Operation

I give in Table 3 the actual cost of power, which is an average for three years figured from well made and complete reports, developed by a reciprocating engine. This plant was probably as skillfully operated and well managed as the average plant in textile mills. The high repair item was caused by the reboring of all cylinders and ports and fitting same with new valves and pistons, which was done in the first year covered by the account. This may be of interest in showing that theoretical economies are not always obtained in practice.

TABLE 3. COST OF POWER PER YEAR PER INDICATED HORSEPOWER AVERAGED OVER THREE YEARS USING TANDEM COMPOUND CONDENSING ENGINES

Repairs	$ 2 [illegible]
Fuel at $4.00 a ton	14 1[illegible]
Labor:	
Engineers	0.77[illegible]
Firemen	1.[illegible]
Transmission	0.[illegible]
Handling coal and ashes	0.7[illegible]
Supplies	0.3[illegible]
Interest, 5 per cent	$ 5.3[illegible]
Depreciation, 5 per cent	5.3[illegible]
Taxes and insurance, 1 per cent	0.6[illegible]
Coal in storage, 5 per cent on 3 months' supply	0.5[illegible]
Total cost per year per indicated horsepower	$[illegible]
Equivalent cost per year per kilowatt	[illegible]

All costs given in this paper are prices of 1908 and 1909; the prices of electric machinery have since been lowered 10 per cent.

Discussion

In the discussion which followed the reading of Mr. Gilmore's paper, Sidney B. Paine, manager of the General Electric Company's mill power department, said that about 500,000 horsepower of electrical equipment has been installed in textile mills up to date. Among the large installations he mentioned 23,000 horsepower in the Amoskeag mills, 80,000 at Lawrence, 40,000 at Lowell, 68,000 in the various mills of North Carolina and 52,000 in those of South Carolina.

The average size of textile mill motors ten years ago, Mr. Paine said, was 75 horsepower, whereas the average size now is 23 horsepower; the change is due to the increased use of individual motors. He also said that the speed of motors used on all textile machines except mules would not vary 1 per cent., and cited a number of instances of increased production due to substituting motors for belt drives, notably with respect to looms.

An Easily Built Switchboard

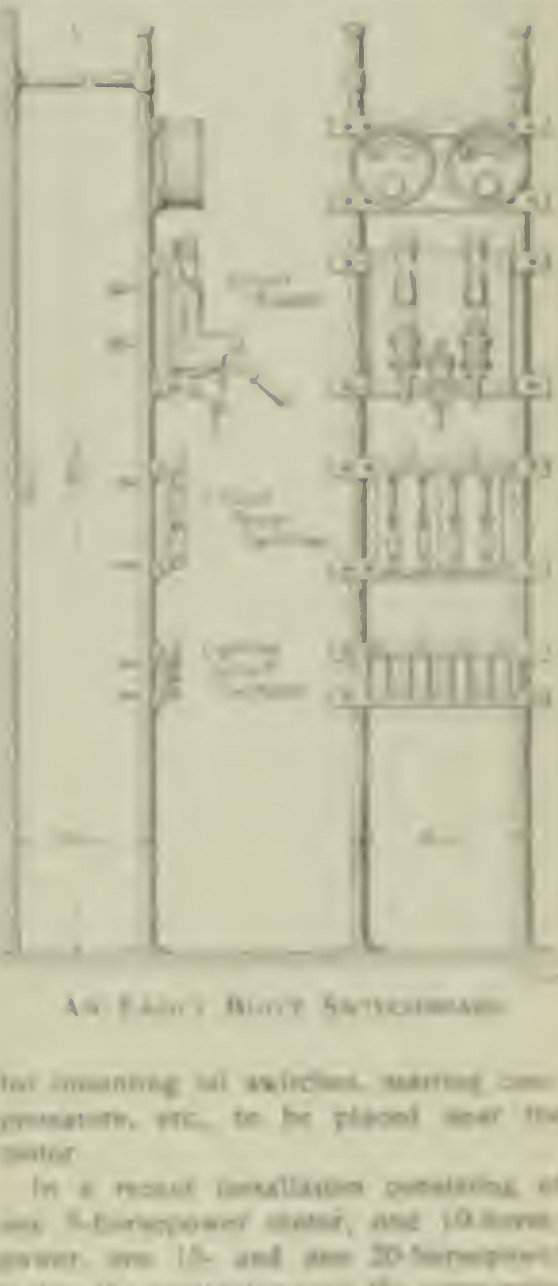
By J. H. Crane

The accompanying sketch shows an inexpensive and serviceable switchboard for use in small machine shops, woodworking establishments or other places where a few motors are to be installed and the owner does not wish to go to the expense of buying a conventional slate or marble switchboard and corresponding fittings. The uprights are 1¼-inch pipes set in floor-plates fastened to the floor, closed at the upper ends by ordinary pipe caps and braced to the wall by 1¼-inch pipes screwed into tees in the uprights and floor-plates on the wall.

The meters, circuit-breakers and switches are supported by pieces of oak or other hard wood ¾ of an inch thick by 2 inches wide, held in place by U-shape axle clips which can be secured at any blacksmith shop or carriage-hardware store. The wiring on the rear should be fastened to the boards by means of porcelain cleats.

The whole outfit can be painted black and presents a very neat, attractive appearance—in fact, it will look much better than a slate board will after being in use six months or longer. It is easy to add as many panels as are wanted and to change the switches at any time.

Such an arrangement can also be used



An Easily Built Switchboard

for mounting oil switches, starting compensators, etc., to be placed near the motor.

In a recent installation consisting of one 5-horsepower motor, one 10-horsepower, one 15- and one 20-horsepower motor, the contractor gave the same price on the total installation, using this style of switchboard, that was quoted for a slate switchboard, with its switches and circuit-breaker, but without the motors.

In a vessel of 5400 tons now under construction, the use of Diesel motors adds 18,000 cubic feet to the hold space. At four voyages a year in the Black Sea trade, this means a profit of $4,000. The saving in fuel would be $20??, and in wages, $1,100. It is also stated that a fishing boat of 140 tons equipped with a Diesel motor is doing the same amount of work in the herring fisheries as is performed by a steam-driven fishing boat of 184 tons.—Scientific American.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Hot Tube Ignition

By Olaf Olafsen

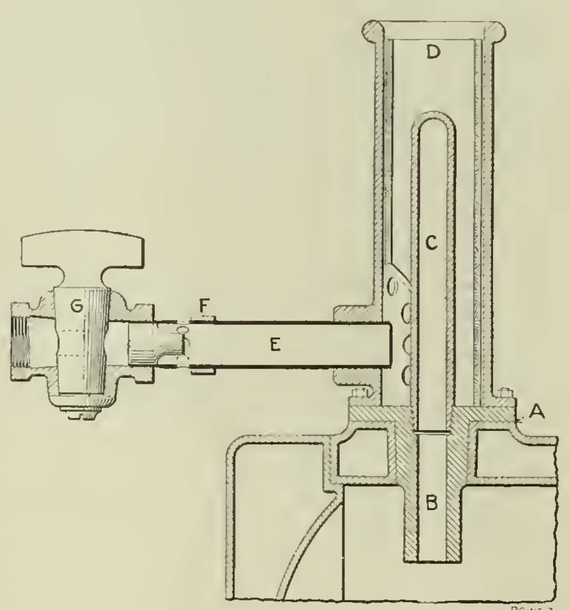
In these days the hot tube is tabooed and not even given consideration by many intelligent men in the gas-engine industry. However, there are thousands of hot-tube igniters in use and a good many are built and sold yearly; consequently, there must be a number of men to whose lot it falls to take care of gas engines equipped with hot-tube ignition. From personal contact with many mechanics, I know that the hot-tube igniter is not universally understood and this article is intended for the benefit of those who are not clear on the subject.

The drawing represents what is most common practice in hot-tube construction today. Mounted upon a pad *A* on the cylinder head or cylinder proper is a flanged bushing *B*, into the upper opening of which is screwed a tube *C* with one end closed. Surrounding this is a chimney *D*, usually of cast iron with an asbestos lining and a boss on one side for the entrance of the bunsen burner *E*. Around this boss are air holes for the admittance of air to prevent the gas flame from smothering in the chimney or from going to the top to get the oxygen necessary to complete combustion.

The bunsen burner is usually made up of a short length of brass tubing with a drilled plug forming the gas orifice at one end. A number of small holes arranged circumferentially about the tube, at a distance from the end about equal to the total length of the orifice plug, forms the air inlet. The amount of air admitted is regulated by a small sleeve *F* which is arranged either to screw or to slide over the holes.

The adjustment of the bunsen burner is one of the most frequent duties of the trouble man. It should never consume more than ten feet of gas an hour for any size of engine and in most cases six feet should be sufficient. Usually an attempt is made to regulate this consumption by means of the cock *G*. This is entirely wrong in principle because it cuts down the pressure and therefore the velocity of the gases flowing through the orifice, and as the amount of air drawn in through the inlet holes depends on this velocity it follows that the air supply will also be cut down and it will be difficult to secure a proper flame.

The proper way to remedy excess of gas is to peen the orifice partly shut and then ream the hole with a fine taper reamer until the proper amount of gas, that is, that just sufficient to heat the tube properly, is allowed to pass. These reamers, ranging in size from a fine needle to a darning needle, may be bought at most large hardware stores for an insignificant sum. A piece of octagon tool steel drilled at one end with a common lathe center drill forms an extremely convenient and mechanical set for closing up the orifice of a burner such as the one shown in the sketch. When the flame hovers at the top of the chimney it is a sure sign that too much gas is being burned or that either the air inlet holes in the burner or those in the chimney are clogged with dirt or that the air sleeve *F* is not properly adjusted and is admitting too much air. It is impossible for the manufacturer to make the gas orifice just right, as local gas pressures vary to such an extent. Should the bunsen tube cause trouble by burning back at the orifice it is probable that not sufficient gas is being delivered and that the orifice should be made larger, or else that the air sleeve *F* is not open far enough. Of course, this may happen in lighting the burner if the flame is applied before the mixture has had sufficient time to fill the tube *E* and attain some velocity through it.



Sectional Elevation of a Typical Hot-tube Igniter

In piping the burner to the source of supply, it is best and often necessary to take the gas from the illuminating pipe line; if taken from the power-supply pipe, it must be drawn from the meter side of the gas bag to avoid the fluctuations in pressure set up by the intermittent suction of the engine. In certain cities a gas bag is prohibited and small gasometers are used which are sealed with oil. To prevent starting the engine with the main gas cock closed and thereby drawing the sealing fluid out of the gasometer into the pipes, the hot-tube connection is taken off between the shut-off cock and the gasometer, on the meter side of the engine; this insures that the tube will never be heated sufficiently to start unless the main gas cock is turned on.

The chimney *D* is a simple casting. The asbestos lining should always be kept intact, as the proper heating of the tube is assisted by it. The tube is usually made of a piece of wrought-iron pipe with the end welded over or a piece of nickel-steel rod having a hole drilled almost its whole length. The nickel-steel tube is far preferable, its life being from six months to a year, under average conditions, while a wrought-iron or mild-steel tube may last only a few days or weeks. The thread is usually either 1/8 or 1/4 inch, gas-pipe size. In former times, porcelain and platinum tubes were used, the former being abandoned probably on account of their brittleness and the latter on account of their cost.

A very important, although apparently minor, part of the hot-tube apparatus is the bushing *B*. First it would probably be best to explain the manner in which the ignition is timed with a hot-tube igniter. I can see the younger gas-engine men smiling at this, but I have seen many hot-tube diagrams showing a regularity of successive explosions which compared favorably with any of those produced by a engine equipped with electrical ignition. It will be evident from the sketch that there is no chance for the tube and the hole in the bushing to be scavenged on the exhaust stroke; therefore, when the piston starts back on the compression stroke with a full charge of fresh gases in the cylinder, these will be forced up through the bushing, compressing the burnt gases ahead of them and possibly mixing for a certain distance beyond the line of contact with them, but this is unimportant as the amount would be practically constant. When the piston has advanced far enough to cause the fresh gases to rise to that part of the tube which is at the ignition temperature, they will be ignited and will shoot a tongue of flame down into the charge in the combustion chamber and ignite it.

Calling the part of the tube and bushing below that point which is heated to the ignition temperature the cool length and the part of the tube above that point the hot length, and bearing in mind the fact that the movement of the fresh gases up the tube will be nearly proportional to the piston displacement at each part of the stroke and that the length of the column of burnt gases will shorten somewhat under the compression, it is clear that a longer bushing, all other conditions remaining the same, will cause ignition to occur later in the compression stroke, because the ratio of hot length to total length is smaller; on the other hand, a longer ignition tube will cause earlier ignition, because the ratio of hot length to total length is greater. Of course, this will not conform rigidly to the laws of compression, as there are too many variables; the proportions must be established experimentally for each design of engine. Further reasoning will show that enlarging the bore of the bushing will cause later ignition, the bore of the tube remaining unchanged.

An example of how these dimensions work out in practice is given in the accompanying table, which presents the practice of one well known engine builder. Unfortunately I am unable to give the exact hight of the bunsen tube above flange here, although it is very close to one inch to the center of the tube. Occasionally the length or bore of a bushing must be changed for some engine which does not come up to the usual performance. This occasions no trouble as a record of the bushings is kept under the shop numbers so as to fill repair orders properly.

It is advisable for a mechanic engaged in adjustments on hot-tube engines not to tamper with either the original length or bore of either the tube or the bushing unless he is prepared to make a thorough test with indicator, brake and gas meter to prove that he is working in the right direction; the long experience and careful work of reputable engine builders are far more efficacious than haphazard field methods. Adjustment of the bunsen burner and of the fuel mixture delivered to the engine will usually cure any ignition trouble. Serious loss of compression is liable to make ignition late and even uncertain, but the fuel mixture in the engine cylinder has considerable effect on the performance of hot-tube igniters. A rich mixture will hasten the rise to maximum pressure and a lean mixture will delay it; I am not able to say just how the mixture affects the rate or the timing of ignition, however.

The bushing B is an important part of the apparatus for further reasons.

Upon one occasion I was called to examine an engine which usually "laid down" about twenty minutes after the full load was applied, the shutdown being accompanied by heavy pre-ignitions and backfiring. Upon reaming the hot-tube bushing I found that it was made of a piece of wrought-iron pipe screwed into a flange and that the joint between the flange and the cylinder was packed with a heavy asbestos gasket. There was also about ½ inch clearance all around the tube in the passage by which it connected with the cylinder. The tube had scaled and wasted away until it was very thin, showing that it had often been above red heat. The cure in this case was to substitute a cast-iron flanged bushing in one piece, with the same size of hole and of the same length, made of sufficient outside diameter to fit the hole through the cylinder wall and having a ground joint instead of packed one, thereby allowing the heat to be conducted away to the water jacket and keeping the bushing reasonably cool.

[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

Had it been possible, the best arrangement would have been to raise the bushing, keeping the original length of hole, so that it projected very little into the combustion space, the free end extending into the combustion space always being liable to overheat unless properly protected as described. This is best placed where the entering charge will sweep over it and keep it cool. Of course, this would cause considerable backfiring if the proper precautions were not taken to conduct a large part of the heat to the water jacket.

In former years many attempts were made at positive timing of hot-tube ignition, this usually being accomplished by a valve actuated by the cam shaft opening the passage to the hot tube at the proper instant. These were of little value as the valve faces and seats were short-lived. Mechanical timing is not advantageous on engines up to 15 horsepower unless operating on gases containing an extremely high percentage of free hydrogen; in such cases it would be far better to employ some other ignition system.

To the best of my knowledge the insurance companies do not distinguish in their rates on gas-power plants between hot-tube and any other method of ignition unless gasolene supplied from a small elevated tank (as is usual with gasolene engines) is used to heat the tube. This is manifestly an extra risk and such an installation should never be allowed except in a small, absolutely fireproof building, such as might be used for a small private plant located in large grounds.

The Status of Gas and Oil Power*

By J. B. Klumpp

The economy of operation of gas-power plants was shown in last year's report to be considerably better than that of steam-power plants, except possibly in those stations where steam-turbine units of larger sizes and most approved design were installed. It is believed that for plants of, say, 2000 horsepower and under, the fixed charges due to investment for gas-power plants, including producers, should not exceed the fixed charges of steam-power plants, including boilers, and it is also believed that the depreciation charges for gas-power plants should not be greater.

What may be considered one of the greatest incentives for the introduction of the gas producer and gas engine is the utilization of low-grade fuels which are unsuitable for use in steam-power development, such as the lignites of Texas, Colorado and Washington State, and the low-grade refuse fuels, as the "culm" of the anthracite-coal mines and the "bone" of bituminous-coal mines. From tests made by the United States Government, and also from the operation of plants installed in the above named districts, it is acknowledged that lignite coal with a high percentage of ash can be handled with efficiency, and from reports of plants in operation, both in this country and abroad, the tailings of coal mines having percentages of ash as high as 50 per cent. have been used with more or less satisfaction. In view of this fact, it is obvious that many gas-producer power plants will continue to be installed throughout certain sections of the United States where such low-grade fuels are in abundance and that central power stations will be erected to distribute electric power at high tension from these points.

The use of anthracite fuel has been successful in a great many types of gas producer and it is in a matter of very little moment which type is adopted for the purpose of handling this kind of fuel—either the updraft, downdraft, suction or pressure type—but the use of bituminous fuels is more complicated and has necessitated the adoption of methods that will produce a gas free of tar and lampblack. For this purpose various meth-

*Part of the report of the Power Station Engine Committee, presented at the recent convention of the National Electric Light Association.

facturers have so designed producers that the tar will either be consumed in the fuel bed, or if appearing in the resultant gas, will be removed by means of special tar extractors. Producers of this type are being made updraft, downdraft and double zone forms and it is fair to say that for a perfect utilization of the fuel at hand, certain modifications must be made in the design and operation of each type of producer to suit the local fuel conditions. In Europe, where the use of gas-producer plants has become more of a general proposition on account of the relatively high cost of fuels and low cost of labor, the adoption of the byproduct installation is more prevalent where bituminous fuels are used than it is in this country. From such byproduct installations a relatively high return can be made from the residuals in the shape of tar and ammonia, but this factor has not been seriously considered in this country, owing to the relative cheapness of fuels and expensiveness of labor; also on account of high cost of the plant necessary to work up these residuals.

During the last few years the design of the gas engine has been simplified in many ways and, while there have been no radical changes in the general type, the construction has been improved by added refinements in the details of the mechanism, and more particularly in the adoption of high-grade materials and the appreciation of the resultant strains and stresses that take place in these materials. This general tendency to improvement has enabled the manufacturers to lighten the engine, reduce the number of working parts, simplifying the machine as a whole and at the same time this general improvement in design and construction has increased the reliability and reduced the repairs of gas engines.

Changes in valve gear have been made by some German manufacturers in returning to the throttling governor. In the same country they also show a tendency to adopt the Lodge system of ignition, which system has no moving parts to the spark plugs, the current being supplied from storage batteries and intensified by Leyden jars, producing a system similar to the ordinary automobile system of ignition.

One of the objections to installing gas-engine units, introduced more particularly by the industrial people, has been the want of auxiliary steam for heating and other purposes, which auxiliary steam is so convenient when a steam-power plant is installed. The opportunity to increase the economy of a gas-engine plant by utilizing the waste heat of the engine jacket water and engine exhaust is apparent and the attempts to do this so far have met with more or less success, but further developments must be made before it can be said to be successfully accomplished.

In discussing the internal-combustion engine, we must not omit those engines utilizing a liquid fuel directly in the cylinder. Such types of engine will always be in demand where the liquid fuels are obtainable at a reasonable cost. The gasolene engine may be included in this classification (this engine having its own special functions, when the high cost of fuel does not prohibit its operation), but in this discussion the heavy-fuel-oil engine only is considered. The method now generally adopted of obtaining power by the combustion of this liquid fuel creates excessive internal pressures in the engine cylinder, which necessitates a high-grade, expensive and heavy engine being built to withstand the pressures. Their use in the past, however, has been very satisfactory, and improvements in design, now constantly taking place, are reducing both their weight and cost. Many engines of this type have been installed during the past year by the American Diesel Engine Company, recently reorganized and now of St. Louis, and the De La Vergne Machine Company. of New York City.

In submitting this report it is desired to bring before the association the fact that development on this line of construction is progressing, and that there are many instances where the gas engine and producer may be installed for our own central-station practice that will prove beneficial to the operator by the economies that will be obtained. The introduction of gas engines for central power purposes will be continued where gaseous fuel is obtainable, either as a byproduct, in the case of coke-oven operation, or where natural gas is available, as the installation of such engines will give economies far exceeding the utilization of the same fuel when consumed under steam boilers. But when such cheap gaseous fuels are not obtainable, the installation of a power plant in each individual case should be carefully studied and the installation, whether gas or steam, should be made on its own merits.

Inspection Plugs for Poke Holes

Mr. Lee's inspection plug, mentioned in the issue of May 16, is worthy of more than passing interest. It is a new application of an old method used by brick and tile manufacturers to determine the temperature of the brick and tile on the inside of a kiln. It had been suggested while the mason was sealing up the kiln door. A piece of 1½-inch pipe 12 inches long was set in the brickwork through the door and when the job was completed a thick piece of window glass was cemented over the outer end of the pipe. This soon smoked up from the dampness of the brickwork and the fresh green fire and the cement cracking allowed the glass to drop from the end of the pipe. The pipe was then plugged with clay until the fires were built up and the contents of the kiln began to turn red; then the clay plug was removed and the glass replaced. This proved very successful and several peep-hole plugs were made in the other kiln doors as well as side walls. We could not obtain mica in those places and the glass had to serve the purpose. The length of the pipe seemed to be such as to provide sufficient dead air insulation to prevent the heat from cracking the glass. I have since seen peep-hole plugs of this kind in use in forge shops for watching the "heat" temperature rise on the work within the forge without opening the door, which would chill the work on the side nearest the door

Corrosion of Water Cooled Exhaust Pipes

In reply to the inquiry under this heading in the May 9 issue, I would say that the preferred method of cooling the exhaust pipe of a large gas engine is by means of a closed water-jacket around the outside of the exhaust pipe proper, the cooling water discharge from the engine jacket passing upward through the pipe jacket. The diameter of the inner pipe should be 10 to 30 per cent. larger than that of the engine exhaust valve to allow the pressure and temperature to drop rapidly. For the first 10 feet of pipe from the engine gray cast iron is most suitable. If bends are required, they must be of large radius. As ample provision for expansion is required, slip joints and rollers under the pipe are necessary.

If internal water injection is applied corrosion is bound to follow, but it can be much reduced by using, as far as possible, extra heavy glazed vitrified acid-proof sewer pipe. Possibly the vitrified portland cement conduit shells, made in halves, in sections three feet long, described in POWER of April 11, can be utilized for this purpose. To enable this type of conduit to withstand the pressure of an occasional explosion in the exhaust pipe, the conduit may be enclosed in a cast-iron or steel pipe, the space between being filled with portland cement grouting; or a thick inclosure of concrete alone will probably hold. Concrete conduit without any protective lining will not stand up as well as it is porous and likely to disintegrate. No matter what construction is used, provision must be made for expansion and for cleaning and draining.

Check Valve in Blowoff Pipe

A few years ago I was engineer in a plant containing two 60-inch by 16-foot return-tubular boilers, set in one battery. The blowoff pipes connected to a single pipe in the rear which led to the sewer. Boiler No. 1 was cut out for cleaning. When I entered the boiler I forgot to close the blowoff valve. After inspecting the inside I had just crawled out when the fireman opened the blowoff valve on No. 2 boiler and steam and hot water rushed into No. 1 boiler. Had I been a minute later I would have been scalded. The next week I got two 2-inch swing check valves and put one in each vertical pipe so that the valve would open to the sewer.

The fireman said it was only wasting brass putting them in. He is now engineer at the plant, and on a recent Sunday was in No. 2 boiler when his fireman opened the blowoff on No. 1. The hot water and steam rushed up the blowoff pipe and striking the disk closed the check in the blowoff pipe of No. 2 boiler. He told me that the check valve had saved his life, as he was directly over the blowoff pipe, examining tubes and braces. His candle was extinguished and enough hot water and steam got by the check to scald his arm slightly. The check is always open and does not interfere with the blowing off of the boilers and requires very little pressure in the opposite direction to close it.

Friction Load Diagrams

The pair of friction indicator diagrams herewith presented in Fig. 1 are worthy of study. They were taken from an 8x10-inch Ames engine having a 1¼-inch piston rod; the engine ran at 250 revolutions per minute. The diagrams are of the friction load. An outside-spring indicator was used with a 60 spring. The reducing motion was of the pendulum type and the indicator cord was about 2 feet long.

There is no reason for believing that the diagrams do not truly represent the action of the steam in the cylinder, although they may contain some unsuspected error. Under the same no-load running conditions the engine produced diagrams identical to those shown, on different days. It seems, therefore, that the peculiarities of the crank-end diagram are due to the valve action and, possibly, to heat interchanges between the steam and the cylinder walls. That the valve is properly set for normal load is shown by Fig. 2.

The point of release R, Fig. 1, distinguishes the expansion line E from the compression line which crosses it. Assum-

Fig. 1. Diagram of Friction Load

ing the diagrams to be correct, it appears that some exhaust steam is trapped in the crank end of the cylinder and compressed during the return stroke to the highest pressure. It also seems that no live steam is admitted to the crank end as the pressure does not rise as high as on the head end and the steam line falls vertically, instead of rising, at the beginning of the stroke. If this interpretation is correct, negative work is done in the crank end, the piston compresses exhaust steam, which in expanding does not return all the work put into it. Upon this basis, the crank-end horsepower is minus 1.20. As the horsepower of the other end is 3.37, the friction horsepower is 2.17.

Fig. 2. Full-load Diagram

The peculiarities of the crank-end diagram suggest the following questions:

Why does the steam line fall vertically at the beginning of the stroke?

Why does the expansion line cross the compression line?

Why is the back pressure after release less than during the return stroke before compression?

Syracuse, N. Y.

Removed Flywheel Blocking

At one time the plant of which I was chief engineer was shut down for repairs. After the boilers had received a thorough overhauling, the firemen were called in to help put things in shape for starting up. Part of the work was the installation of new piston-ring packing in the blowing-tube cylinder of the vertical 42 and 84 by 60-inch blowing engine.

The engine flywheels had been properly blocked and I was sure that no movement could occur, but some of the men who were putting in a new electric-lighting outfit, wanted some blocking and removed it from the flywheel. This left the large engine unprotected and placed lives of three men working in the blowing tub in jeopardy.

Entering the engine room I noticed that the blocking had been removed and lost no time in getting a piece of steel rail, and placing it between the spokes of the flywheel to prevent it from turning. Then I told the men to drop everything and come out.

A commotion was heard inside as three men, one of them a nervous Swede, tried to get out of the manhole at once. Finally, the two men managed to break the Swede's hold and one held him down while the other climbed out. When the Swede got outside he beat it for the door and that was the last I ever saw or heard of him.

The piston remained in place for about 10 minutes more. I had just got the boys to work blocking the wheel once more, when the rigging gang, hoisting a connecting rod into position on one of the other vertical engines, let go of one end which swung with considerable force against the blowing tub. The flywheel immediately turned, but the rail stopped it before the piston moved more than 30 inches of its stroke. The rail certainly did its work for the three men would have been killed had the piston moved when they were working inside.

I read an account some time before this occurred where two engineers were killed because they neglected to properly block a flywheel while working in a cylinder.

Putting in Gage Glasses

When putting in gage glasses I have noticed that in nearly every case the little washer that is furnished with the connections is put in the bottom of the nut on top of the gasket.

The proper place for it is between the gasket and the threaded end of the connection.

The washer in this position makes a division between the gasket and the connection and the nut can be turned without the gasket sticking and bunching up in the connection, as it is almost sure to do if the washer is not properly placed.

I have found it good practice to smear the glass and washer with finely powdered graphite, before putting them in place. This prevents the gasket from sticking to the glass, which will crowd the glass and possibly cause it to break. The graphite should be put on dry, as oil will rot the rubber.

Faultily Marked Corliss Valve

A simple 16x24-inch Corliss engine pounded badly. Each shift engineer took a turn at setting the valve according to the data given by the factory blueprint, and they had failed to stop the pound. The bearings were carefully taken up, but the trouble still continued.

The chief engineer was advised of the trouble and after noting the action of the engine decided it was due to improper valve setting, notwithstanding the fact that the valves were set as per instructions.

The blueprint gave the lap with the wristplate in mid travel as 3/16 inch for the steam valves and 1/16 inch for the exhaust valves, and the lead with the valve gear hooked up and the crank on the dead center as 3/32 inch.

The chief got out his indicator and took a diagram and then adjusted the cutoff rods and took a second diagram. The lack of compression and also the fact that the exhaust was late, causing the toe of the card to point decided him to advance the eccentric. Another diagram was taken which indicated that the engine needed more of the same medicine, but the steam was being admitted too early and caused a hump on the top of the card; also advancing the eccentric alone a reasonable amount would not give quite enough compression. He, therefore, lengthened each exhaust-valve rod a turn and the steam-valve rods a turn and a half each and then advanced the eccentric another ¼ inch on a 6-inch shaft. As a result the pound had disappeared.

Upon examining the factory marks on the valves and eccentric, the steam valves had ⅜-inch lap, and the exhaust valves had ⅛-inch lap when the wristplate was in mid travel. Then the engine crank was placed on the dead center and the steam valves had 3/32 inch lead as per factory direction.

The eccentric had been advanced on a 6-inch shaft so that it stood ¾ inch, by the old marks on the shaft, ahead of its original position.

La Fundicion, Peru.

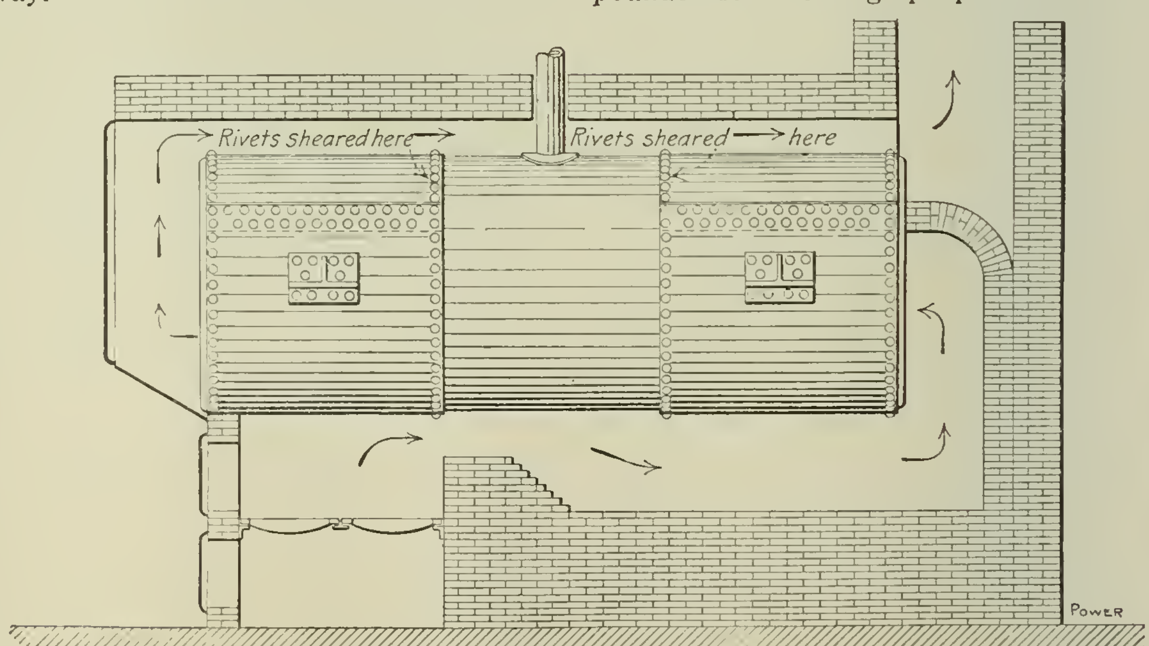
A Boiler Explosion Averted

"Some years ago," said an old engineer, "I took charge of a newly installed power plant. There were two 70-inch by 16-foot return-tubular boilers.

"These boilers had been put in with the idea of superheating the steam by bringing the hot gases back over the top of the shell, as shown in the illustration, the stack being located at the rear end of the boiler.

"Things went on apparently well for a few weeks, but one day I noticed water oozing through the brickwork near the top of the setting.

"It called for an investigation, and upon going in on top of the shell, it was found that in the seam nearest the fire, the rivets had begun to shear, some having been sheared over ⅛ inch. The plates had been left entirely unprotected and as there was nothing but steam on the inside, the seam had begun to give way.



Showing Where Rivets Sheared

"A boilermaker was called and the needful repairs made, after which the top of the shell was covered with fine loam, and no more trouble was experienced. The other boiler was also taken off and the same conditions were also found to exist on the end plate."

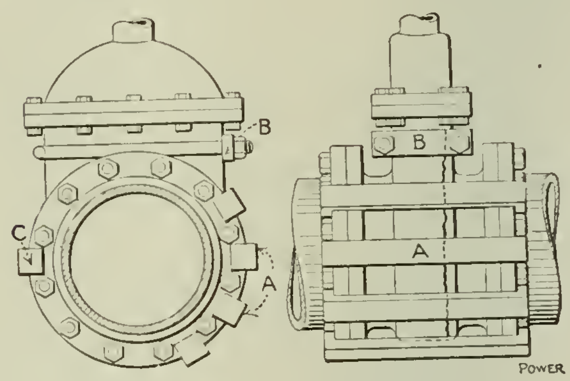
Philadelphia, Penn.

Temporary Valve Repair

An emergency repair job was recently made on an 8-inch gate valve that was in a water line and split, as shown in the illustration.

The valve was drawn together by four ⅝x1½-inch iron clamps *A*, shrunk on as shown. A yoke piece was made to fit around the neck of the valve, the ends



How the Valve Was Repaired

being threaded for nuts which held a cross piece *B* in place on the cracked side of the valve neck. The clamp *C* was used to hold against the other four clamps. This arrangement completely closed the crack.

A Drip Problem

There are two lines of steam piping in the plant where I am employed, one a 12-inch heating main, the other a 2½-inch auxiliary steam main; each pipe is fitted with a reducing valve in the engine room. The boiler pressure is 110 pounds per square inch and is reduced to 5 pounds for heating purposes and 70 pounds for the auxiliary steam lines. The piping was arranged as shown in Fig. 1 before making the change, the drip being piped as shown at *A*. It was made up of 1-inch pipe, taken out of the bottom of the 12-inch ell. A ¾-inch drip was taken out of the tee on the 2½-inch line, with valves placed as shown; both drips were connected to one outlet.

In order to drain the 12-inch main, a hose was connected to the 1-inch drip valve and discharged out of doors. After

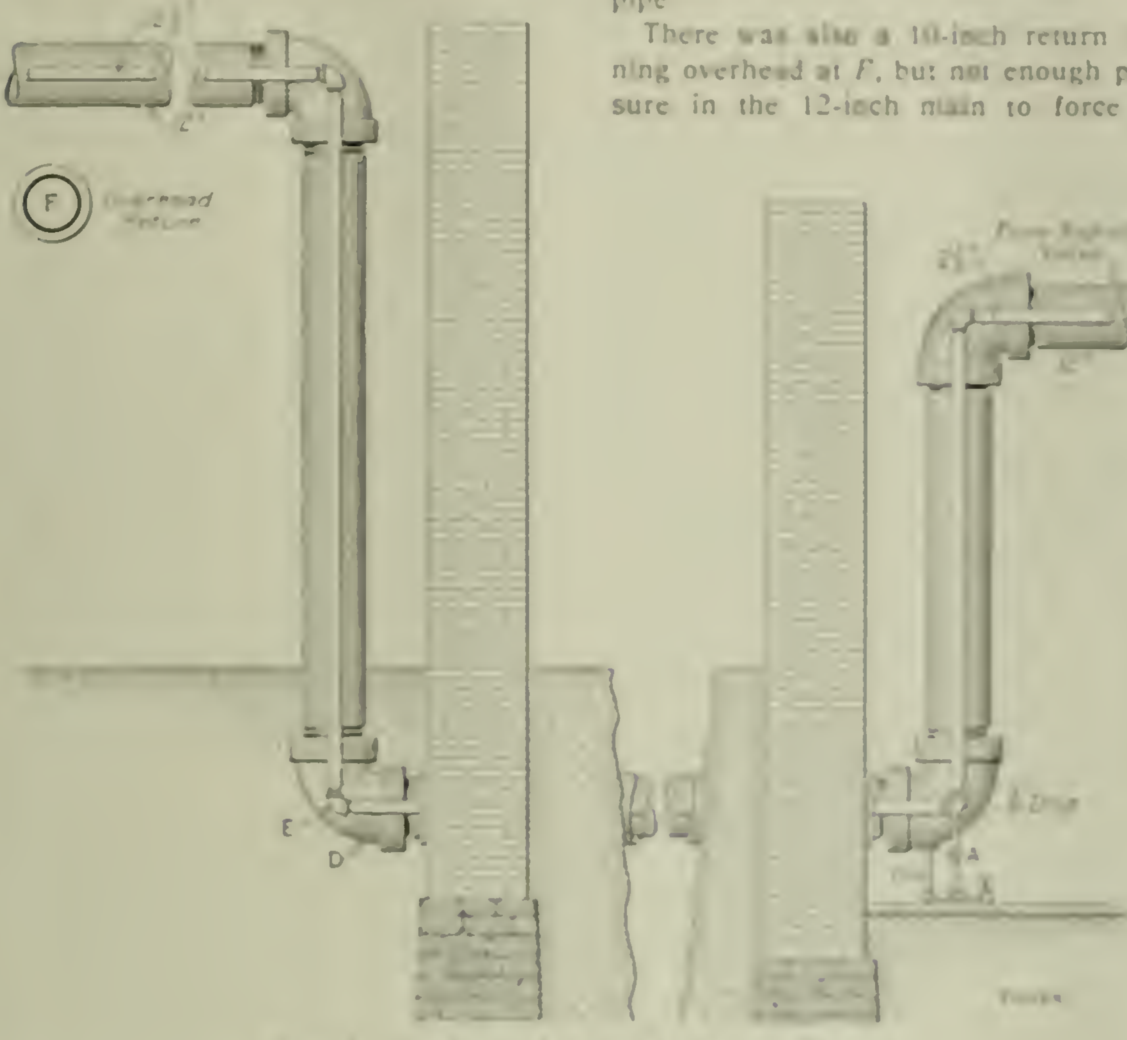

Fig. 1. Original Arrangement of Piping

opening the valve it sometimes required over an hour to drain the pipe. The ½-inch valve *A* was shut all the time and the steam in the 2½-inch line took what condensation there was over into another building. In the engine room the pipes dropped down a distance of 8 feet and ran out through the wall into a conduit across the street, then into another building, where it ran up 12 feet and overhead to three other buildings. This was an unhandy and dangerous arrangement and caused frequent rumblings in the 12-inch heating main due to water. This necessitated getting busy with the hose and drawing the water out through the drip valve. If anything should happen to the valve *A*, and the drip valve were shut, as is always the case except when drawing out the water, the steam would have a direct flow into the 12-inch main and the high pressure might burst some of the radiators.

Changing this system of piping was not as easy as it would seem. To drain both lines at *A* would mean using two traps, one for the high- and one for the low-pressure steam pipes. I could not put the low-pressure trap at *A* because there was insufficient pressure to discharge the condensation from the trap overhead and across the engine down into the receiver, and there was no space under the floor. Both pipes on leaving the engine room had a slight pitch toward *D* and I determined to drain the lines at that point. The main return pipe from the buildings ran a distance of 20 feet from *D* and 8 feet underground in a 10-inch conduit made of cast-iron water pipe.

There was also a 10-inch return running overhead at *F*, but not enough pressure in the 12-inch main to force the water into it against the low-pressure in the pipe if using an ordinary separating trap. Having an old return trap, I overhauled it and connected it as shown in Fig. 2. I broke the elbow at *E* and arranged the piping as shown. I also drilled and tapped a hole in the bottom of the 12-inch ell, and made a connection to the automatic valve at *N*. The discharge was piped to the return pipe *F*. A 1½-inch relief valve was put in this return pipe and set to blow at 10 pounds pressure so that if anything should happen the valve *N* would not shut tight and the pressure could not increase to a dangerous point in the heating system. The pipe *O* supplied the trap with steam and also drained the 2½ line of condensation, thus draining both lines with one trap.

Mattapan, Mass.

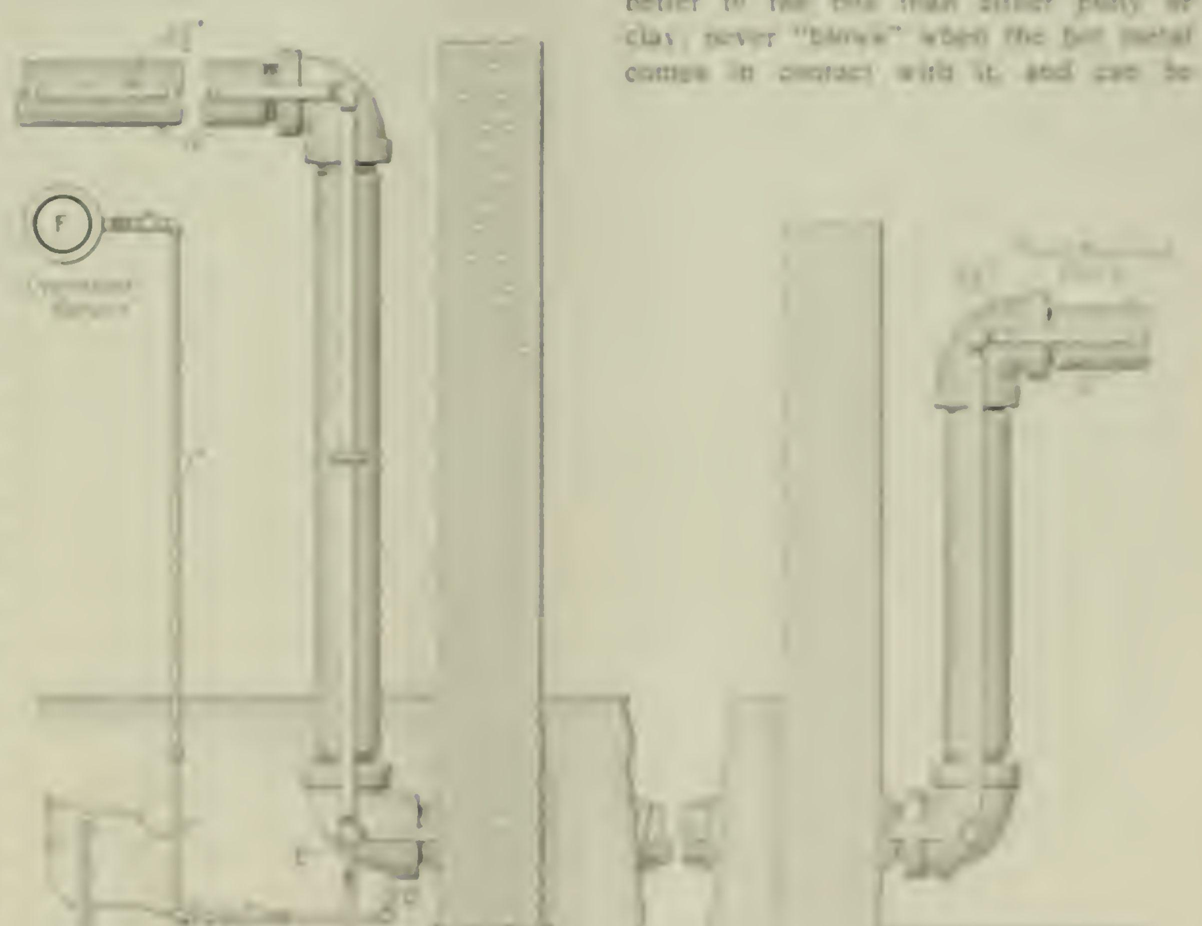

Fig. 2. Separate Trap Connection

Mixture Used in Babbitting Bearings

While visiting the power plant of the Anderson Traction Company recently, at Anderson, S. C., my attention was called to a little wrinkle in babbitting boxes.

Instead of using putty or clay for plugging up the ends of the boxes while the babbitt is being poured, some old asbestos pipe covering is ground up and mixed with cylinder oil to the consistency of a stiff putty. This mixture has these advantages: It is proof against the softening influence of heat, sticks far better to the box than either putty or clay, never "blows" when the hot metal comes in contact with it, and can be used over and over without loss or hard putty.

S. Kirlin.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Did Not Hook On

I submit the following to S. E. Mead, regarding the indicator diagram from the low-pressure cylinder of a cross-compound engine which appeared in the May 23 number. While the diagram from the end which did not hook on shows area, it is negative area. Starting with the piston at the beginning of the stroke, the pressure at this point is due to the compression of the steam trapped by the exhaust valve on the preceding return stroke. While the engine is passing the center this steam loses some of its heat and therefore the expansion line does not follow out the compression line. In this case the expansion line is the lower line of the diagram. The steam on the forward stroke will have to expand to the point of release, which would give a constant drop in pressure if no more steam was admitted to this end of the cylinder. The area of the exhaust port for a velocity of 4000 feet per minute would be about 200 square inches or for a velocity of 6000 feet per minute about 135 square inches.

At the middle of the expansion stroke the steam below the exhaust valve is

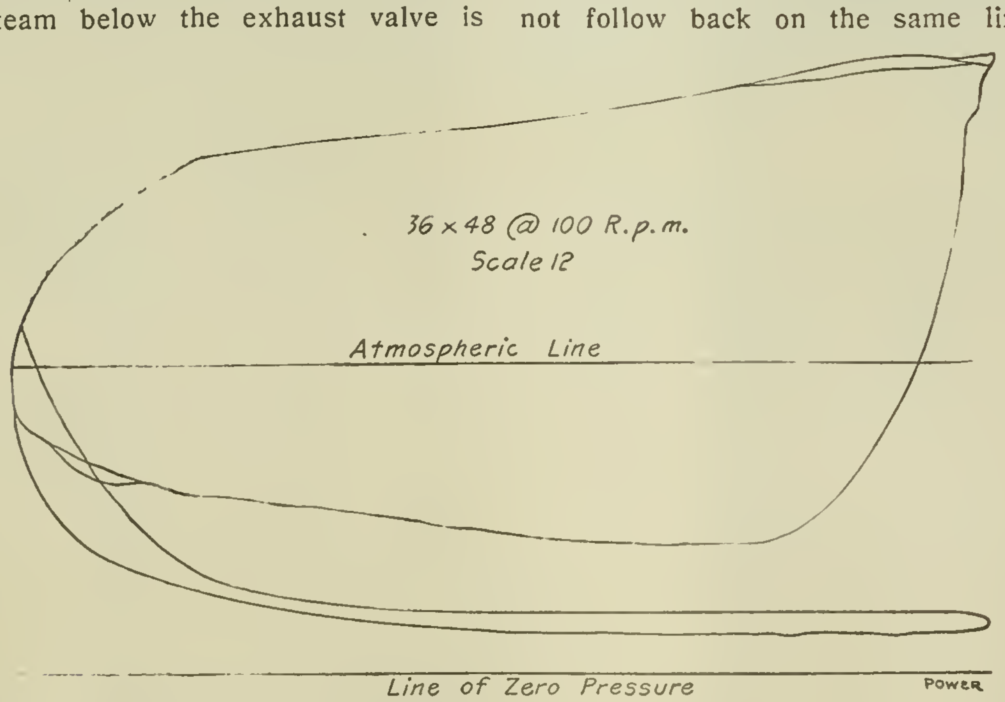

Diagram from Low-pressure Cylinder of Corliss Engine

about 5 pounds higher than that in the cylinder. Taking the smaller area,

135 × 5 = 675 *pounds*

lifting this valve from its seat. I believe this exhaust valve lets a little of this steam into the cylinder and holds up the expansion line.

After the compression begins in the opposite end of the cylinder the condenser removes the excess pressure down to the upper line of the diagram under discussion, the exhaust valve opening, and the pressure in the cylinder raises to that in the exhaust pipe connecting with the condenser.

On the return stroke this pressure holds nearly constant, rising a little with the velocity of the returning piston until the closing of the exhaust valve, when the steam is compressed to the highest point of the diagram, losing some heat and pressure as the piston is nearly stationary when the crank is passing the center.

Lester Fitts.

West Fitchburg, Mass.

Mr. Mead asks why this diagram has any area, why the expansion line does not follow back on the same line as the compression, and why the expansion line runs practically parallel with the atmospheric line.

In experimenting with an indicator a few weeks ago, I prevented one steam valve from hooking on and took an exact duplicate of Mr. Mead's card except that mine was from the high-pressure cylinder.

Consider the diagram to have been taken from the head end of the cylinder and start the diagram just as the piston starts to move from the crank end; steam is then exhausting into the condenser through the head-end exhaust valve. This subjects the cylinder and the indicator connected to the head end to the pressure existing in the condenser, which is practically constant and therefore accounts for the line parallel to the atmospheric line which Mr. Mead calls the "expansion line," when it really is the exhaust and compression line. When the exhaust valve on the head end closes for compression this line takes an upward turn; this is the compression line which ends as the piston reaches the head end of the cylinder.

As the piston starts on the return stroke the steam valve does not open, the exhaust valve is also held closed, the small amount of steam compressed in the head end condenses and expands rapidly, as the volume increases, until it reaches a point lower than the pressure in the condenser; just how much lower this will be than the pressure in the condenser depends on the tightness of the valves and piston.

The area represented by this diagram is work done in moving the piston against the unbalanced pressure between the condenser and the head end of the cylinder. This work is done during this stroke by the flywheel.

A consideration of the different events and their relation to the diagram should make the diagram plain.

Lowell, Mass.

Getting a CO_2 Recorder

The article in the issue of May 9 on The Value of the CO_2 Recorder, written by H. S. Vassar, was very interesting.

I am the mechanical engineer for a Nevada concern engaged in the mining and reduction of copper ores. We have a 10,000-horsepower plant, 160 miles of railroad and extensive shops, employing about 2000 men. The plant is four years old and has been very successful throughout.

I have been given a free hand in operating the plant, the management only demanding that the cost per horsepower per annum be as low as was consistent with proper upkeep.

As coal costs about $6 per ton in Nevada, I have been very keen about anything which would reduce its consumption per indicated horsepower, and so fell an easy victim to the CO_2-machine man when he appeared.

I was getting an evaporation of 9.40 from and at 212 degrees Fahrenheit with coal which analyzed as follows:

Free carbon, 53.5 per cent.; volatile, 35.5; ash, 4.8; water, 6.2; total, 100 per cent. This gave 12,975 B.t.u. per pound of coal and indicated a boiler efficiency of 70 per cent. Daily records of coal and water were kept, recording thermometers were placed in the hotwell, the heater, the econnomizers and the flues, and I also had recording pressure gages on the stack, the forced draft and the steam header. The CO_2 recorder, seeming to be the final touch required to give complete data on the plant and put me in a position to evaporate the last possible drop of water per pound of coal, I placed a requisition for one forthwith. Three months later the machine arrived, without instructions for assembling, piping or operating. I sent for the instructions, which were received a couple of months later. Then I discovered that some of the ground-glass connections were loose enough to leak and not loose enough to get in any packing, but after some experimenting I found that a mixture of glycerin and litharge would seal the opening and not dissolve under the action of the fluids used in the machine.

Then I found that the rubber tubing was old and leaky. It was replaced. The marking pen was poorly made, and after fooling with it for some time I replaced it with a thin sheet-silver pen which we made at the plant. Next the draft obtained by bypassing the economizer proved too small to pull the gas sample through, and this I corrected by putting in an aspirator worked by compressed air. It then developed that the amount of draft must be regulated within very narrow limits; too much pulling the solution through and too little gave no results at all, this feature causing more trouble than any other one thing about the machine.

Of course, there were incidental occurrences along with these; the cotton thread between the float and counterweight broke twice in the night and resulted in mixing the various solutions; then mud kept getting into the water line and choking up the needle-like jet which furnishes power to operate the recorder. I finally got so I could make the machine work for a few days at a time, then something would happen, which meant a complete readjustment throughout.

I believe that for six months I devoted more attention to the machine than to the rest of the power plant, and in that time I acquired sufficient skill to keep the recorder going for a few days at a time.

As a result of my spending so much time in the fire room I improved the system of firing in vogue, made some improvements in the methods of coal and ash handling, and found some air leaks in the flue system which were cooling the gases passing through the economizer. None of these improvements, however, were due to the records from the machine.

During the periods in which the recorder condescended to record, I would select one battery and experiment with the different methods of firing, keeping track in the meantime of the rate of evaporation per pound of coal. I was by this means able to spot a few of the firemen who were too deliberate in their movements when the fire door was open, but I could not get any relation between boiler efficiency and the percentage of CO_2.

McGill, Nev.

Isolated Plant versus Central Station

From time to time I have noticed in the columns of Power articles, both pro and con, regarding the isolated power plant. After reading these articles I believe that both the arguments in favor of and against the isolated plant have very little real bearing on the subject. It seems to me that this is a matter which must be decided individually, as each existing case has its own characteristic peculiarities which must be considered and which enter largely into its determination.

For instance, in the May 23 issue, Mr. Rushmore cites a case as an example where the isolated plant is a great deal cheaper than buying power from a central station and gives very convincing figures substantiating his claims. One cent per kilowatt-hour is certainly cheap for power from a station of only 350 horsepower rated capacity. He has certain existing conditions, however, such as using part of his producer gas for purposes other than power, which practically preclude all thought of getting power from a central station.

On the other hand, there appears in the same issue, on page 822, an editorial which states that the manager of a certain hotel says "that if he had it to do over again he would install central-station current." The editorial further states that if this manager would pay wages that would insure competent engineers to run his plant, he would have no cause to regret having his own power plant; nevertheless, he is not satisfied with his present installation.

Naturally I do not wish to advance this letter as an argument in favor of the central plant; I merely wish to point out the fact that the isolated plant is not universally the better proposition, although it may be so in a majority of cases.

I had a little experience a few years ago regarding the power question in a small shop of which I had charge, where we gave up generating our own power and secured it from a power company.

When I took charge, the power plant consisted of four gas engines, two of which were rated at 50 horsepower each and the other at 30 and 20 respectively, making a total of 150 horsepower. We used natural gas, getting it from the local gas company. Three of the engines were belted to direct-current generators and the fourth to one of the line shafts on the main floor. This equipment was located in the cellar, was difficult of access, and every spring was subject to considerable water seeping in and damaging the machinery.

We had some ten or twelve motors, all smaller than they should be, scattered throughout the shop to run the machines.

The engineer in charge of all of this equipment was getting $75 per month, plus about $25 for overtime, which he managed to put in on some pretext or other. Questioning this man as to the operations of his engines, etc., he told me that the whole plant was very much run down and sadly in need of a thorough overhauling. I also learned, much to my annoyance, that much time was lost in starting the engines in the morning—we were only running single turn—particularly on Mondays, because of losing over Sunday the air pressure in the receiver tank used in starting up. Often about a dozen men would be in the engine room pulling away at the belts, trying to turn the engines over. In addition, we received regular complaints and threats to move from one or two of our tenants on the upper floors who needed power for light manufacturing.

I lost no time in getting at the problem of better power facilities and, after some figuring on the subject, decided to call in a central-station man and see what he had to offer. He agreed to furnish us power on a sliding-scale basis, similar to that spoken of by Mr. Rushmore in the article mentioned above, at the rate of 2½ cents per kilowatt-hour for the first 1000 kilowatt-hours and 2 cents for all over and above that amount. The minimum charge per month, however, must be $150.

This offer was accepted and we immediately began changing over. I found there were large line losses under the old system so we had the entire building rewired and, as far as practicable, particularly on the larger machines, we installed individual drives.

The current put in was three-phase alternating current with induction motors. We decided upon this system largely because of the great expense for repairs on the old direct-current motors, the repair work being done by an outside concern.

While this increased the initial cost somewhat, we figured that the continued saving would justify the expense. We also figured that we would only pay for the current actually used and instructions were issued to always stop the motor when changing work on the machines, etc.

Our tenants' agreements guaranteed a total minimum power charge of $50, thus reducing ours to $100.

After the new installation was completed, we disposed of the old engines, generators and motors as well as the engineer. Summing up the whole situation, I found that our tenants were perfectly satisfied and that we were getting better power service than ever before, and at no increased cost. We were also able to run one or more machines overtime as our work occasioned, without the necessity of operating a 50-horsepower engine to run a 10-horsepower motor and pay a man in addition to watch the engine.

I do not deny that it might have been possible to fix up the old plant so that we would have had practically as good results, but I doubt that it could have been done as cheaply, and I also doubt that the cost of our power would have been any less. The installation of an entirely new plant, modern in every respect, would undoubtedly have given cheaper power, but with a small concern such a large outlay of money as this would entail is a serious question.

I give this example merely to show that "circumstances alter cases."

EVERARD BROWN.

Pittsburg, Penn.

Writing for the Technical Papers

I quite agree with Joe Smart, whose criticism on my advice to writers is based upon the axiom, "If worth doing at all, do it well." However, there are altogether too many who are deterred from telling us many interesting facts because they are afraid of their ability and of the labor involved in avoiding mistakes in diction and spelling—and fear that the editor will turn them down. If there is a good story in your system, get it out. When you have got the first one out, others will follow more easily. Of course, it would be real nice if each one of us had a typewriter, an Encyclopædia Britannica, and a Century and a Funk & Wagnalls dictionary. But once having seen some of his ideas in print a few times, and found out how nice the water really is, he is a dead one indeed if he is not bitten with the idea to improve himself. It is at this stage of the game that the suggestions outlined by Mr. Smart should be adopted. The main thing is to get the first message out.

Too many good stories die stillborn, because the writer endeavors to make a literary monument of them and is smothered in the mass of detail raised by his own hand, details which do not affect the worth of the idea, but which cause the embryo author to take a course around the block to reach the house next door. I do not deny the value of writing and rewriting; then rewriting and setting the manuscript to one side, perhaps to be entirely rewritten at a later date. I consider this time well spent, but the new writer, the one I am after, has neither the time nor the patience to do this, though later on he will, if ambitious and properly inoculated with the desire to write.

Before one can run he must learn to crawl and then to walk. The best way for the new writer telling his first story is to tell it in the same way he would relate it to one of his mates. If he has a message, the editor will come back at him to get all he has left out. Of course, this takes time, but POWER has found it worth while to do this.

Cleveland, O.

Belting vs. Electric Transmission

Replying to the communication of Henry D. Jackson, which appeared in the May 2 issue of POWER, I am disappointed, to say the least, that he regards my letter in the issue of March 21 as "taking exception" to his article in the February 14 issue.

A perusal of my letter will, I think, satisfy any impartial reader that the general trend of its subject-matter is in corroboration of Mr. Jackson's exposé of cases where owners of shafting transmission have been "flim flammed" by adopting motor drives.

There is no occasion for commenting on his enlargement and confirmation of several points suggested in my letter. But I do wish to disclaim having attempted to make so thorough an enumeration of advantages of electric drives as to demand designation of a "tabulation of advantages."

As to the additional advantage of motor drives pointed out by Mr. Jackson—that by their use greater uniformity of speed is obtained than by shafting transmission —it is a fact that this is not true in all cases. Occasional drop in voltage and in speed of motors is liable to be experienced with current supplied from the best power plants due to variation in speed of engines or other prime movers, though speed may be corrected more quickly and more easily than with shafting transmission.

The influence which slip of belts has on "production factor," mentioned by Mr. Jackson, cuts a small figure in the average manufacturing plant having properly designed shafting transmission. If speeds are found to fall away from intended ratios, what is easier than to adopt ratios of pulley diameters which will compensate the slip?

One advantage of electric transmission which has not been referred to is that, with or without economy for power, it has wiped out of existence many poorly designed systems of shafting transmission.

Viewed solely from the standpoint of economy for power, the advantages of electric motor drives cannot materialize by the insertion of motors up to the point where the cost of power by shafting transmission balances the cost for power by motor drives. Beyond that point we may confidently look for economy in favor of the motor drive; but no hard-and-fast rules can be laid down to be safely used by tyros in determination of that point. Each proposition for substitution of shafting drive by motor drive, or choice of initial installations, must stand on the merits of conditions, and for successful determination the conditions require intelligent and disinterested engineering analysis.

Average American manufacturers pride themselves on their alertness in adopting improvements that are conducive to economy, but when it comes to inaugurating improvements they are seldom moved to engage advice beyond their own organization. It is not until mistakes have become unendurable that they are brought to realize that something different might have been.

FRANKLIN VAN WINKLE.

Paterson, N. J.

The Need of License Laws

There have appeared in recent issues of POWER several articles on how the average engineer might better his condition and fit himself for promotion. I hearily agree with the suggestion that each State or city adopt license laws. If an engineer were compelled by law to satisfactorily discharge his duties, many of the accidents occurring today would be avoided. During a visit to a small country town a saw and cider mill, which also boasted of a small grist mill, came under my observation. There was a small slide-valve engine, about 10x22 inches, running, or trying to run, at about 120 revolutions per minute. While examining the engine I was accosted by the engineer, who was also the owner, the sawyer and the mill operator. Upon learning that I was an engineer he proceeded to enlighten me regarding his experience, to the edification of several spectators, as follows:

"So you be an engineer, be ye? Wal, what dy'e think of that fer an ingine! Never laid out a dollar on her in 15 years. No, siree; never had the cylinder head off. The feller that fixer her up fer me told me not to let anybody monkey with her but myself, and, b'gosh, I ain't either, and she's better'n she ever was.". I remarked that she must be a pretty good engine to run that length of time without any repairs. "Wal, the feller that fixed her up was a mighty good mechanic, but he did have a job to rig her. Yer see, when ther ingine first come here ther blamed stuff that goes in the cylinder was all broke ter pieces and was sent in a pail. That feller ha'd some job fixing them pieces together. He said he had to buy a bigger biler as ther old thing was leaky and didn't hold steam enough."

I said that probably the piston was down and that steam might be blowing through to the exhaust.

He replied: "No, siree; how in thunder could the piston get down? It was a tight fit after the feller had got all ther pieces together, for he had wired them all up. As he hadn't taken ther cylinder head off how in thunder could ther durned thing cum down?"

As I watched him he prepared to saw a log, having obtained the necessary steam. As soon as the log approached the old engine slowed up badly.

He explained this by saying that, "Ther governor took some little time to git a hold on her; she didn't always work that way."

Let those who oppose the passing of a license law visit such a plant as the above and I am confident they will cease their opposition.

Bridgeport, Conn. H. TAYLOR.

Piston Rings

In Lloyd V. Beets' article on packing rings in the May 2 number, Mr. Handley's sketch showing side plates fastened on the ring lap with small screws is a poor apology for a joint and there is not much merit in the lap joint offered by Mr. Beets. I have had these same joints

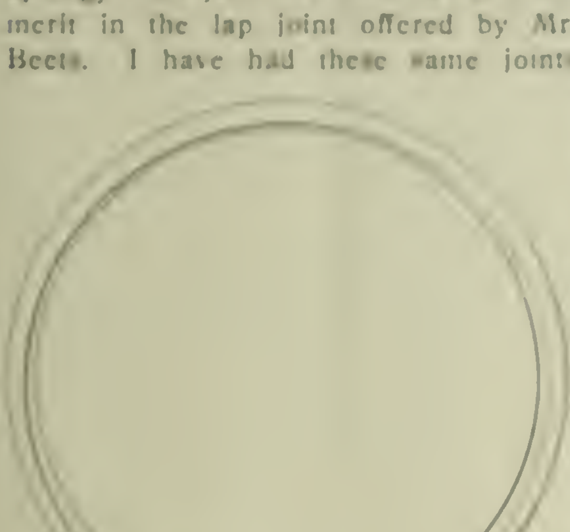

FIG. 1. ONE METHOD OF MAKING TIGHT PISTON

to contend with in practice, both to repair and to replace, and the small screw that holds this lap in place can never be kept tight. The only way to make this joint secure is by using rivets of brass or copper. The small springs will not stay in place for long, and when they wear off will cut the cylinder or the side plates. Both constructions from a practical point of view are useless and unsafe.

Fig. 1 shows one of the better ways of making a tight piston, the block *E* at the bottom of the piston being simply a section turned to fill the groove. With a well formed ring making a joint at *M* on either side there will be no doubt about making a satisfactory job. I have seen this type of ring give satisfactory service after being in constant daily use for a period of 10 to 12 years. The tension of the ring keeps the joints in contact until the ring has been completely worn out.

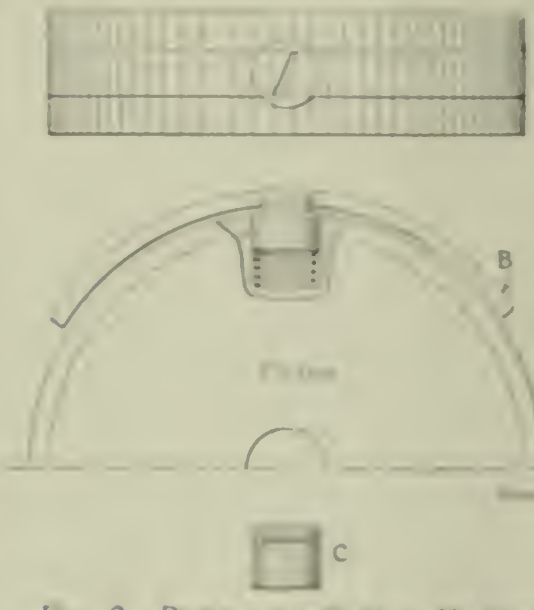

FIG. 2. PLUG AND SPRING METHOD

Fig. 2 shows another method of making a good ring joint. A bronze plug is sunk into the ring groove, as shown, with a heavy spring beneath it to set it out. As the spring is placed beneath the plug there is no chance for it to break and damage the cylinder. A ring fitted to the groove, with a dowel on the side so that the ring will not turn too far, will insure a good tight piston. The ring is shown set out of place at *B* in Fig. 2 and a cross-section of the ring at *C*.

C. R. MCGAHEY.

Baltimore, Md.

Return System

In the April 18 number, page 610, William Bopp asks if the drips from the steam mains, separators, reheating coils and four engines which are collected in a manifold in the basement 20 feet below the boiler water line, and having 10.5 pounds pressure less, can be returned to the boiler by the Holly system.

The condensation in this manifold may be returned by a Holly system, of which the discharge chamber has a vertical hight of 42 feet from its bottom end above the boiler water line, the diameter of the riser and other pipes to be determined by the size of the job, of which no mention is made. The average Holly receiver is 30 feet below the boiler water line, and many of these are 50 feet or more.

RUSSELL B. HOBSON.

New York City.

Test for Valve Leakage

In answer to S. Kirlin's article in the issue of April 25 referring to the high steam consumption of a four-valve engine, I would suggest that if he close the steam and exhaust valves, open the indicator cocks and the throttle, he will see a display of high-pressure steam that will explain to his entire satisfaction that the cause of the high-steam consumption of this engine is not the long dry pipe but leaky valves.

Many engineers will no doubt be surprised to learn that the loss due to valve leakage amounts, in many cases, to 50 per cent. or more of the steam used.

O. H. LINDEMAN.

New York City.

Central Station Failure

The failure of central-station service due to fire or other acts of Providence certainly furnishes a strong argument in favor of the isolated plant.

Such an instance occurred recently in the central district of Philadelphia when an early morning fire damaged the plant to the extent of about $250,000 and interrupted the service for several days. While the actual fire damage was comparatively small, it resulted in temporarily putting the entire plant out of commission and in causing immeasurable inconvenience to its consumers.

As the result of this failure of service many small manufacturers were unable to operate their machines and had to dismiss their employees. In some of the large office buildings it was impossible to run the elevators and many business men and clerks had an enforced holiday. In some of the large stores the loss of power for elevator and for lighting service made it necessary to suspend business. This caused a loss of about $250,000 in sales alone.

These few instances serve to show the large financial loss that manufacturers, mechanics, business men and merchants may suffer through getting their service from a central station. It now remains to be seen whether they will profit by their experience.

In abandoning their isolated plants many of power overlook the possibility of such a contingency as cited above, and would be their sorrow they have found to be small. Possibly, if they take advantage of the Philadelphia instance's experience, overhaul their power plants and secure the services of an efficient engineer at a suitable salary, they may be surprised to find that not only are continuity of service and independence assured, but that there is also a saving in the cost of power. Such a result is not impossible.

C. WISE.

Philadelphia, Penn.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Effect of Eccentric Advance

What effect has increasing the angle of advance of a plain slide-valve engine eccentric on the amount of port opening?

C. N. M.

It does not affect the port opening because it does not change the valve travel. The effect of angular advance of the eccentric is to bring all of the events earlier in the stroke. Lead and compression are increased and release and cutoff hastened.

Momentum of Railway Train

A railroad train weighs 600,000 pounds and is running on a level track at the rate of 45 miles per hour. Suppose the steam shut off and no brakes applied. How far will it run before coming to rest?

J. McC. C.

The train velocity in feet per second would be

$$\frac{45 \times 5280}{3600} = 66 \textit{ feet}$$

The energy stored in the train would be

$$\frac{WV^2}{2g} = \frac{600{,}000 \times 66^2}{2 \times 32.16} = 40{,}634{,}328 \textit{ foot-pounds}$$

The sum of the products of the average resistances into the distances through which they are overcome must equal this number. Each axle bearing, for example, has a certain resistance to turning which depends upon the weight it carries, its diameter, its condition as to smoothness, temperature, lubrication, etc. This resistance measured in pounds applied at the radius of the bearing and multiplied by the number of feet through which a point on the surface of the bearing would travel would be the number of foot-pounds absorbed by this particular bearing. Then there is the rolling friction of the wheels on the track, the friction of the engine pistons, valves and connections and the windage, a very important resistance when the speed is high and diminishing as the speed increases.

The subject of train resistance is a complex one and not enough is known about it to solve the present problem with the information given.

Opening of Drain Cocks

Should the drain cocks on the cylinders of a duplex pump be open when starting up?

E. S. H.

Drain cocks are provided on steam cylinders for the purpose of drawing off any condensation that may interefere with the proper action of the machine. While no material damage may result from the starting of a direct-acting steam pump, as would be in the case of an engine, the pump will start more easily and more quickly with steam than with water. Some engineers allow the drain cocks on steam pumps at the end of long steam lines to blow a little all the time to make sure that water does not accumulate in the cylinders and make the pump action irregular.

Alternating-current Generator and Motor Speeds

Does the speed of an alternating-current generator affect the speed of an induction motor taking current from its circuit?

H. E.

Yes; the speed of the motor is directly proportional to the frequency, under any given set of operating conditions, and the frequency is determined by the generator speed.

Transformers

How many kinds of transformers are there?

H. E.

That depends on what you mean by "kind." There are single-phase and three-phase transformers; also constant-potential and constant-current transformers. Any of these may be of either the core type or the shell type. Read Mr. Meade's article in the issue of March 29, last year.

Effect of Pulley Coverings

Does covering a pulley increase its efficiency? Is canvas a suitable covering? What kind of cement is used to hold it? Can a steel pulley be covered as effectively as a wooden one?

E. L. D.

Pulley coverings increase the friction of the belt; consequently the power that may be transmitted is also increased. Canvas is frequently used and is secured by glue. Steel and iron pulleys may be as readily covered as wooden pulleys if the metal is cleaned and painted.

Object of Two Eccentrics

What is the object in placing two eccentrics on Corliss engines?

O. T. E.

An additional eccentric was first put on Corliss engines for the purpose of getting an early opening of the exhaust valves without reducing the range of cutoff. Incidentally, it is used to provide for a range of cutoff beyond half stroke.

Water and Oil in Compressed Air

We have been experiencing trouble from water coming through with the air from our compressor. Sometimes small particles of oil will pass. The air, as it leaves the compressor, is warm and it occurs that if this air were cooled to a point lower than it would again become and drained at the point of lowest temperature, that it would not again form water.

O. J. B.

An aftercooler, as it is called, built something after the manner of a closed feed-water heater, or a surface condenser, will lower the temperature to a point where most of the water will separate from the air. From the aftercooler the air should go to a large receiver with inlet at the top and outlet about half way up on one side. Here the remaining water and oil will fall to the bottom and may be drawn off.

Curing Premature Ignition

A single-acting gas engine runs smoothly at light loads but thumps badly from premature ignition when fully loaded. The compression can be changed by screwing the piston rod into or out of the crosshead block; will that help matters?

E. B.

Possibly, reducing the compression by screwing the piston rod into the block one or two threads may cure the trouble. It is possible, however, that your ignition is advanced too far for full-load conditions. Better try adjusting the ignition for less advance before you make any such fundamental change as altering the compression. Also examine your exhaust gas and see if it is black and sooty; if it is, the premature ignition is due to too rich a mixture.

POWER

A Heating and Ventilation Department

For some time there has been a demand for a heating and ventilation department. We have, of course, published articles on these subjects from time to time, but there has never been a definite location in the paper to which readers interested in such matters could turn and find all the material contained in any one issue.

Beginning with this issue the new department will alternate with the refrigeration department, therefore appearing every other week. Material such as will be useful to the practical operating engineer is specially solicited, although some consideration of the fundamental underlying principles and directions for figuring the amount of heating surface required, the amount of boiler surface necessary to supply it, etc., will not be out of place.

"Old Sol" will, of course, deliver all the heat that is necessary for the present, but now is the time to get the system in shape for next fall. Tell the other fellow the troubles you have had and what you are doing to overcome them. We need this kind of material to make the department a success.

The Central Station Viewpoint

The article on "Analysis of Industrial Power," which appears elsewhere in this issue, is representative of the central-station point of view. Undoubtedly, in many small plants the cost of power is figured without due regard to the fixed charges; items of interest, depreciation, and obsolescence are ignored, and as a result the apparent cost represents the operating expense only.

All items which legitimately belong to the fixed charges should be included; but, as a rule, the central-station advocates are not content to play the game fair, and insist upon burdening the isolated plant with all sorts of fictitious charges. These tactics are employed in order to offset the enormous overhead and distribution charges which the central station is forced to carry. The isolated plant does not have to pay a *franchise tax*; it does not have to pay high-salaried officials nor expert solicitors for canvassing new business; and it is not burdened with the initial cost and upkeep of an elaborate distribution system.

According to the reports of the Public Service Commission, the actual operating expense of a large central station in New York City forms only twenty-six and one-half per cent. of the total cost of production, the remaining seventy-three and one-half per cent. being made up of overhead and distribution charges. Furthermore, this same company is capitalized at over four hundred and forty dollars per kilowatt of rated capacity. Considering that a small up-to-date plant may be installed for about one hundred dollars per kilowatt capacity, the comparison is striking. In view of the foregoing, it would make interesting figures if some of the arguments of the central-station people were applied to their own plants.

Reverting to the previously mentioned article, a statement will be found to the effect that tenants in a building are obliged to pay a *pro rata* share of the plant investment and other fixed charges; hence, when comparison is to be made between two similar plants only the operating costs need be considered. Granting this, why should the plant be charged again with these fixed items of expense when comparison is to be made with central-station service? Surely the tenants' rent is not reduced.

Furthermore, it is contended that a plant should show a return upon the capital invested equal to that of the average manufacturing business. This is the "marginal principle" upon which we have expressed opinions on several occasions. It will suffice to say that this principle is applicable only when a man is at the limit of his credit.

In Table 1, which represents a report for an isolated plant using exhaust steam for heating, provision is made for the time and thought given to the management of the plant by the superintendent. In Table 2, however, which represents a report covering a case where power is purchased from a central station and a separate heating plant is installed, the superintendence item is omitted. It would seem that the supervision and attention in the second case would require nearly as much of the superintendent's time as in the first case.

Again, it is claimed that the presence of a power plant materially increases the insurance rate on the rest of the building. This contention is groundless, for where the requirements of the building laws and the Fire Underwriters' Code are met, it has no effect upon the rest of the establishment.

Perhaps the most absurd contention of all is that which refers to the loss of output due to a variation in voltage in the case of the isolated plant, and a consequent charge against the plant to cover this loss. While it is true that few small plants are equipped with voltage regulators, still, with a good engine governor and a watchful attendant the voltage should be kept within two or three per cent. If it varies as much as five per cent. there is something wrong with the equipment or the method of operation, but the isolated plants as a class should not be held accountable.

Where there are a number of customers supplied from a central station by a feeder of considerable length, it is impossible for them all to receive current at the same voltage. If the regulation at the switchboard is effected so as to supply those nearest the power house at the specified voltage, those at the end of the line suffer, and *vice versa*. In any event, there is a significant drop in voltage which is apt to be greater than that in the average isolated plant.

As there are two sides to every argument it is only fair that both the central-station and the isolated-plant advocates be heard. However, the intelligent engineer or superintendent will not be misled by unreasonable claims of either side but will select the sound arguments and formulate his opinions thereon.

Ignorant or Careless?

One State and one municipality have this year taken steps forward in the matters of engineers' licenses and boiler-inspection legislation. On the other hand, bills providing for such supervision have been turned down by the legislatures of Colorado, Connecticut, Indiana, Iowa, Maine, New Hampshire, New Jersey, New York, Oregon, Pennsylvania and Rhode Island. Just why such reactionary and unsound views should be held by the legislators of these States is not clear.

We have been reliably informed that since the creation of the Board of Boiler Rules by the legislature of Massachusetts, there have been installed in New Hampshire, Connecticut and Rhode Island boilers that have been forbidden entry and installation in Massachusetts because they were manifestly unsafe for power-plant purposes.

By what mental process a Connecticut law maker arrives at the conclusion that a boiler which is unsafe in Massachusetts is safe in his own State is not easily imagined. Why a New Hampshire legislator is willing to have his State called the dumping ground for worn-out Massachusetts boilers or is opposed to having it known as a commonwealth where some regard is paid to the common safety of its people is also very obscure. In fact, it is incomprehensible that any class of men could be so completely forgetful of the duty they owe to society as to deliberately sidetrack or kill any proposed measure to enhance public safety.

It is not to be expected that legislators should know all about these things without being shown, but it would seem that the most ordinary degree of intelligence and common regard for human life would prompt them to investigate the merits and meaning of measures of the kind under discussion before condemning them. It is assumed that legislators have ordinary intelligence; if this assumption is justified, then some of them evidently do not care anything for the hazard to life and property represented by an uninspected or improperly operated steam boiler.

Opportunities for Self Advancement

There has never been a time when the young man had more or better opportunities for self-advancement than at present. Few consider the strides that have been made within the last twenty-five years or that will be made in the future. Each succeeding generation of young men holds the mistaken idea that the day of opportunity and possibilities to succeed belongs to the past. They lose sight of the fact that success is attained by earnest, hard work.

Looking back twenty-five years, many of us can remember when a boiler carrying one hundred pounds pressure of steam per square inch was out of the ordinary. Men saw the need of high steam pressure and boilers were designed to meet the requirements.

It is but a few years ago that the electric light was in the experimental stage and the electrically propelled street car was unknown. But the opportunity was at hand and as a result artificial daylight has been obtained and street cars are counted by thousands.

The gasolene engine is another instance. The possibilities of this type of prime mover were made apparent, and from the once unreliable unit used to run a wood saw, gasolene engines are now built in capacities ranging as high as 5400 horsepower.

So fast have been the developments along mechanical and scientific lines that we take a new discovery or invention as a matter of course, exclaim "What next?" and go on with our work. Men pay the toll for a wireless message much the same as they would for a shoe shine, and seldom consider the thought and energy which have been expanded in perfecting the wireless apparatus.

An engineer may say, "I am not an inventor." He does not invent, it is true, but every engineer can discover some method whereby power can be developed cheaper than under old conditions.

Every man has his opportunity. Some profit by it, others do not see it at all and others think it is not worth while.

One thing to remember is that when the chief engineer of a plant wants an assistant he will not select the man who has not shown that he has qualifications for filling the position.

Every chief has his eye on his subordinate, and unless the man can show that he is capable and willing, has original ideas and exercises them, besides having a practical knowledge pertaining to his work, he cannot expect that he will be the fortunate candidate for advancement.

It is not a bad idea to learn to work, but one cannot do that while looking at the clock with one eye and for Saturday night with the other. One of the mistakes made is to assume that a certain work is beneath one's dignity. The successful men are those who have formed the habit of doing the best they know how, no matter what task has been given them. A capable workman will not be asked to do the common work after he has shown his worth. Giving a dollar's worth of work for eighty cents' worth of wage is a practice that leads to ultimate success. It is the man who fears he will give more than he receives who fails to see the opportunities as they appear.

There are opportunities before you now. They will be before you tomorrow. Wake up and make use of some of them.

In all phases of the steam engineer's vocation there are efforts and resultant achievements and the intensity and intelligence of the efforts determine the value of the achievements. Perfunctory, half-hearted effort never "gets anywhere"; neither does ignorant groping around, however vigorous.

Have you noticed how some men neglect the oil supply and then wonder why that bearing ran hot?

Have you ever noticed how overbearing some chiefs are with the firemen and ashmen?

Recording instruments in a power plant are valuable instruments, but if you do not know how to read and handle them they might just as well be in the other man's plant.

Leakage past a solid plug or piston valve is a hard matter to determine, but that there is leakage is well known. The amount depends on many things; probably the first is the quality of the material of which the engine was built; the second, possibly, the accuracy with which the engine was built; and, thirdly, the care with which the engine is handled.—*The Engineer*.

Heating and Ventilation

Considered as power plant problems. Layout and operation of systems and apparatus

The National District Heating Association

The third annual convention of the National District Heating Association was held at Pittsburg, Penn., on June 6, 7 and 8. The sessions were held in the banquet hall of the Fort Pitt hotel, the first being called to order at two o'clock on Tuesday afternoon, when President George W. Wright, of Baltimore, presented his annual address and the association was welcomed to the city by representatives of the mayor and the Chamber of Commerce. E. J. Keifer, of Easton, Penn., presented a progress report of the committee on data and the committee was continued to complete its work, which has been largely preparatory.

At this and subsequent sessions the following papers were presented, several of which with their discussions will be treated at length in other columns and issues: "Investigation of the Transmission of Heat through Radiating Surfaces," by Prof. John R. Allen; "Heating Franchises," by A. C. Gillham; "Results of Measuring Station Load by Venturi and General Electric Meters," by F. C. Chambers; "The Heating and Ventilating Equipments of the City Investing Building, New York City," by J. Byers Holbrook; "The Preparation of a Rational Rate System," by R. D. De Wolf; "Superheated Steam," by W. E. Dowd, Jr.; "Handling Customers," by George W. Wright; "Best Systems of Radiation for Economy and Steam Consumption When Fed from a District Heating Station," by Walter J. Kline; same for hot water, by A. C. Rogers.

On Tuesday evening the delegates and visitors were entertained at the Grand theater. On Wednesday afternoon they were taken to the Westinghouse shops, and in the evening a reception was given upon the roof of the Oliver building, which was handsomely illuminated and decorated for the occasion. On Friday they were the guests of the National Tube Company at its McKeesport works.

The election resulted in the choice of the following officers for the ensuing year: A. D. Spencer, Detroit, president; W. Patridge, Springfield, Ill., first vice-president; R. D. De Wolf, Rochester, N. Y., second vice-president; Cadwalader Evans, Jr., Pittsburg, third vice-president; D. L. Gaskill, Greenville, O., secretary-treasurer; E. J. Keifer, Easton, Penn., and J. L. Hecht, Chicago, executive committee.

The next place of meeting is fixed by the executive committee, but Chicago was favorably considered.

Hot Water Heating Systems and Methods of Connection to a District Heating System*

By A. C. Rogers

To illustrate this paper a number of diagrammatic sketches have been made in isometric to show to better advantage the different systems of piping, but before describing each illustration, it might be well to state that district hot-water heating is a forced feed and that the best results and greatest economy come from maintaining a gravity flow and outflow to all radiators. By reason of this forced feed all heating systems are very sensitive, some more than others, but as a class very much more than a regular gravity heating system.

A general supervision of house installations when connected to district heating is incumbent upon the engineering department of the heating company. This holds good for hot water as well as steam heating and is largely practised by all companies. In new work this may be easily accomplished but when contemplating heating systems already installed and being locally heated the engineer may expect to meet difficulties both in the system and with the owner. An owner may be indifferent to results and economy when running his own heating plant and yet may be very exacting when getting service from a district company. The engineer often meets with systems that cause him to wonder how heating was ever thought of or accomplished.

Fig. 1 illustrates a single-belt one-pipe hot-water gravity system which was used more some years ago than now, although when properly laid out and installed gives very good results. The feed of all radiators is taken off at the top of the main and the return enters the side of the main. In this system there is a gradual drop in temperature as the water flows along the main, due to the cooled water in the radiators dumping back into the main, and the radiators must be figured for this drop to give the results desired. The method of adjusting for district heating in this case is as follows: The boiler is cut out by putting valves in the flow and return pipes or blank flanges or blind gaskets in flange unions as at *E F*, the expansion tank is cut off by a valve or by capping or plugging the leads to it; the service is cut in by tapping the main at *J* and *K*. Service valves *G* are always put on the service inside of the building wall and the regulating valve *H* is placed on the service return pipe just before leaving the building; by proper adjustment of *H* the results are fully up to all that was ever accomplished by local heating if not better.

In Fig. 2 a system the same as Fig. 1 is illustrated except the system has two belts and in addition to the instructions for Fig. 1 the return has two connections, and regulating cocks *H* are installed on both returns and adjusted to equalize both belts, preventing a short-circuit in either belt and giving an equal distribution.

Fig. 3 is an illustration of the well known two-pipe underfeed gravity system, and the following method is given: Blank off the boiler at the feed and the return and also the expansion tank; tap the feed service in at the boiler as at *J* and tap the return in at the extreme end of the return main away from the boiler as at *K*; this method prevents short-circuiting and promotes a balancing that is otherwise troublesome.

A single-belt two-pipe underfeed gravity system with parallel mains but opposing flow is shown in Fig. 4. The writer would place this system at the head of all underfeed work. The [illegible] of themselves will practically make a balance in the [illegible], and a building, even though quite large, with allowance for the mains can be accommodated on one belt. This system will work by gravity without any pitch to the mains [illegible] the [illegible] of the mains [illegible]. The method of connecting to the district heating may be readily outlined.

Fig. 5 is a sketch of [illegible] a portion of a multiple underfeed system, only the

P—Bypass of full pipe with radiator branches taken off with y's or branch tees.
R—Secondary garage service.
S—Bypass with customary three valves to form it.

headers being shown. When this work is encountered the following connections are made: Tap the main flow header at *J* and tap each return marked *C* at *K*, installing a cock *M* for regulation on each unit; the boiler is blanked off as before at *E* and *F*; by adjusting *M* with an opening in each to suit the duty a balance is made and short-circuiting prevented.

Fig. 6 is a one-pipe forced-feed series system for district work only. The sketch shows first a small pipe bypass *N*; the pipe being smaller than the main favors a flow through the radiator; next a bypass with a cock for adjustment or a union with a disk with a hole of proper size, shown at *O*; and next a full bypass as at *P* with branches taken off with *Y* fittings or branch tees; there are some places, as in Fig. 11, where this is the only arrangement possible, but for house or residence work this system is not now allowed.

Fig. 7 shows a forced-feed heating coil, such as for factory and garage work; the feed is connected to the bottom of the coil and the return is taken out at the top; by this method a full pipe is assured and the coil is self-freeing of air, all air being driven out and no air vents being needed; the sketch shows a coil running along the wall with a right-angled branch and a continuation through to another room; headers cannot be used in this work on account of short-circuits and a return-bend coil is used; where a header coil is met with disks or cocks for regulation in each coil of pipes are necessary.

Fig. 8 shows a method of supplying a garage after heating a residence; the garage service is shown and marked *R*, this system being cut in the return pipe only and for control a bypass *S* with three valves is installed; by this method the garage is fed when wanted and otherwise cut out; when the garage is on, regulator *H* is opened for larger feed and good results are obtained.

The standard two-pipe pressure-gravity system which is locally called "double belt" and is the system most generally used, is shown in Fig. 9; it gives perfect results, is low in friction and balances up with no drawbacks; it is very sensitive though and a trap in a radiator branch is fatal to that radiator; this belt on, say, 20x30 feet can supply 1200 feet of radiation with ample results; larger belts are made in 2-inch and 2½-inch plate sizes. Fig. 10 shows the same system for locations where the radiators are placed in a narrow ceiling; it is a three-pipe belt and gives good results.

Fig. 11, a system installed in a large garage, is a series-pipe job with radiators and coils both. A radiator located on the floor above is shown. The front of the garage having large doors and also a side door with cement floor causes the belt to be carried over the opening; traps are thus formed and while not detrimental to heating with this job, yet for safety when the system is shut off drips are placed on all low points.

Two other systems should be mentioned. In both the feed is carried to the top of the building and fed downward, the return being in the basement. The runs of the mains are similar but the branches for the radiators are different. In the first a single pipe making a vertical series is used in which all radiators on that branch are in series. In the other the radiator branches are fed in multiple and the feed supplies all radiators, while a separate return pipe carries the cooled water from the radiators. Both can be used on pressure work, but the writer would strongly urge the last system for both gravity and pressure work. These overhead systems are recommended for buildings of more than three stories high and where attic room can accommodate the main.

An Improved Heating System

By V. T. K[illegible]

I have been experimenting considerably on our heating system, and have finally got it as I think it ought to be to give good service.

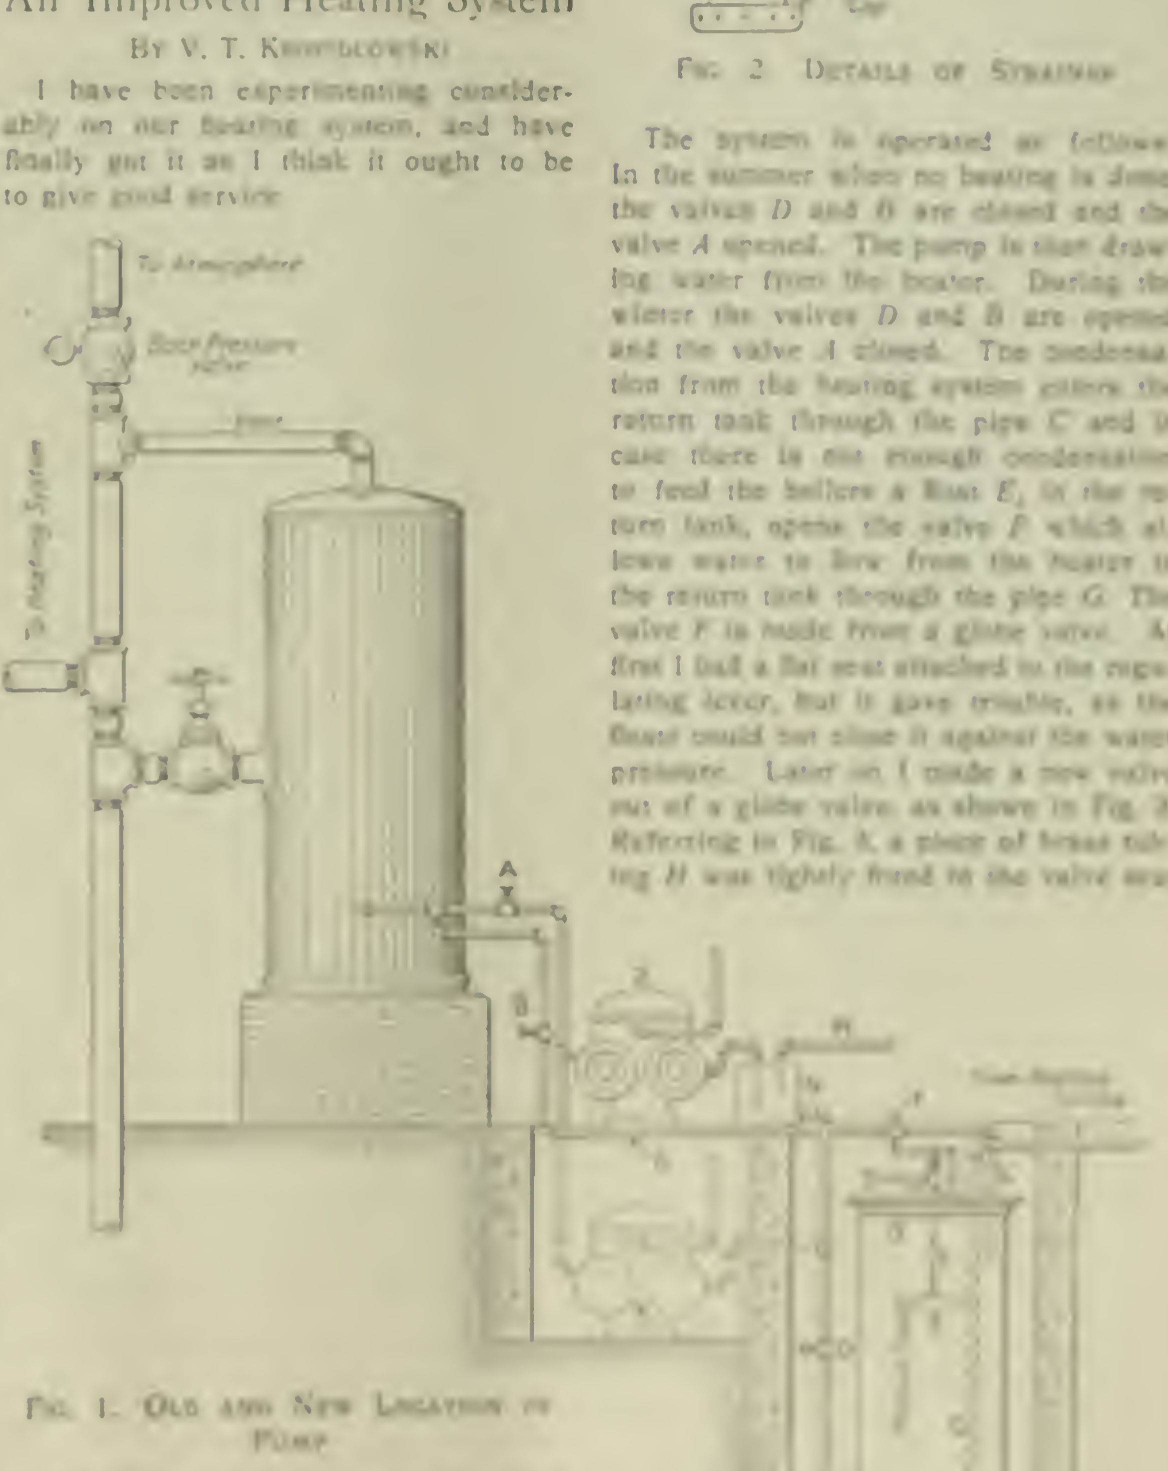

Fig. 1. Old and New Location of Pump

Originally the feed pump was located at *X*, Fig. 1, because it was possible to obtain hotter feed water, as the height of the suction lift was reduced to a minimum. It was soon found, however, that there was still vapor enough to break the vacuum. The pump needed frequent repairs and, as the pit was rather small, the pump was placed as shown at *Z*.

To overcome the vapor trouble I found a small air-tight vessel *N* to use as an air reservoir and connected it up as shown. *M* is the cold-water injector shown in detail in Fig. 2, which is self explanatory.

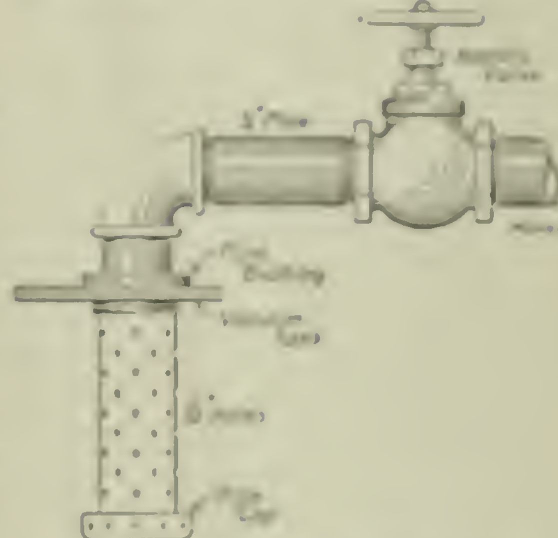

Fig. 2. Details of Strainer

The system is operated as follows: In the summer when no heating is done, the valves *D* and *B* are closed and the valve *A* opened. The pump is then drawing water from the heater. During the winter the valves *D* and *B* are opened and the valve *A* closed. The condensation from the heating system enters the return tank through the pipe *C* and in case there is not enough condensation to feed the boilers a float *E*, in the return tank, opens the valve *F* which allows water to flow from the heater to the return tank through the pipe *G*. The valve *F* is made from a globe valve. At first I had a flat seat attached to the regulating lever, but it gave trouble, as the float could not close it against the water pressure. Later on I made a new valve out of a globe valve, as shown in Fig. 3. Referring to Fig. 3, a piece of brass tubing *H* was tightly fitted to the valve seat and a brass plunger J was turned to the form shown and fitted to the brass tubing so as to work freely. The holes K and L were drilled at a proper location and the stem screwed into the plunger.

Water enters the port M, in the plunger, and the water finds its way through the holes L into the space N, which surrounds the plunger, and exerts its pressure upon the plunger both ways, and thus keeps the plunger in balance. The float has only the weight of the plunger and lever to lift. When the water in the tank gets below its level the float pulls down on the plunger until it passes by the holes K, when the water from the heater will pass to the tank through the passage M and holes L and K.

The arrangement at O, Fig. 1, is made as shown in Fig. 4 and needs no explanation other than that a brass packing nut P has been made and screwed into the pipe bushing, as vapor arising from the tank was a nuisance.

The floats had to be made in sections, because the tank had already been made with the heads riveted on and only a 5-inch hole in one head.

Fig. 4 will give an idea as to how the floats were made. Five of the floats were connected together with a rod after placing them, through the 5-inch hole in the tank, after which the stem R was connected to the float lever.

Referring again to Fig. 1, S is an overflow to the sewer in case the floats get

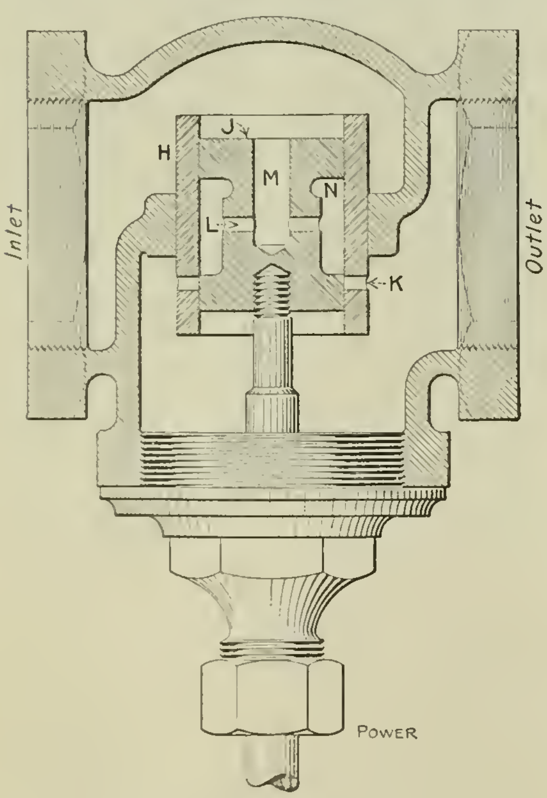

Fig. 3. Sectional View of Valve

stuck or something else happened to flood the tank. Fig. 4 shows how the sewer communication was attached to the tank.

I found it necessary to put in a needle valve for regulating the injection water as, with a globe valve, I could not get a fine enough adjustment and there was a loss of heat due to an excessive amount of injection water. The finer the water can be sprayed the better, as it then takes less water to keep the vapor down, and, consequently, less heat is extracted.

With this arrangement I can feed the water to the boilers at a temperature of 198 degrees. If another pump were available the water could be pumped from the return tank into the heater and the water heated to about 210 degrees. I was convinced, however, that the cost of an extra pump and the steam it would

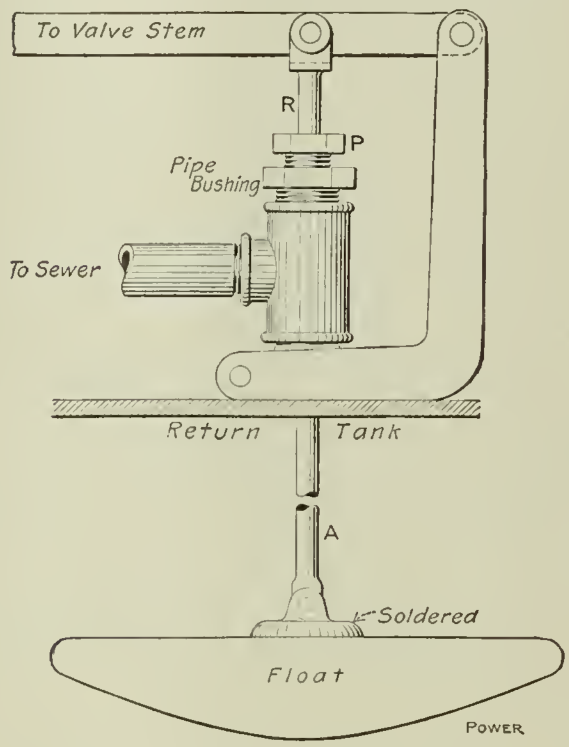

Fig. 4. Details of the Float

consume would cause a greater loss than the cost of the coal it would take to furnish the difference of heat units between 198 and 210 degrees.

Running Condensing on the Heating System

An interesting experiment has recently been made at the First National Bank building, Chicago, in utilizing the heating system of the building as a surface condenser during nights and Sundays, when the heating requirements were not severe but when, nevertheless, electrical current must be furnished 24 hours a day.

It is obvious that this arrangement can only be used when the heating system is partially filled with steam. In practice it has been used when the temperature of the outside air ranged from 40 to 60 degrees and it is estimated that during the months of March, April, October and November conditions will be favorable for its operation.

The heating system is an ordinary Webster installation, controlled by thermostatic valves operated by compressed air, and the method of proceedure is merely to shut off the compressed-air control, which has the effect of opening all the radiator valves of the building to the exhaust. The vacuum pumps then pull a vacuum of 12 to 21 inches through to the engines.

The accompanying curves show the coal consumption and kilowatt-hour load for the month of March. The experiment was not started until March 11 and it is easy to note on the curves what the effect has been.

On March 9 with a load of 2400 kilowatts the coal consumption was 38 tons. On the next Sunday with the heating system used as a condenser and a load of 2200 kilowatts, the coal consumption dropped to 26 tons, showing a saving of twelve tons for the day with practically the same electrical load.

It will be noted that on the following two Sundays the conditions were practically the same, each showing a saving of approximately twelve tons of coal over that obtained before the change was made.

Another point is worthy of remark. On March 6 with an electrical load of 6600 kilowatts the coal consumption was 49 tons, while on March 19 the heaviest peak of the month, 7000 kilowatts, was carried on a coal consumption of only 44 tons. This shows in a striking manner the economical effect of the arrangement.

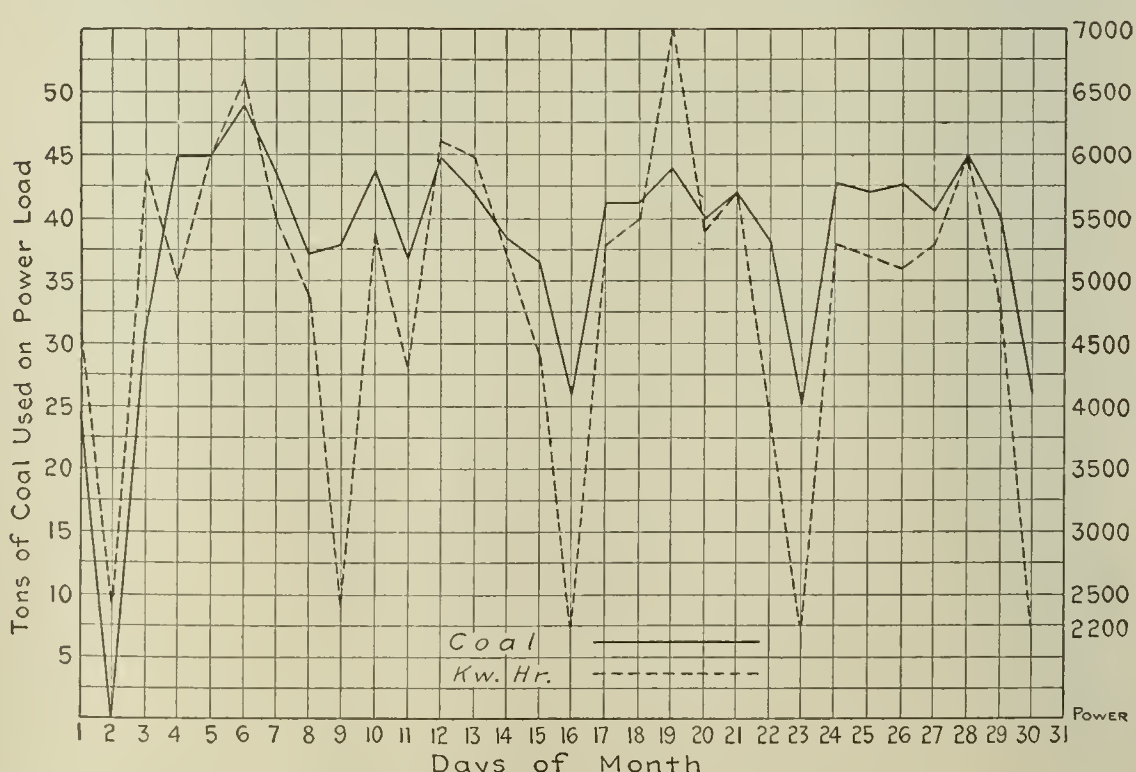

Chart Plotted from Daily Log

Reciprocating Blowing Engines*

By W. Trinks

By increasing the piston speed of the blowing engine to that of the power gas engine or the power steam engine, the first cost of the reciprocating blower is reduced. Standard types of American blowing engines, although satisfactory at low piston speeds, have not, as a rule, been successful at high speeds such as are employed in machines of European design.

During the past twenty years, American blowing-engine practice has assumed rather set forms; certain types of valves and engines have dominated the market, and their operation furnishes today the blast for more than 90 per cent. of the pig-iron industry in this country. A few years ago, however, the contentedness of American builders and users of blowing engines was rudely shattered by a double European invasion: the gas engine and the turbo-blower.

The gas engine, although more economical of fuel than the steam engine, is more expensive in first cost. To reduce the cost per horsepower, high piston speed must be employed; thus the piston speed has been increased from the 300 feet per minute, heretofore considered standard in steam-driven blowers, to 600 feet per minute in modern American gas-driven blowers. In Europe reciprocating blowers run at piston speeds of 750 feet per minute, the gas engines for the generation of power running at speeds very close to 1000 feet per minute.

An understanding of the reasons why the standard types of American blowing engines are so successful at medium speeds and what their shortcomings are at high speeds will be facilitated by a study of the valve motion and of the throttling losses through the valves.

As a high velocity through valves is harmful, the tendency is to keep the velocity at a fairly constant low value; and since the piston of an engine has very nearly harmonic motion, it follows that the valve should also have harmonic

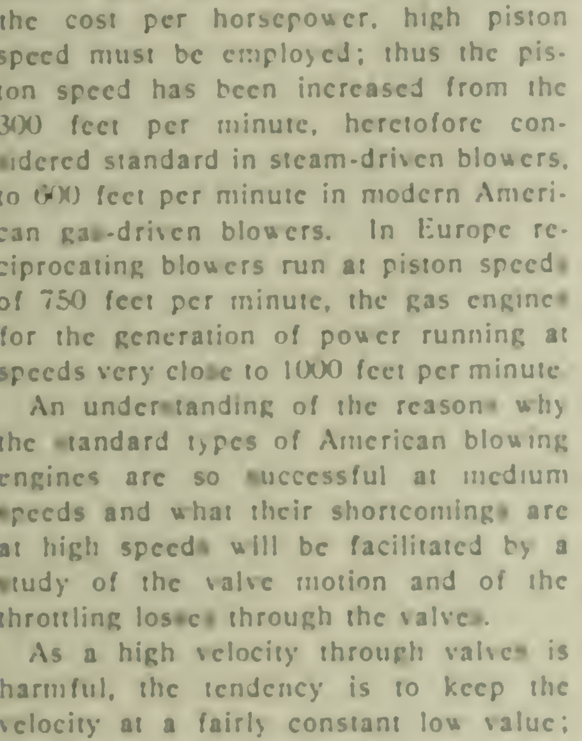

FIG. 1. IDEAL VALVE MOTION ON A DISPLACEMENT BASIS

motion. Fig. 1 shows the valve lift on a displacement basis. The inlet valve is open practically throughout the stroke; the outlet valve should pop open near the middle of the stroke and close at the end.

*Abstract of paper presented before the American Society of Mechanical Engineers at Pittsburg.

Fig. 2 shows this same ideal diagram on a time basis. It will be noted that the curves intersect the base line at an angle, indicating that if these ideal-motion curves are realized the valve will strike a blow in seating. The velocity of striking depends upon the lift of the

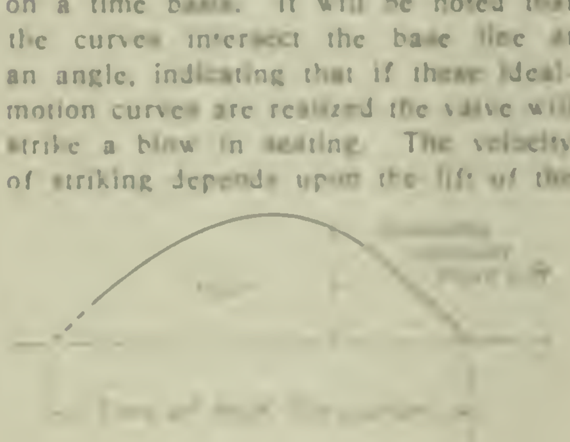

FIG. 2. IDEAL VALVE MOTION ON A TIME BASIS

valve and upon the time of one revolution, which means that high-lift valves, while successful for low rotative speeds, become impractical for high rotative speeds.

Engineers have striven to design valves and valve gears for blowing engines so that these valve-motion curves are approximated. There are, however, two circumstances which interfere with attaining the ideal. One is the quantity of air under a lift valve, which lessens the discharge through the valve during its lift and increases the discharge during the closing period; the other is the mass of the valve, which has frequently baffled designing engineers.

Practically all automatic-lift valves close late, depending upon the rotative speed of the engine, lift of the valve and spring loading. The lower the rotative speed and the valve lift and the greater the spring load closing the valve, the nearer the valve is to the seat in the dead-center position of the crank. Tests and calculations show that in ordinary American blowing-engine practice the valves close so near the dead center that for all practical purposes they may be considered as closing "on time" and without the injurious effects of late closing, namely, the slipping back of the air and the hammering of the valve.

The behavior of the outlet valves is similar to that of the inlet valve with two exceptions: First, the valve has to

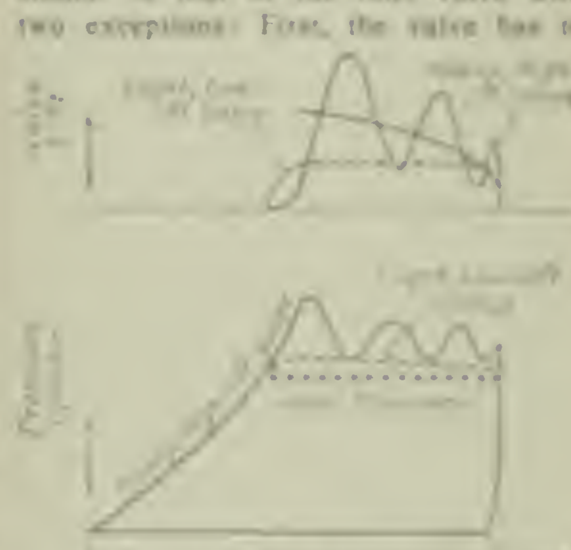

FIG. 3. ACTUAL MOTION OF OUTLET VALVES ON DISPLACEMENT BASIS

open when the piston is moving fastest; second, the pressure difference on both sides of the valve increases rapidly at the dead center. In Fig. 3 the ideal and the actual valve-lift curves are shown in connection with an indicator diagram on a displacement basis. The slower the rotative speed of the engine, the lighter the valve and the smaller its lift, the more perfect is the approximation to the ideal lift curve. High rotative speeds, heavy valves and small areas uncovered by the valve for a given lift cause the pressure in the cylinder to rise considerably over that existing in the blast space and store up a considerable amount of kinetic energy in the valve which must be taken care of by a cushioning device; otherwise fluttering or hammering results. The pressure drops rapidly under the valve immediately after the crank has passed the dead center, and particular care must be taken to have the valve close promptly in order to avoid hammering.

Throttling loss through valves involves two factors: loss of velocity head and surface friction. The vast majority of valves are so designed that surface friction, such as occurs in long pipes or ducts, is practically absent. For this reason, losses due to velocity head only will be considered. Fig. 4 gives the throttling loss for various piston speeds and for various ratios of valve area to piston area. In this chart the valve area does not mean the so-called free valve area, which is a rather imaginary or conventional quantity, but rather the area actually offered to the flow of air at the narrowest part of the valve. It is assumed that the valve has harmonic motion and that the coefficient of discharge is 70 per cent. For a number of valves this latter figure was found to agree closely with the tests.

As long as the clearance volume of the engine is small, mechanical operation of the inlet valve is scientifically correct, because the opening and closing points of the valve remain practically fixed in spite of variations of blast pressure. Conditions are quite different with the outlet valve. Its correct opening point varies with the blast pressure and losses occur if the valve opens at a fixed point and if the blast pressure differs from the one for which the engine was designed.

Naturally, the experiment of running the standard types of valve gears at higher speeds was tried. Comparatively little trouble was experienced with the mechanically operated inlet valves, except that in some of the designs the throttling loss was much greater than might be expected. At 600 revolutions per minute the standard valve gears gave throttling losses ranging from 0.4 to 1 pound per square inch, and engineers were trying to increase inlet-valve areas up to 20 per cent. or more. At the discharge end serious troubles occurred with an increase in speed.

If the American standard valve gears are used for piston speeds of 600 feet per minute or above, inlet-throttling losses of 3 to 6 per cent. of the ideal blowing work occur, and outlet-throttling losses of 7 to 12 per cent. of the ideal blowing work. Besides, power for mechanical operation of the valves increases and other troubles of wear, breakage or regulation appear, depending upon the valve gear.

For piston speeds up to 600 feet per minute and for rotative speeds up to 65 revolutions per minute, the Slick tub, employing a movable cylinder, has been very successful. The design has been severely criticized as "wagging the dog and holding the tail still" and the author confesses that he felt the same way when he saw the first Slick compressor more than ten years ago at the Edgar Thompson Steel Works, but the ingenuity of the design is forcibly impressed upon anybody who attempts to produce the same combination of large areas and small clearance space in some other way. If 65 revolutions per minute are exceeded with this type, trouble begins. The inertia forces of the heavy cylinder are hard to take care of and heat the eccentric which moves the cylinder.

Engines employing the Mesta combination inlet and outlet valve have been very successful up to piston speeds of 820 feet per minute. In this type rocking valves, two for each head, control both inlet and outlet; the inlet passes at the side of each valve, the outlet through the center of the valve. Automatic cup outlet valves are located beyond the rocking valves and are protected against the return closing slam by the mechanical closing of the rocking valves. This latter design has been used on vacuum pumps and compressors for over 20 years. Its adaptation to high-speed blowing-engine practice required doubling the valve equipment for the purpose of obtaining large areas without excessive diameter of rocking valve. The pot outlet valve is cushioned very little and is loaded lightly

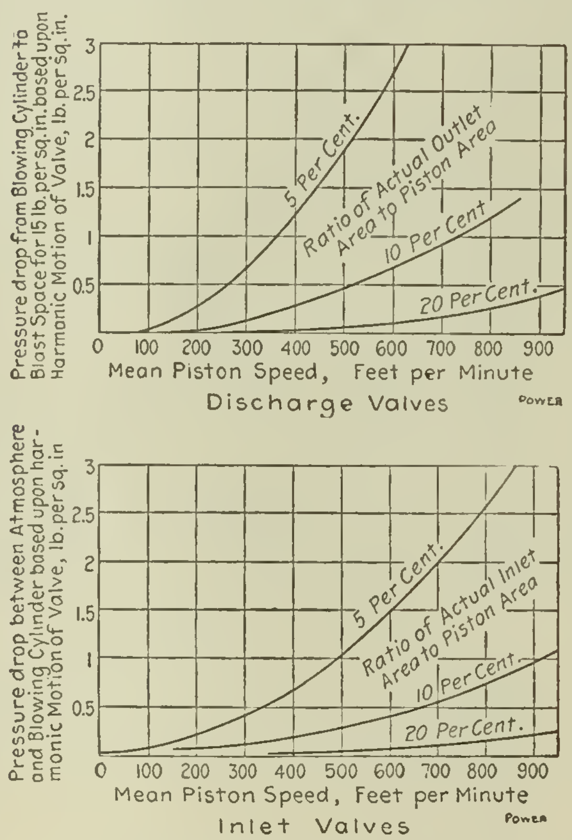

FIG. 4. PRESSURE LOSS THROUGH VALVES DUE TO VELOCITY HEAD

so as to fly out of the road of the blast without fluttering.

In Europe the high-speed blowing engine is an accomplished fact. There the problem has been attacked along altogether different lines. European engineers long since realized that the harmful kinetic energy stored up in a valve is proportional to its mass and to its travel, and that both should be cut down.

Furthermore, European engineers do not hesitate to use large clearance spaces if by so doing other advantages can be gained, and they meet with success. Matters are different in this country. Clearance in a blowing engine seems to be an eyesore to the American furnace man. The influence of clearance can be summed up in a few words.

a Clearance volume increases the necessary size of blowing tub for a given weight of air to be pumped per stroke.

b The larger size of blowing tub results in a small increase of friction work and, therefore, in a larger size of power cylinder.

c The influence of the increased heat-exchanging surface on the true volumetric efficiency is small.

On the other hand, clearance allows the use of very large valve areas, which decrease throttling work and cause better filling of the air cylinder and also allow higher piston speeds, or in other words, a smaller and cheaper engine. The higher piston speed makes possible the use of a more efficient prime mover, namely, the gas engine. When the truth of this is realized, recognition of the merits of the modern European high-speed blower should present no difficulties. The plate valves are so light in weight and the spring load can be made so small that for the greater part of their working time the valves rest against the guard or stop; this, of course, greatly reduces fluttering. Furthermore, there are no wearing parts and no sliding surfaces or sticking or binding from gummed and dusty oil. The low lift does not allow the valve to acquire destructive velocity in closing. If a sufficient number of valves are used the pressure loss through the valves is small and the filling of the cylinder is almost perfect. The life of the valves is long, provided that they are made of the proper high-grade steel and that the spring loading is properly proportioned. If a valve should break, it can easily be replaced because the valves are light; besides, the inlet and outlet valves are alike so that only a few need be carried in stock.

Particular emphasis is placed upon the almost silent operation of these valves, both by users and builders. No separate cushioning means are employed except that in the Hoerbiger-Rogler valve an elastic plate softens the impact of the opening stroke before the valve strikes the guard. This cushioning alone does not suffice, but another circumstance comes in helpfully. Thin films of oil coat the valve plate, cushion plate and guard. The squeezing of the air and oil between these plates provides a sufficient cushion to prevent injury to the valve.

From a study of the various types of valves and valve gears, it appears that at the present time the low-lift, alloy-steel plate valve promises to become the standard valve for high-speed blowing engines, because there is neither wear, binding nor sticking; no lubrication is required; there are very small throttling losses; it can be used for the highest speeds; it is inexpensive; and it does away with mechanical gearing, oiling and adjustment.

No matter with what valves a reciprocating blower is equipped, its delivery remains discontinuous; that is, it delivers air impulses comparable to a constant delivery, over which is superimposed a wave motion or vibration. If the blower discharges directly into the blast main, then vibrations are transmitted with undiminished strength and shake the whole line. In steam-engine practice this evil was cured long ago by placing a large steam or water separator near the engine to damp the vibrations of the pipe line. If a similar request is made of a furnace man for the air line, a great deal of resistance is encountered. The author knows of only one furnace plant in this country where a large tank or equalizer was installed for each blowing engine. The pipe lines thus connected are practically free from vibration.

In conclusion it may be said that the reciprocating blower has made wonderful strides in the past decade toward becoming a successful high-speed machine. While the increase of piston speed was started by the gas engine as a matter of necessity, it has also benefited the steam-driven blowing engine, and isolated furnace plants can now work with two air cylinders instead of three, because one will successfully blow a furnace in case of emergency, or else three smaller units may be used.

The combination of the high-speed reciprocating blower with the blast-furnace gas engine makes the use of the latter profitable even in the Pittsburg district where coal is cheap. The latest group of furnaces in this region has been equipped with slow-speed reciprocating steam-driven blowers. If a high-speed gas-driven blower had been on the market, the result would probably have been different.

A gas-driven blowing engine with a piston speed of 800 to 900 feet per minute and a high rotative speed will be the most formidable competitor of the turbo-blower, if European experience may be taken as a guide. There are engineers in this country who have already carried into practice higher piston speeds for gas engines for electric power, and interesting developments in this line of work may be expected in the next five years.

DISCUSSION

The following discussion applies to both Mr Trinks' paper and that of Mr. Rice, printed in the June 13 issue:

Mr. Johnson: It is generally accepted that the turbo-blower is much more efficient at low pressures than at high pressures, whereas the reciprocating blowing engine is more efficient at high pressures. A condition in the design of the latter is that the air cylinder must be large enough for the greatest volume to be handled, and strong enough for the highest pressures attained. This results in the large and massive construction which makes such machinery so expensive.

The turbo-blower, on the other hand, suffers because it must have stages enough to furnish the highest pressure likely to be required, although, in ordinary operation, this pressure may be needed only a very small part of the time.

Therefore, the best and cheapest blowing engine is a combination of these two types: a turbine-driven blower delivering air, partly compressed, to a reciprocating blowing engine, which will compress it to the desired pressure. The steam from the reciprocating engine could be used to drive the turbine.

In general, the valves of a blowing engine are a source of difficulty, it being almost impossible to get an inlet valve of sufficient area to allow the cylinder to fill without heavy loss by suction, and at the same time be quick enough to give the desired results at the speeds required in modern engines.

The advantage of maintenance is undoubtedly with the turbo-blower, as compared with the reciprocating engine. However, the magnitude of the alternations of stress in the reciprocating blower is greatly reduced by delivering partly compressed air, and the difficulties of the inlet-valve gear are practically eliminated by delivering denser air under pressure.

The governing of such a combined unit is extremely simple. The ordinary governor on the engine does all that is necessary and no governor other than one to prevent racing is needed on the turbine. The steam from the engine passes directly to the turbine, and as long as conditions remain constant, the speed of the turbine will remain unchanged. If, however, the pressure required by the furnace increases, more steam is admitted to the engine by the governor and this increased quantity of steam causes the turbine speed to increase slightly and, in turn, deliver air at a higher pressure. This automatically compensates for any slight lag due to the greater load on the engine and for the lower volumetric efficiency of the reciprocating blowing engine at higher pressures.

C. G. de Laval: It is well to consider the distinction between a blower and a compressor, in which connection it would appear that the machine described by Mr. Rice is not a compressor but a turbo-blower. It is of the multi-stage type and has no rubbing surfaces, the rotating parts revolving freely with ample clearances.

The turbo-compressors manufactured by a number of German firms are made up of multiple cylinders according to volume and pressure. The general principle includes high-speed impellers incased in cylindrical chambers, properly cooled both radially and axially. These impellers draw in the air and discharge it, converting the velocity into potential energy in the form of air pressure, the action being similar to that of a centrifugal-pump impeller.

It does not appear necessary to use six stages, arranged in series, for pressures as low as 10 or 20 pounds per square inch. A turbo-blower built on the Rateau principle for 6000 to 12,300 cubic feet of free air per minute at pressures of 8 to 15 pounds and speeds of 3400 to 2000 revolutions per minute, requires only three stages as against the six stages in the one described by Mr. Rice. For pressures of 80 to 150 pounds it is not necessary to employ more than ten to fifteen stages.

European practice has shown that turbo-compressors with capacities of 6000 cubic feet of free air per minute and above, will give from 70 to 80 per cent. efficiency; for capacities of 3000 to 6000 cubic feet, the efficiencies are from 65 to 70 per cent., and these efficiencies decrease to less than 50 per cent. at one-half and quarter loads.

The use of a turbo-blower in connection with reciprocating compressors has been tried recently in England. The existing compressor was coupled to a turbo-blower, the exhaust from the low-pressure steam cylinder passing to the steam turbine; the turbo-blower takes air at atmospheric pressure, compresses it and discharges to the reciprocating compressor where the pressure is stepped up to 60 pounds. This combination has doubled the capacity and has shown a net gain of 17 per cent. over that which would have been secured had an additional reciprocating compressor been installed. Furthermore, it saved the expense of an addition to the building, which would have been necessary on account of the large space occupied by an additional compressor.

Mr. Baker: Taking all factors into consideration, under certain conditions of fuel cost, the turbo-blower is a close second to the gas-blowing engine. The fuel consumption of the latter is affected by a number of different efficiencies, namely, the efficiency of the blowing tub, which may be called the compression efficiency, the volumetric efficiency, and the mechanical friction of the blowing tub. The sum of these efficiencies is the shaft efficiency, which may be compared with the so called shaft efficiency of the turbo-blower.

The compression efficiency is the ratio of the work required to compress adiabatically to that actually required in the blowing tub; this amounts to about [illegible] per cent. The losses are due principally to the inertia and friction of the discharge valves, the friction of air passing through the suction and discharge passages, and to late opening of the suction valve.

The volumetric efficiency has been actually determined by a long series of tests on various engines, and has been found to be about [illegible] per cent. The losses are due to defective clearance, friction of air through the suction valves, leakage of air past the valves and piston, and to the effect of preheating the incoming air.

The mechanical efficiency of the blowing tub is not easily determined, but was estimated at 90.4 per cent. These make a total shaft efficiency of 75.8 per cent. which may be compared with 68 to 70 per cent. efficiency for the turbo-blower.

Mr. Cardullo: Builders of blowing engines could take lessons from the pumping-engine manufacturers, and build engines with smaller discharge valves. The valves illustrated by Mr. Trinks are 18 or 20 inches in diameter and of a type which is unsatisfactory in water-pumping work. Although they will be more satisfactory in air work than in water pumping, the objections are of the same character and at high speeds are of the same validity as the objection to similar valves in water pumps. The difficulties could be overcome by substituting a large number of small valves of suitable material, about three inches in diameter.

Mr. Freyn: As far as thermodynamics is concerned, the turbo-blower indirectly uses two and one-half times as much gas as the gas-blowing engine. Regarding the relative cost of the two types of installation, based upon actual figures, consider four or five 100-ton blast-furnace plants, with eight gas-blowing engines installed, six operating the furnaces and two spares, and six turbo-blowers, four operating the furnaces and two spares. Under such conditions it will be found that, taking the thermal efficiency, the constant operation and the fixed charges into consideration, the gas-blowing engine is in the lead, even with coal at $1.80 per long ton.

In isolated blast-furnace plants, however, where the gas has no value, the turbo-blower is the proper installation, especially in plants having one or two furnaces where a constant supply cannot always be depended upon. But for any large plant, particularly blast-furnace plants connected with steel works, it is out of the question to put in turbo-blowers.

There is no doubt that in large steel works it is possible to have electric installations which furnish power at a very cheap cost to the municipalities and industries in the neighborhood. In this connection the gas-blowing engines lead the turbo-blowers.

I cannot see any opportunity for turbo-blowers, with the exception of the one case which Mr. Johnson pointed out, but I have, however, a better suggestion to offer. This is to utilize the waste heat from the gas engine for generating low-pressure steam by which turbine blowers may be run to compress the blast for the furnace.

Mr. Ehrhart: In Mr. Rice's paper is to be found the statement: "The pulsations in pressure above noted are an inherent characteristic of all centrifugal blowing apparatus." I believe that in a machine which is not a positive pushing machine, like a reciprocating engine, this pulsation should be avoided if possible. This is especially important where two machines are delivering air into the same line, in which case they should have the same characteristics.

Furthermore, in the case cited by Mr. Rice, the efficiency at one-third of the rated volume is about 45 per cent. In some blowers with which the Westinghouse Machine Company has been experimenting for the past five or six years, it has been found that by merely altering the shape of the blower the efficiency has been brought up to nearly 70 per cent. at one-third load. I do not believe this point has been brought out before, but blowers are now on the market in which the light-load efficiency is within 5 per cent. of what it is at full load.

Discussion on "Purchase of Coal"

The discussion of Mr. Randall's paper upon the purchase of coal, which was published in the June 13 issue, is herewith presented.

Mr. Rice: It is important that a plant be designed to use coal of lower quality, and all attention should not be directed toward the method of buying coal, the effect of which is to defeat the conservation of our natural resources. The emphasis of this paper, unwittingly perhaps, is to direct purchasers to be more particular with the coal dealer; hence, the latter tries to meet the specifications, with the result that he uses the best coal and neglects to find a market for the poor coal.

Mr. Baker: Quite a number of plants in the East are successfully burning a very low grade of fuel, which it would be impossible to burn by ordinary method. This is accomplished through the use of the steam jet, which, from the thermodynamic point of view, is perhaps bad engineering, yet it enables the fuel bed to be kept cool enough to prevent trouble from clinkers.

Professor Carpenter: I do not see how the ideas that have just been expressed constitute an argument against the necessity of testing coal and of purchasing it by analysis. I have lived for a great many years in those districts bordering on the anthracite-coal regions, where we have had to take the poor stuff that nobody else would use. The coal operators are anxious not only to dispose of their coal, but also some of their heaps of slate, some of which reaches the breakers and rock crushers; and, no doubt, thousands of dollars have been paid by the consumer to help dispose of these slate piles.

Professor Goss: I want to emphasize the statement to which Professor Carpenter has called attention. The coal operator must take much more responsibility for the suitable preparation of his coal, and everything should be done to encourage him in improving the product delivered to the consumer. The inferior coal, of course, should be brought out of the ground and should be saved; but before it is delivered to the consumer the operator should wash and sort it or otherwise put it in proper form.

Mr. Barker: If the plant can be so designed and low-grade fuels are available, it is profitable to change the equipment to use the low-grade fuel. However, the variation in the low-grade fuels is such that it is not profitable for the average plant to attempt to burn them without special attention. For instance, the small size of anthracite which comes to the New England market contains from 14 to 24 per cent. ash. It may be conserving some of our natural resources if this 24 per cent. of ash can be burned at all efficiently, but if the ash can be kept down to 18 per cent., the coal can probably be used to advantage. It may be either burned alone or mixed with a good grade of bituminous coal, but if this coal comes to the market with a variation of 14 to 25 per cent. of ash, there should surely be some correction for this variation in quality.

Mr. Baker has suggested the use of the steam jet in burning low-grade fuel. The steam jet is a very efficient piece of apparatus where a small size of anthracite is burned, providing the fireman is familiar with the apparatus. However, I have found a number of cases where the steam jet was a very inefficient piece of apparatus in a power plant, on account of improper regulation.

Pennsylvania State Convention

The Pennsylvania State Association of the National Association of Stationary Engineers held its twelfth annual convention at Johnstown on Friday and Saturday, June 2 and 3, Cambria Association No. 21 being the host. The delegates and visitors were welcomed to the city by Mayor Wilson, to whom a fitting response was made by Past President Charles A. Garlick. Addresses were made by C. W. Leitenburger, chairman of the local committee; Past President Joseph H. Carney, National Treasurer Samuel D. Forse, and State President F. M. Zimmerman.

On Friday afternoon a visit was made to the Cambria mills. On Friday evening a banquet was given at the Merchant's hotel at which Mr. Forse acted as toastmaster and George D. Yohe, the first president of the Pennsylvania State Association; Martin S. Corbett, president of the local branch, and the speakers of the morning, besides several of the representatives of the Cambria works, made addresses.

The election resulted in the choice of George Bu. Miller, of Pittsburg, as president; D. N. Arms, of Johnstown, vice-president; Thomas C. Green, of Pittsburg, secretary; D. E. Seely, of Du Bois, treasurer; John G. Louis, of Sharon, conductor; E. H. Nettle, of York, doorkeeper. The next convention will be held at York.

Convention of the American Order of Steam Engineers

The twenty-fifth annual convention of the supreme council of the American Order of Steam Engineers was held at Philadelphia, Penn., during the week commencing June 5.

There was a large gathering of delegates from the several councils connected with the organization, the meetings being held in the Parkway building on Broad street.

The large auditorium on the main floor of the building was tastefully decorated and was uniformly and artistically arranged for the exhibit of the American Supplymen's Association. The exhibit this year was the largest yet held, and the demand for booths was so great that many of the exhibitors were given space on the stage, which was fitted up as a reception room, and proved to be one of the most popular places in the hall.

The convention was a lively one for the delegates. There were seven sessions of the supreme body, and considerable important business conducive to the welfare of the association was transacted.

At the Wednesday morning session a recess was taken and permission granted to William G. Le Compte, of Jenkins Brothers, to occupy the floor. Mr. Le Compte stated that he was the bearer of congratulations from his firm to the members of the American Order of Steam Engineers, and in a neat speech presented to the supreme council a handsome solid ivory, gold-mounted gavel, and to each subordinate council a similar gavel, silver mounted, in commemoration of the silver anniversary of the organization.

There was a varied program of entertainment. On Monday afternoon a visit was made to the new John Wanamaker building. An excursion on the Delaware river took place on Tuesday afternoon. Dancing and other enjoyments were indulged in, and abundant refreshments were served.

THE EXHIBIT HALL IN ODD FELLOWS' TEMPLE, PHILADELPHIA

On Thursday afternoon the delegates and guests took special trolley cars for a family outing to Washington park. There were outdoor events of all kinds, the fun ending in a baseball match between the engineers and the supplymen.

The big feature of the entertainment program was the "silver jubilee" banquet on Wednesday evening, at the Scottish Rite hall. There were over eight hundred seated at the tables, including the ladies and their escorts. After an appetizing dinner had been served, George W. Richardson, the toastmaster, introduced the following speakers: Frederick Markoe, supreme chief engineer; Franklin S. Edmonds, of the Board of Education, and Lieutenant Hope, of the United States Army Engineers' Corps.

During the evening a pleasing entertainment was given as follows: Joe McKenna, Jenkins Brothers, songs; Jim Devlin, Peerless Rubber Manufacturing Company, monologues; Billy Murray, Jenkins Brothers, popular songs; Jack Armour, POWER, stories and recitals;

THE AMERICAN ORDER OF STEAM ENGINEERS AT PHILADELPHIA

George C. Gray, Watson & McDaniel Company, Scotch songs; Mr. Ryder, Bird-Archer Company, magic; George C. Davis, Thomas Warley & Co., songs.

At the Thursday morning meeting of the delegates the following supreme officers were elected:

Lewis G. Schlehner, chief engineer; George W. Goodwin, first assistant engineer; Florian J. Armbruster, recording engineer; C. F. Noble, corresponding engineer; Thomas J. Donovan, treasurer; T. M. Montgomery, senior master mechanic; F. S. Miller, junior master mechanic; Walter Long, chaplain; Richard Sullen, inside sentinel; William Eccles, outside sentinel; William Parient, trustee.

It was voted to hold the next annual convention at Allentown, Penn.

At a meeting of the American Supplymens' Association on Thursday morning the following officers were chosen for the ensuing year:

Harry Winner, Garlock Packing Company, president; Frank Martin, Jenkins Brothers, vice-president; Fred L. Jahn, Watson & McDaniel Company, secretary; John W. Armour, POWER, treasurer.

The following gentlemen comprise the executive committee: F. V. Stein, H. W. Johns-Manville Company; George C. Davis, Thomas Warley & Co.; J. F. Boreland, France Packing Company; S. McCullam, McCullam & Co.; Albert Schade, Schade Valve Manufacturing Company; Charles A. Hopper, Keystone Grease Company; Charles P. Sanville, McArdle & Cooney Company; Harry E. Souders, John R. Livesey Company; Charles Camp, Strong, Carlisle & Hammond Company; Arthur L. Rice, *Practical Engineer.*

The exhibition hall was formally opened on Monday evening at nine o'clock by A. R. Foley, president of the American Supplymen's Association, who introduced Charles E. Carpenter and Supreme Chief Frederick Markoe, who made appropriate addresses.

There were 81 exhibitors occupying 84 booths. Their names follow: American Engineering and Manufacturing Company, American Order of Steam Engineers, American Steam Gauge and Valve Manufacturing Company, American Pulley Company, Anchor Packing Company, Ashton Valve Company, H. Belfield Company, Bird-Archer Company, Cyrus Borgner Company, A. B. Botfield Company, Brogan & Co., Cancos Manufacturing Company, Corbett Supply Company, Crandall Packing Company, Dearborn Drug and Chemical Works, R. and J. Dick Company, Engineering Equipment Company, Fairbanks Company, France Packing Company, Frick Grate Bar Company, Garlock Packing Company, Greene, Tweed & Co., Harrison Safety Boiler Works, Home Rubber Company, Homestead Valve Manufacturing Company, E. F. Houghton & Co., Huhn Metallic Packing Company, Paul B. Huyette Company, Jenkins Brothers, H. W. Johns-Manville Company, Keasbey & Mattison Company, Keystone Lubricating Company, Lagonda Manufacturing Company, John R. Livesey Company, George W. Lord Company, Lunkenheimer Company, Mason Coal Company, McArdle & Cooney, McLeod & Henry Company, W. B. McVicker Company, Michigan Lubricator Company, National Tube Company, Nelson Valve Company, Ohio Blower Company, Parkersburg Iron Company, Peerless Rubber Manufacturing Company, Philadelphia Bourse, Philadelphia Electrical Construction Company, Philadelphia Grease Manufacturing Company, POWER, *Power House,* William Powell Company, *Practical Engineer,* Pringle Electrical Manufacturing Company, Quaker City Rubber Company, C. J. Rainear & Co., William C. Robinson & Sons Company, E. J. Rooksby Company, Roto Company, Sarco Fuel Saving and Engineering Company, Schade Valve Manufacturing Company, S-C Regulator Company, Smooth-On Manufacturing Company, *Southern Engineer,* Frank H. Stewart Electric Company, Strong, Carlisle & Hammond Company, Trill Indicator Company, Under-Feed Stoker Company of America, H. B. Underwood & Co., Vacuum Oil Company, V. V. Fittings Company, R. G. Von Kokeritz & Co., Thomas C. Warley & Co., Watson & McDaniel Company, Warren Webster & Co., Elisha Webb & Sons Company, Whetstone & Co., Wise & Bailey, Wilkirk Electric Company, O. F. Zurn Oil Company.

The loss of power in a gas engine owing to its installation at considerable elevations above sea level may be roughly estimated at about $3\frac{1}{3}$ per cent. for each thousand feet. The decrease in barometric hight is about one inch for 950 feet of altitude.

New York State N. A. S. E. Convention

The delegates from the several branches comprising the New York State Association of the National Association of Stationary Engineers assembled at Albany, N. Y., to hold its sixteenth annual convention on June 9 and 10.

The Globe hotel was the headquarters and in German hall, situated a short distance away, the sessions of the convention were held, as was also the mechanical display.

On Friday morning, June 6, at 10:30, the convention was called to order by Charles Schabacker. After the reports were read and the various committees appointed, an adjournment was taken.

There were two additional sessions of the delegates on the morning and afternoon of Saturday.

On Friday afternoon a resolution was passed that a committee be appointed to request Senator Seth G. Heacock to use his influence to get the State license bill out of the hands of the committee and introduced into the senate on as early a date as possible.

AT THE N. A. S. E. STATE CONVENTION, ALBANY, N. Y.

An earnest appeal to the members was made by J. Douglas Taylor, secretary-treasurer of the life and accident department of the National Association of Stationary Engineers, requesting them to use their best efforts to induce the members of their local associations to join this excellent insurance organization.

The unanimous support of the delegates indorsed James R. Coe as State deputy for appointment by the incoming national president of the main body at Cincinnati in September next.

The election of the State officers then resulted in the following selections:

B. C. Dunsmore, Buffalo, president; George O. Kaley, Brooklyn, vice-president; E. E. Pruyn, Rochester, secretary;

William Downes, New York, treasurer; Harry Bache, Syracuse, conductor; James T. Fitzgerald, Little Falls, doorkeeper; Matthew Bender, Albany, chaplain.

Yonkers was selected as the city in which to hold the next annual meeting, subject to the approval of the Yonkers association.

There were many features of entertainment, including trolley rides to the places of interest about the city and visits to many of the large plants.

On Friday afternoon the assemblage was given the opportunity of calling at the executive chamber to shake hands with Gov. John A. Dix.

On Saturday afternoon the delegates had a delightful sail on the Hudson river.

At Keeler's hotel on Saturday evening a banquet was held to which the ladies were invited. Covers were laid for fully two hundred. There was a varied program of toasts, songs, stories, recitations and instrumental music which was highly appreciated. The addresses were made by the following gentlemen: Arthur L. Andrews, Charles Schabacker, Hon. Judge T. McDonough, Edward H. Kearney, William B. Jones, Hon. John Williams, Counselor James H. Quinn.

The entertainers were Joe McKenna, Jenkins Brothers; Frank Corbett, Consolidated Safety Valve Company; Jim Devins, Peerless Rubber Manufacturing Company; Billy Murray, Jenkins Brothers; Jack Armour, POWER.

A pleasing diversion to the ceremonies occurred when toastmaster Hugh F. McCoubrie called for Past State President Schabacker and presented him a handsome mantel clock on behalf of the delegates of the State association. Mr Schabacker made an appropriate response.

The exhibits were well located in the main auditorium on the second floor of the convention hall. The booths were unusually large and comfortable, and were occupied by the following firms: Albany Belt and Supply Company, Albany Chamber of Commerce, Albany Lubricating Company, Ashton Valve Company, Bird-Archer Company, Ball Engine Company, Crandall Packing Company, M. T. Davidson Company, Dearborn Drug and Chemical Works, Fairbanks Company, Garlock Packing Company, Greene, Tweed & Co., Harrison Safety Boiler Works, Holmes Metallic Packing Company, Home Rubber Company, Homestead Valve Manufacturing Company, Jenkins Brothers, H. W. Johns-Manville Company, Keystone Lubricating Company, Lunkenheimer Company, McLeod & Henry Company, W. B McVicker Company, Morehead Manufacturing Company, *National Engineer*, Nemcs Brothers, George M. Newhall Engineering Company, New York Belting and Packing Company, Ohio Blower Company, Otis Elevator Company, Peerless Rubber Manufacturing Company, Philadelphia Grease Manufacturing Company, POWER, *Practical Engineer*, J. L. Quimby & Co., Ratz Company, Royersford Foundry and Machine Company, *Southern Engineer*, C. E. Squires Company, Strong, Carlisle & Hammond Company, W. N Swartbout & Co., George H. Thacher & Co., Union Steam Pump Company, Yarnall-Waring Company.

SOCIETY NOTES

The American Society of Heating and Ventilating Engineers will hold its semi-annual meeting in Chicago, Ill., on July 6, 7 and 8.

The third annual convention of the Engineers-Janitors' Association of the Public Schools of New York State will be held in Syracuse on Friday and Saturday, August 4 and 5, 1911, at Fobes hall, Educational building, corner of West Genesee and North Clinton streets. The association was organized two years ago in Albany, and within that period two cities in the State have had pension bills passed to aid the janitors in their declining years. Other cities have had their boards of education awakened to the fact that the engineer-janitors of their schools were not receiving a just compensation for the work required of them and have tried to give them what was due them as far as they were able.

PERSONAL

Martin G. Langguth, Portland, Ore., has been appointed engineer-in-charge of the power plant in the State house at Salem.

At a dinner given to Col. E. D. Meier in honor of his seventieth birthday at the Beaux Arts Club, New York City, on May 29, the employees of the Heine Safety Boiler Company gave him a complete surprise by presenting to him a fine Zeiss telescope and microscope. Among those present were men who started when the company was formed over thirty years ago.

After the dinner, Colonel Meier left for Pittsburg to preside at the spring meeting of the American Society of Mechanical Engineers, where he was honored by a testimonial from the society.

NEW PUBLICATION

THE SPONTANEOUS COMBUSTION OF COAL WITH SPECIAL REFERENCE TO BITUMINOUS COALS OF THE ILLINOIS TYPE. By S. W. Parr and F. W. Kressmann. Has just been issued as Bulletin No. 46 of the engineering-experiment station of the University of Illinois.

The Bulletin describes a series of experiments directed toward the determination of the fundamental causes underlying the spontaneous combustion of coal. These causes may be summarized as follows: (1) External sources of heat, such as contact with steam pipes, hot walls and the impact of large masses in the process of unloading, height of the piles, etc.; (2) fineness of division; (3) moisture; (4) activity of oxidizable compounds, such as iron pyrites. An historical review of the literature upon the spontaneous combustion of coal is given in the appendix. Copies of this bulletin may be obtained gratis upon application to W. F. M. Goss, director of the engineering-experiment station, University of Illinois, Urbana, Ill.

Engineering Societies Library

The facilities offered by the library of the Engineering Societies, at 29 West Thirty-ninth street, New York City, have recently been called to our attention. The library is formed from the combined libraries of the American Institute of Electrical Engineers, the American Society of Mechanical Engineers and the American Institute of Mining Engineers, and contains over forty thousand volumes on engineering subjects. It is open for reference to the general public, without charge, every day and evening, except Sundays. The library is supplied with all the published indexes, has most complete sets of periodicals both domestic and foreign, and has a well trained reference staff.

Students residing in New York City and vicinity are especially invited to use the library in their researches on technological subjects. The library is on the top floor of the United Engineering Societies building, is quiet, well lighted and ventilated. Those who are prevented from visiting the library by distance or business engagements may nevertheless receive assistance. It is prepared to furnish references on engineering subjects to persons at a distance, and also to furnish transcripts, translations and photographic reproductions of diagrams and maps. For such work, if extensive, a moderate charge is made. Correspondence is welcomed; telegraphic and telephonic inquiries will receive especial attention.

Fort Wayne Electric Works Merged with General Electric

On June 1, the Fort Wayne Electric Works was merged with the General Electric Company, of Schenectady, N. Y. Its business will be continued under the name of Fort Wayne Electric Works of General Electric Company. The same lines of apparatus and supplies will continue to be manufactured and sold under the immediate direction of the same organization as heretofore, with F. S. Hunting in responsible charge as general manager.

Moments with the Ad. Editor

A department for subscribers edited by the advertising service department of Power

The priest who had been summoned in haste, as a substitute, to officiate at a funeral, was making a few remarks about the deceased. Wishing to make some allusion to the departed one, he suddenly realized that he didn't know the name or even the sex of the one in the coffin. To get the necessary information, without letting anyone know his predicament, he turned quickly to Pat, who was a mourner, and asked, under his breath, "Pat, is it a brother or a sister?" "Neither," replied Pat, "it's a cousin!"

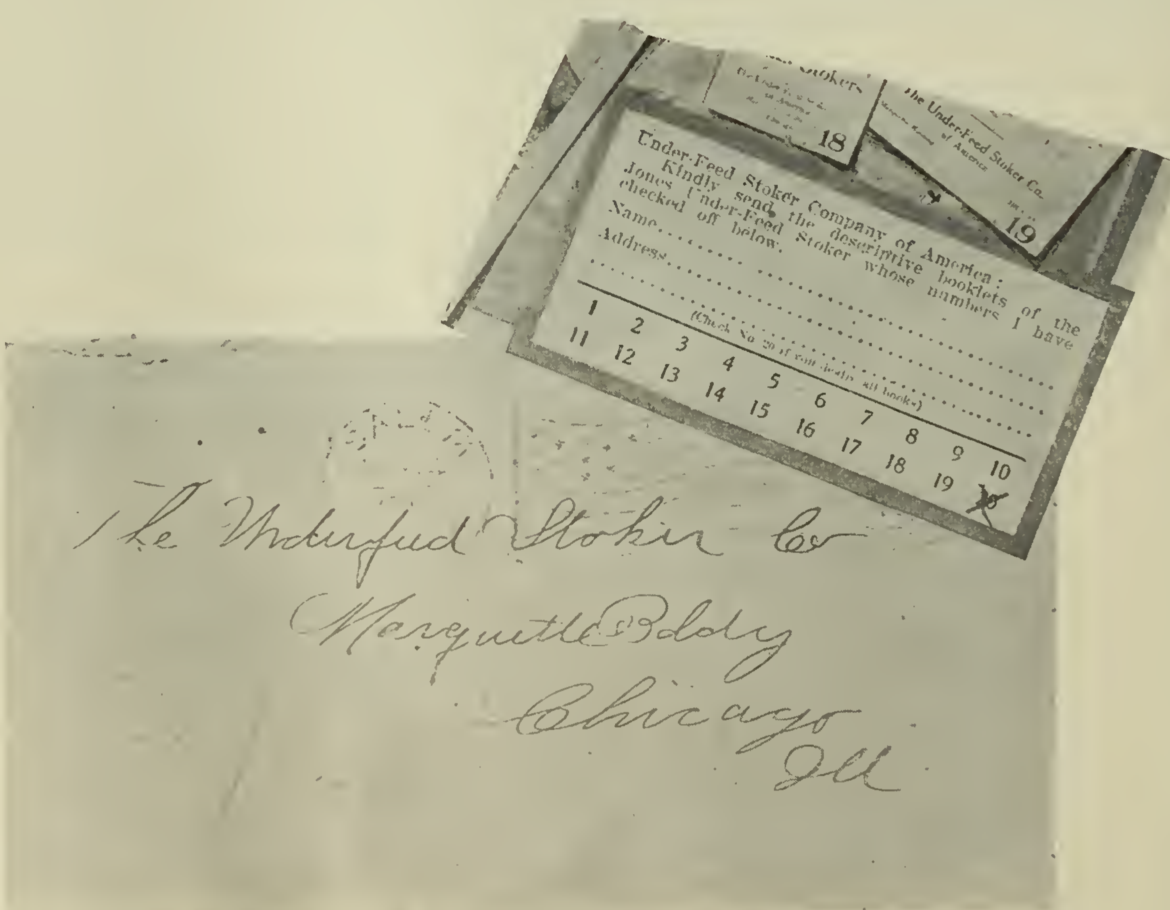
All of which shows that there are times when one's name and identity are important.

The other day the Under-Feed Stoker Company of America sent us the clipping from their POWER ad. and the envelope which are reproduced here.

Some engineer, in Salem, Mass., read their ad. in POWER and was so interested in their proposition that he sent in the coupon asking for all 20 of their booklets and even offered to pay for them if necessary—*but*, he failed to give his name and address.

No doubt he is still wondering why the advertiser hasn't made good his offer to send the printed matter.

And this occurrence is not so unusual as you might think.



Perhaps it isn't often that the reader neglects to give his name and address, but in a great many cases he fails to answer necessary questions which the advertiser asks—answers to which he must have before he can send out intelligent information.

Readers should realize that the ads cannot tell *all* there is to be told about a product.

The complete story is left to the catalogs, booklets and letters which the advertisers have prepared to send to all who become interested through the advertisements.

It is this expansive modern way of doing things that has made advertising a great educational force.

The advertiser does his part at great expense of time and money—

You do your part by reading the ads. and giving the advertiser a fair chance to send you intelligent information on how his product will benefit your plant.

And don't forget to say who and where you are.

We have printed this case because it contains a little "moral" for our readers—and also in the hope that the Salem engineer will read it, realize his mistake and send along his name and address.

POWER

Vol. 33 NEW YORK, JUNE 27, 1911 No. 26

OBSERVE the surprised and agonized look on the face of Alvah, Jr.

Why is Al so astonished and pained?

Simply because he has just eaten one green little apple; that's all. The pained expression is the result of the colic the apple has given him; his surprise is due to the fact that he *didn't know* that green apples cause gripes.

* * *

Every little while you read about someone accidentally shooting a sister, brother or dear friend. The fool always pleads: "I *didn't know* it was loaded."

* * *

Continually, gay youth is rocking the boat. When, as a result, two or three are drowned, the idiot whimpers that he *didn't know* he was incurring any danger.

* * *

Alvah's lack of knowledge concerning the painful possibilities of green apples does not mitigate the discomfort he is suffering amidships.

Because the unintentional murderer didn't know it was loaded, the funeral is not less sad or solemn.

Because the reckless young fool didn't know that the boat could be upset, the resuscitation of the victims of his folly is not less hopeless.

If a man unwittingly violates a law his plea that he *did not know* that said law existed is not sufficient defense. He must pay the same penalty as the man who deliberately breaks the statute.

Now, what in all Gaul has this to do with the price of kilowatts, as one might say?

Just this: Both man and nature agree that ignorance is no defense.

The engineer who unknowingly operates a weak boiler is just as much in danger of suddenly losing his life as is he who, knowing that a boiler is in bad shape, deliberately continues to work it.

The man who ignorantly operates an engine, pump or other machine in such a condition that it is liable suddenly to fail and thereby cause serious loss in money, time and patience, runs just as much risk of losing his job as does the man who is wilfully negligent.

The engineer who *does not know* of the leaks existing in his plant is no more excusable than he who does know, but neglects to stop them. Both are in the shadow of the "big hook."

But, why say more?

Illustration after illustration could be submitted tending to show that the consequences of lack of knowledge are far more severe than the labor involved in acquiring a sufficient amount of it.

When we speak of knowledge, we do not mean book knowledge alone; we mean such knowledge as will make you the best man for your position. This must include, then, a thorough knowledge of your plant—its capabilities and its weaknesses.

Learn the game and all its rules first, then get the philosophy.

Remember: Ignorance is no defense.

The Steam Turbine in Germany

By F. E. Junge
and E. Heinrich

A description of the Bergmann turbine, the important features of which are: a small number of stages; a high degree of expansion before the steam enters the turbine proper; solid attachment of blades, and avoidance of the critical speed at which vibrations of the shaft are set up.

The Bergmann Elektricitäts Gesellschaft, of Berlin, builds steam turbines of the pure impulse type, combining velocity and pressure stages. The steam enters the inlet chest at full pressure and expands in the nozzles down to a pressure of about one atmosphere. Such a high degree of expansion, permitting the formation of a compact steam jet of equivalent velocity without loss, requires the employment of conically divergent nozzles. In cylindrical nozzles the steam does not expand further than the critical ratio, which is a ratio of the pressure in front of the nozzles to that behind the nozzles and this, with dry saturated steam, is about 0.58. Whether the steam pressure before the nozzles be increased or that behind the nozzles diminished, the exit pressure will never be less than 0.58 of the initial pressure; hence the velocity of the steam will never be higher than that proportional to the critical pressure drop.

This critical velocity is practically identical with the velocity of travel of sound in steam of corresponding density; namely, about 1476 feet per second. If the pressure in the space behind the mouth of the nozzles is kept below the critical pressure, the steam emerging from the nozzle assumes the pressure of the surrounding medium; but the energy of this further expansion is entirely absorbed by the breaking up of the jet and by the formation of eddies and stationary fluctuations. A compact jet of definite direction and higher velocity can only be attained by means of a conical prolongation of the cylindrical nozzles in which the expanding steam converts the whole of its energy contents into velocity without considerable loss. By thus expanding from the boiler pressure down to the condenser pressure velocities of 4000 feet per second and higher are attained.

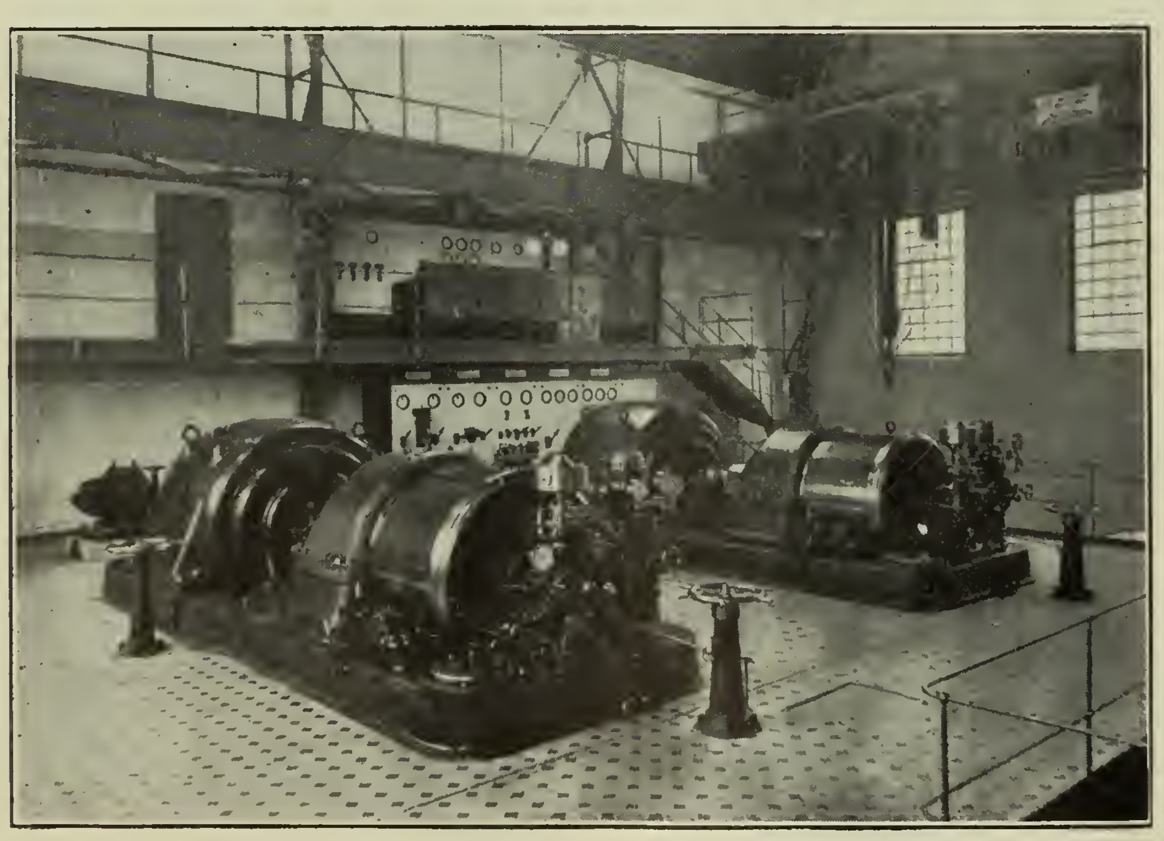


Fig. 41. Two 1500-kilowatt Bergmann Turbines

In the admission nozzles of the Bergmann turbine, expansion is carried down to one atmosphere, giving velocities of from 2600 to 3000 feet per second, and temperatures of about 300 to 340 degrees Fahrenheit. The diagrams in Fig. 42 show the relation of pressure and velocity. One row of blades being insufficient to utilize the whole velocity of the steam at normal blade speeds, the steam after leaving the first row of running blades is reversed in the following series of stationary blades and impinges upon a second row of runners at a suitable angle. In this second row the remaining velocity of the steam is utilized or absorbed, leaving just enough to effect its onward movement and issue. The process of energy conversion and also the process of regulation are the same, essentially, as in the turbines of the Allgemeine Elektricitäts Gesellschaft, previously described.

Before entering the nozzle chamber the steam passes a valve, controlled by the governor, which throttles the steam according to the requirements of the load.

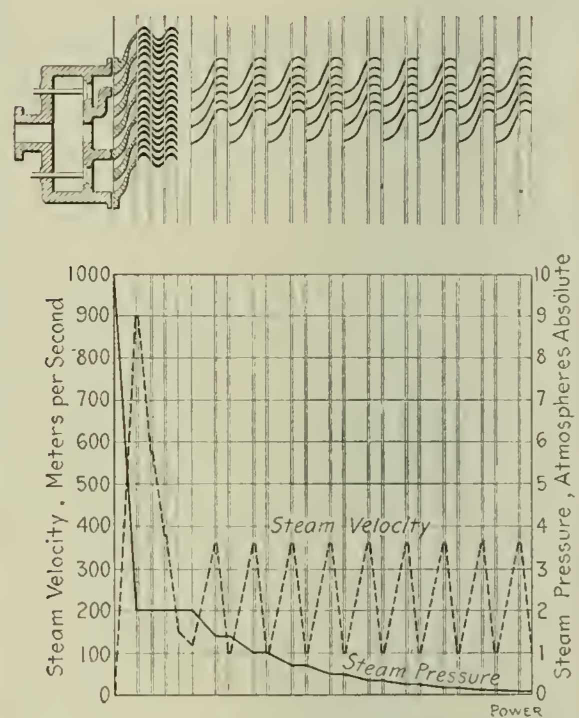

Fig. 42. Relations of Pressure and Velocity

But as throttling involves a loss it is desirable to have the full steam pressure at all loads in front of the nozzles; therefore, when entering the nozzle chamber, the steam is made to pass a number of valves which give admission to the various groups of nozzles, each group containing a different number. By combining various groups any number of nozzles are made to operate on the turbine. In this way both the cross-section and the quantity of steam admitted are adjusted to every condition of the load and the unavoidable losses at partial loads are reduced to a minimum (see Fig. 43).

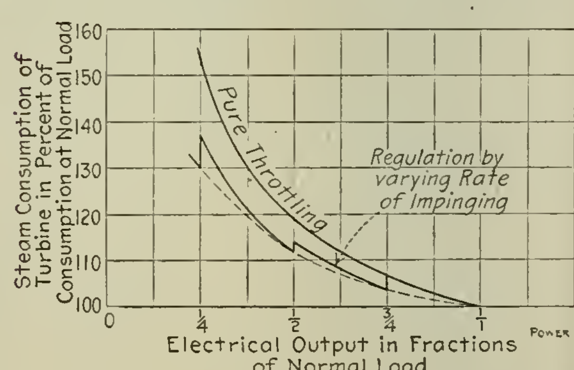

Fig. 43. Results with Different Means of Regulation

In some turbines the nozzles are distributed symmetrically over the whole circumference of the casing. But there is the disadvantage in such an arrangement that the blade channels must be filled and emptied behind each nozzle, involving losses through shock and eddies, and by a symmetrical arrangement these losses are multiplied; whereas by concentrating all the nozzles into one closed segment the losses are minimized. the whole circumference of the disk. Fig. 45 shows the first running wheel with two rows of blades. The remaining pressure drop is then divided into so many stages that the velocity of the steam in each stage remains below the velocity of sound, which is the upper

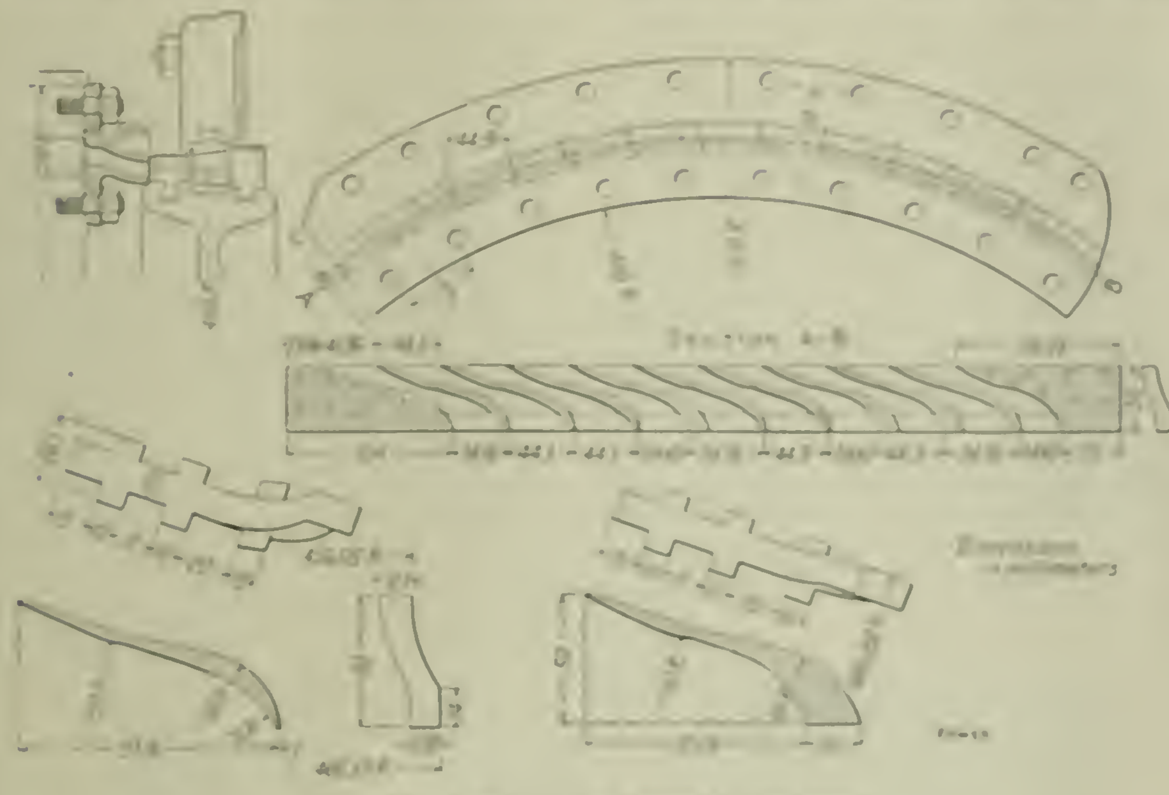

Fig. 44. Details of Nozzle Segment

Fig. 47. Ring on Stationary Disk

Fig. 44 shows the details of a nozzle segment for a turbine of 550 kilowatts running at 3000 revolutions per minute. The latter arrangement, moreover, has the advantage that the high admission pressure and the high temperature of superheat occur only in a comparatively small section, which can be designed with limit of the velocity attained by steam in prismatic nozzles. The latter are, of course, simpler in construction than conically divergent nozzles, and the shock and friction losses are much smaller at lower speeds. In the pressure stages, speeds range from 1000 to 1150 feet per second and can be effective-

Fig. 45. First Running Wheel with Double Row of Blades

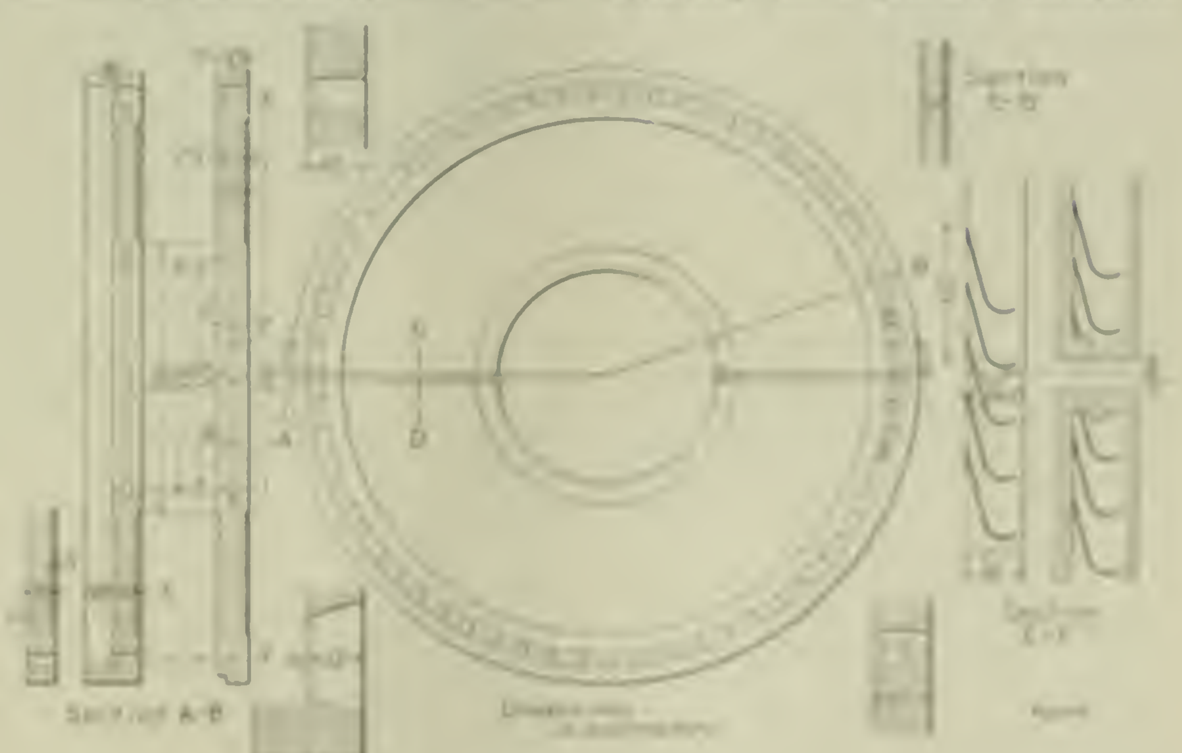

Fig. 46. Guide Disk

due consideration to the high pressures and temperatures without affecting the other castings of the turbine.

After leaving the second row of blades of the velocity wheel the volume of the expanded steam is so large that the succeeding blades can be distributed around ly utilized in wheels having only one row of blades.

The guide-blade channels which serve to impart the required velocity and direction to the steam in each stage are made of nickel steel and are cast in the circumference of the guide disks (see Figs. 46 and 47). The latter are divided in the horizontal center plane so that the upper half can be lifted together with the upper part of the casing. The hubs of the running wheels are fastened to the turbine shaft in the ordinary manner and rotate within the hub bores of the guide disks with as little play as possible and without friction. They are forged in one piece of steel with the hubs, the blades being inserted on the circumference. The cross-sections are so dimensioned that the drop of pressure occurs exclusively in the guiding channels.

The pressure on both sides of the running wheels is the same so that the disks may be bored for balancing or for equalizing minor pressure differences. There is the other advantage, previously referred to, that with the same pressure before and behind the running wheels there is no axial thrust in the system, the small thrust bearing at the end of the shaft serving no other purpose than that of keeping the running wheels in their exact position. A running wheel of the pressure stage with blades attached is shown in Fig. 48.

In order to avoid atomizing and eddying in the jet, the blade channels of the velocity wheel are accurately proportioned to the weight of steam flowing; this requires blades considerably thicker at the middle than at the edges. Until lately these blades were made of a special bronze but are now made of 25 per cent. nickel steel. In the simple pressure wheels the danger of atomizing is less imminent, wherefore the blades of nickel-steel plate are found to give satisfaction. Their method of construction is primarily dictated by the demand for light weight; yet they must be rigidly fastened on account of the stresses due to centrifugal force and possibly to friction with the stationary part of the system. The attachment of the blades is a special feature of the Bergmann turbine, being covered by a German patent. Blades subjected to stress on the testing machine show a resistance to dislodgment of 4600 pounds for each blade.

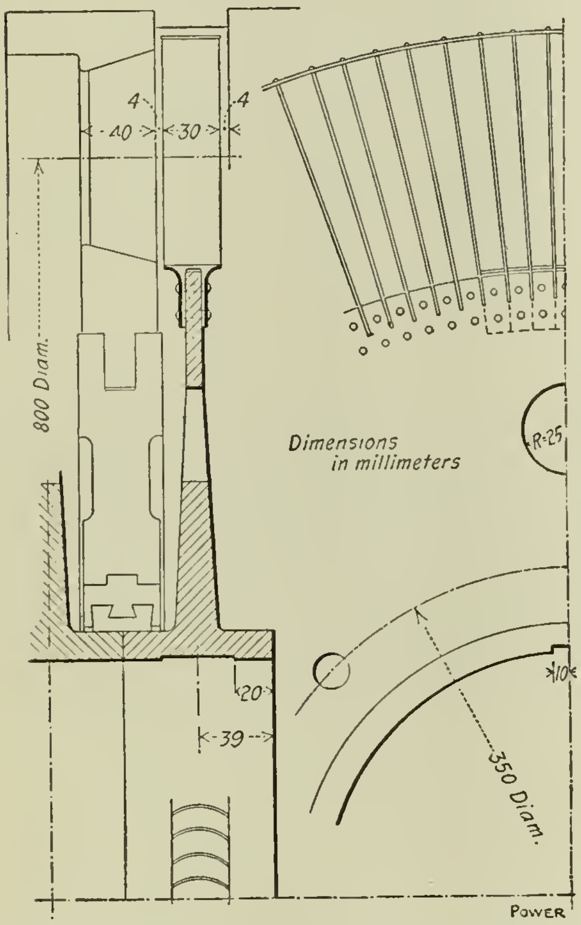

Fig. 48. Running Wheel at Pressure Stage

The arrangement of the frame and bearings is similar to that of the Allgemeine Elektricitäts Gesellschaft turbines. The two back bearings are cast in one piece with the casing, there being no possibility of any except rotary motion between the fixed and movable parts. The front bearing is centered into and bolted on the cover of the turbine casing, which is a steel casting; hence, there is no possibility of unequal expansion through influx of heat and the unavoidable play between the fixed and rotary parts can be accurately provided for. This is of importance especially where the hubs of the running wheels pass through the bushings of the guide disks, and where the turbine shaft passes through the stuffing boxes in the heads of the casing. The radial clearance between the fixed and movable wheels is only a few thousandths of an inch; nevertheless, it is a source of loss, because the steam which passes from one side of the disk to the other renders no useful work. It is therefore important to keep this clearance not only as small as possible but also as constant as possible. The same holds true of the packing boxes.

Another reason for maintaining rigidity of construction and true concentricity of position of the fixed and rotary parts lies in the movement of the shaft. Shafts of normal dimensions making 3000 revolutions per minute and over, usually run above the critical speed. The latter corresponds to the number of revolutions at which the deflection due to the centrifugal force acting on the unbalanced masses of the shaft produces the maximum vibration. Heavy shafts running above the critical speed are apt, when passing through that speed, to vibrate badly, involving serious wear upon the bushings of the guide disks. If, in addition, there is a fault in erection or a shifting between the shaft and the casing owing to unequal expansion, the clearance may become so large that the steam consumption is increased excessively. It is desirable therefore to let the turbine run below the critical speed, even when the normal speed is 3000 revolutions per minute. This means that a shaft should be designed for a critical speed of about 4000 if one takes into consideration momentary increases and unavoidable deviations of practice from calculation.

The critical speed depends solely upon the deflection of the shaft through its own weight, plus the weight of the wheels, in such a manner that with a decreasing deflection the critical speed increases. Therefore, in order to get practical speeds the deflection of the shaft must be kept as small as possible. But the deflection grows in direct proportion to the load and as the cube of the distance between bearings; hence, the weight of the rotary part, and especially the distance between the bearings, must be kept as small as possible. The Bergmann construction of blades satisfies the first requirement of light weight, while the combination of one velocity wheel with from three to five pressure wheels results in shortening the distance between the bearings, so that the shafts are moderately heavy and the critical speed lies far above the normal. Unless these precautions are taken the actual steam consumption of turbines will be considerably higher than the consumption ascertained in shop tests, upon which guarantee figures are generally based.

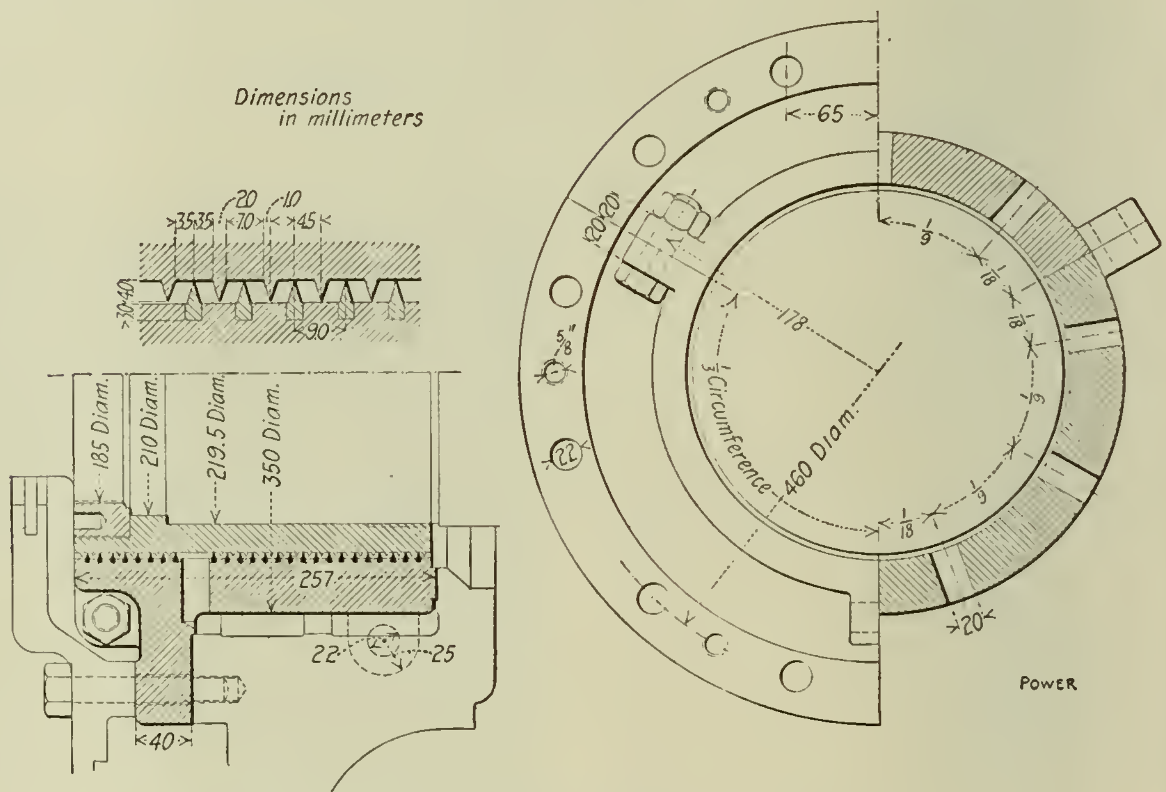

Fig. 49. Details of High-pressure Stuffing Box

The packing of the Bergmann turbine is of the labyrinth variety, both on the high-pressure side, where the pressure is about 15 pounds above the atmosphere, and on the low-pressure side, where the packing separates the vacuum space from the atmosphere. The rings on the cover which project into the annular grooves of the bushings on the shaft are divided into two groups of different sizes, the space between them connecting from the high-pressure to the low-pressure stuffing boxes. Details of the high-pressure stuffing box are shown in Fig. 49. Thus the steam emerging from the first is used in the second as a packing medium against the influx of air from without. At light loads, when there is not sufficient surplus steam in the high-pressure box, live steam can be introduced into the connecting pipe, while at heavy loads the surplus steam not utilized in the low-pressure packing box is discharged into one of the middle stages of the turbine.

The construction of the bearings does not differ from the ordinary. They are lubricated with oil which is supplied under about two atmospheres pressure by a rotary pump. After passing the bearings the oil is collected in a tank where it is filtered and used over again. The bearings are cooled partly by means of a water-jacketed worm pipe inserted between the oil pump and the bearings, and partly by water cooling the bearings themselves.

The same worm gear which drives the oil pump also serves to actuate the vertical shaft of the governor. This is of

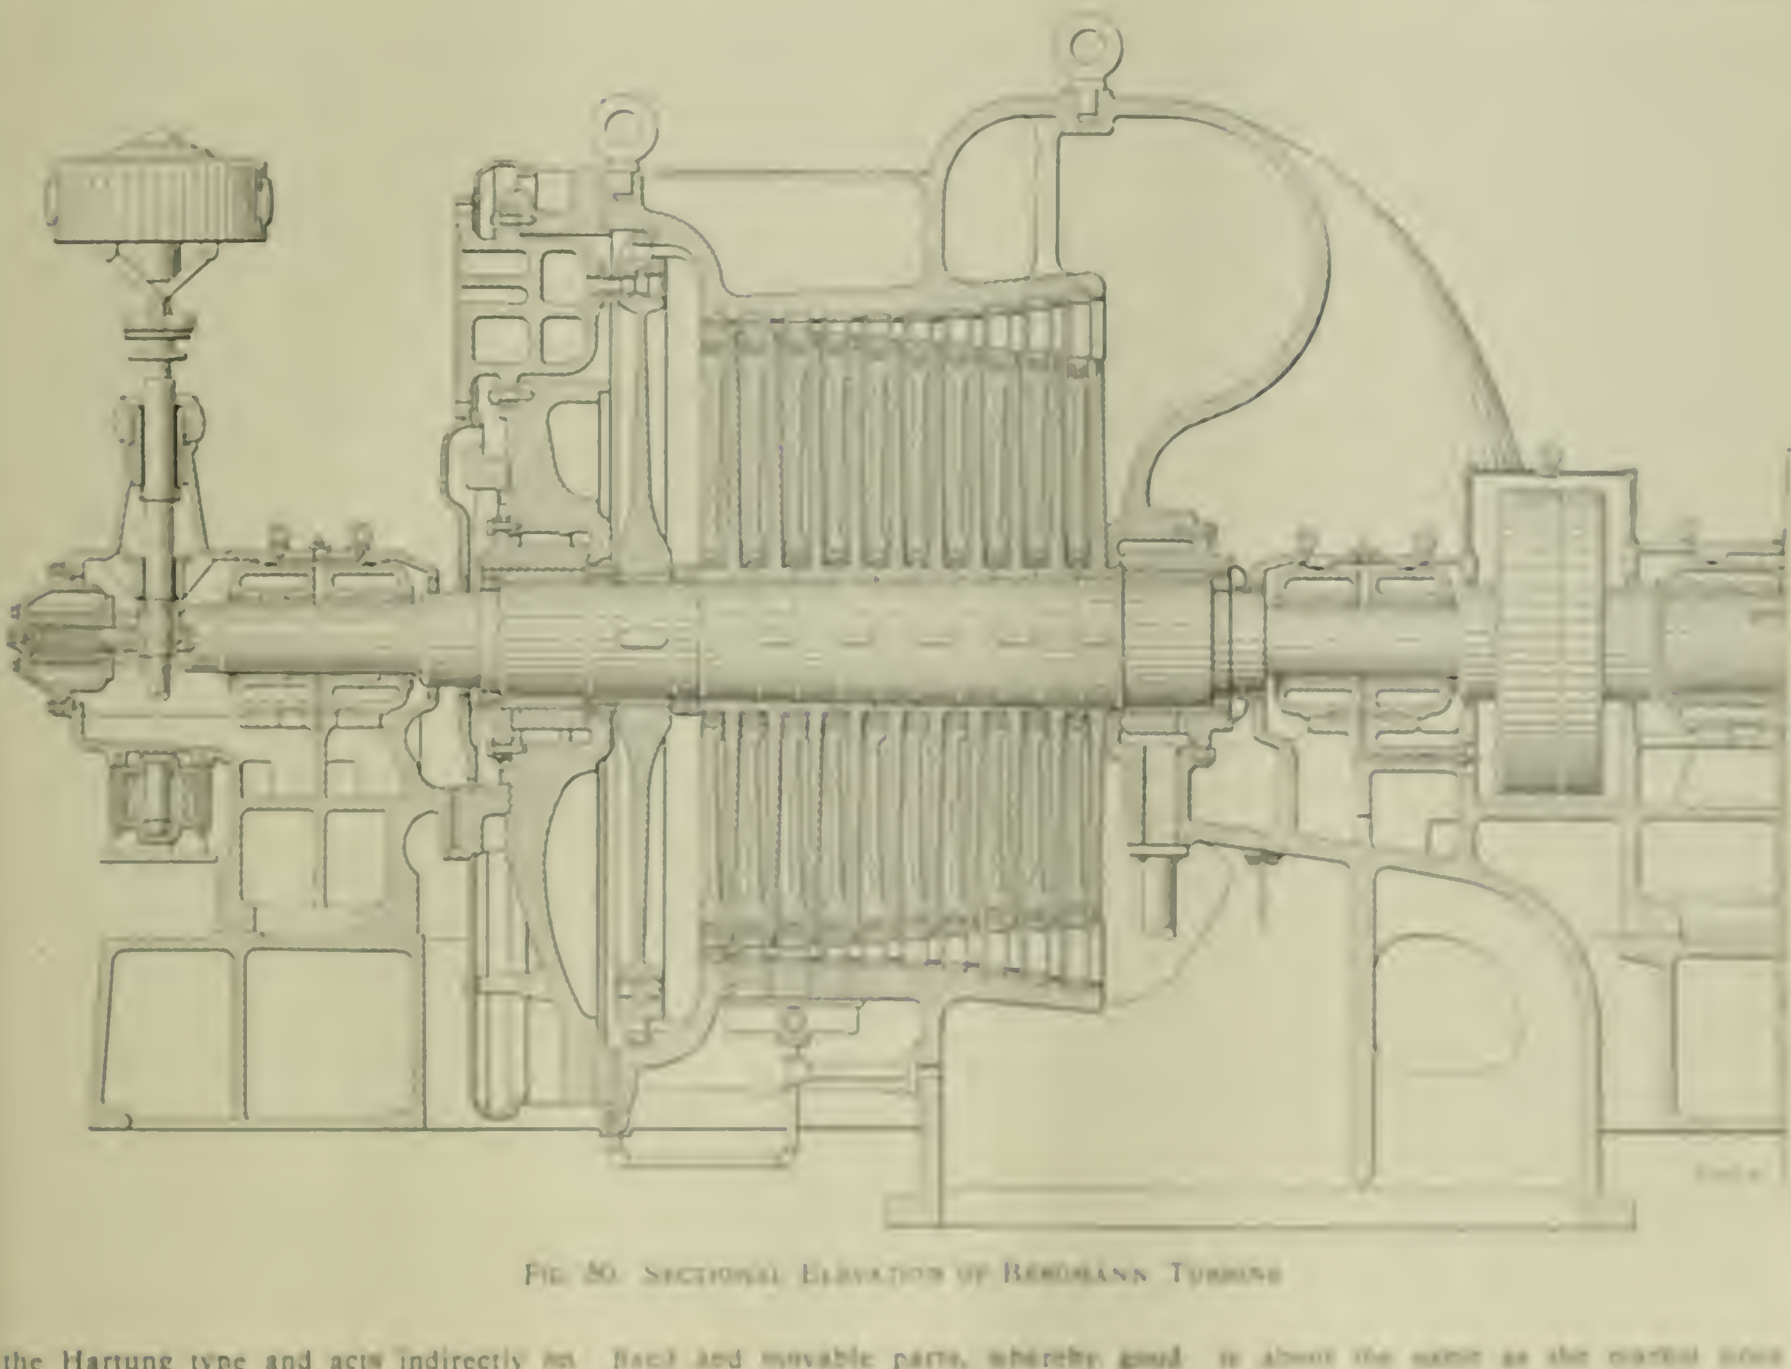

Fig. 80. Sectional Elevation of Bergmann Turbine

the Hartung type and acts indirectly on the main admission valve through a balanced pilot valve. The latter admits oil under pressure below or above the main governing piston which is fastened on the same stem with the throttle valve. In addition to this automatic regulation there is, within certain load ranges, regulation by hand, inasmuch as one or more groups of nozzles may be closed so as to obtain the benefit of the full steam pressure behind the throttle valve and therefore in front of the inlet nozzles. In addition there is the customary safety regulator closing the main admission valve automatically when the speed exceeds certain limits.

Summarizing the notable features of the Bergmann turbines, they will be found fairly representative of the standard construction of steam turbines in Germany; and are as follows: Far-reaching expansion and cooling of the steam before it enters the turbine proper, whereby moderate temperatures in the casing are secured; the smallest number of stages compatible with moderate speed, therefore short length of machine; avoidance of the critical speed and of vibration and other troubles connected therewith; the construction of the casing and bearings in one piece on a common frame plate and accurate concentric position of the fixed and movable parts, whereby good steam economy is guaranteed; no lubrication of packings and therefore no oil in the condensate; solid attachment of blades, which can be exchanged without having to dismount the turbine; and great resistance of blades against bending and shearing. Fig. 80 shows a longitudinal section through the complete turbine.

A mixture of Pintsch gas with air is explosive within a gas percentage range of 5 to 13 per cent., and it develops its maximum power at a percentage of about 11 per cent.

Metal Welding in Germany

Consul-General A. M. Thackara, of Berlin, states that there are many systems of metal-welding apparatus made and used in Germany. The use of welding apparatus has very materially increased in recent times. The quite general replacing of the older hydrogen by the acetylene apparatus makes the process not only cheaper but also more generally applicable. The calcium carbide is readily obtainable, and its generation is very simple.

In the case of the latter system, the acetylene gas is generated directly from calcium carbide by the apparatus itself. The cost of acetylene gas thus produced is about the same as the market price for hydrogen gas, but only about one-fifth as much acetylene gas is required for a given piece of welding. Furthermore, the considerably higher temperature obtained with acetylene gas makes possible the welding of metals of greater thickness. The temperature limit for hydrogen is 1900 degrees Centigrade (3452 degrees Fahrenheit) and of acetylene it is 3500 degrees Centigrade (6332 degrees Fahrenheit). The metal thickness that may be welded by the two systems are ¾ and 1½ inches respectively, leaving a margin of ¾ inch in favor of the acetylene gas.

Schedule of Flanged Fittings

The committee on standardization of the society working in conjunction with a similar committee of the National Association of Master Steam and Hot Water Fitters presented the following report on standard weight and extra-heavy flanged fittings at the spring meeting of the American Society of Mechanical Engineers:

Standard or extra-heavy reducing elbows carry the same dimensions center to face as the regular elbows of the largest straight size.

Standard or extra-heavy tees, crosses, laterals or Y-branches, reducing on run or outlets, carry the same dimensions face to face and center to face as the largest straight size.

If flanged fittings for lower working pressures than 125 pounds are made they shall conform in all dimensions except thickness of shell to this standard, and guaranteed working pressure must be cast on each fitting.

Companion flanges for these fittings must be standard dimensions.

Where long-turn fittings are specified

it has reference only to elbows, which are made in two dimensions, to be known as "elbows" and "long-turn elbows," the latter being used only when so specified.

All standard-weight fittings must be guaranteed for 125 pounds and extra-heavy fittings for 250 pounds working pressure, and each fitting must have some mark cast on it indicating the maker and guaranteed working steam pressure.

All extra-heavy fittings and flanges to have a raised surface 1/16 inch high inside of the bolt holes for a gasket.

Standard-weight fittings and flanges to be plain faced.

Bolts to be ⅛ inch smaller in diameter than bolt holes.

Size of all fittings scheduled indicates inside diameter of ports.

For outside dimension pipe use corresponding size of inside dimension fittings.

These dimensions, both standard and extra heavy, refer to either cast-iron or cast-steel fittings and rolled-steel flanges.

The committee consists of H. G. Stott, chairman, superintendent of motive power of the Interborough; E. B. Hutton, past president of the Society; I. E. Moultrop, of the Boston Edison; H. P. Norton, Bureau of Steam Engineering, Navy Department, and J. T. Whittlesey, of the Public Service Corporation of New Jersey.

Training Mr. Duffy

By Danny Hogan

"Daly do be trainin' me," said Duffy, "how to set a slide valve."

"An' what," asked Doolin, "is a slide valve? Ye have a cylinder an' a piston —to let in the steam and to let it out again at the right instant is all 'tis for. 'Tis easier than layin' out an 18-inch stack. Them engineers, Duffy, get worked up over simple matters and get stuck on others. Ask Daly when you meet him how would he indicate a turbine engine an' tell me what he says."

"About the butt-strap joints," said Duffy, "Daly said the City Hall bunch would ask all kinds of questions, as this biler matter is considered greater than the engine."

"An' right he is for once," replied Doolin. "The steam biler is the most important machine in the world. The lap-joint seam is discarded in respectable society as ondecent and the butt joint is now the rage. To explain why, Duffy, 'tis only necessary to say the lap seam is not a true circle and when pressure is on it results in a bendin' action along the seam. As the pressure varies, so does the bendin'. Ye may bend a piece of steel back and forth but at last it will break. Now the butt joint, properly made, is a true circle and hence the bendin' action is absent. To avoid bendin' stresses the shell must have all parts truly cylindrical. It's a simple truth, is it not? Now to rivet the ends of the circle together we must have straps—one inside and one outside. The common rule is to have each strap 1/16 inch less in thickness than the plate, and this is safe practice. The common practice also makes the pitch in the outer row either double or four times that in the inner row or rows. Ye noted in the table I gave you that a steel rivet in single shear is allowed 42,000 pounds per square inch and in double shear 78,000 pounds, for in the latter the rivet would be cut in half in two places and but one in the lap seam. Ye would think one could use very much smaller rivets with a butt joint as the rivets are near double as strong, but, mind ye, in all the problem a tight job is needed. True, we don't need the diameter to be

$$T \times 2,$$

but within ordinary practice we find this a good rule:

$$T \times 2 - 1/16 \text{ inch} = \text{diameter of rivet hole}$$

and gives a tight job at that.

"Suppose, now, ye have a ½-inch plate of 56,000 pounds tensile strength, an' you want a butt-strap joint triple riveted. The straps would each be 7/16 inch thick and the rivet hole 15/16 inch. In a section of the joint there would be four rivets in double shear and one in single shear an' the shear value is

$$53{,}843 \times 4 + 28{,}988 = 243{,}560 \text{ pounds}$$

"Now note, Duffy, in the single-shear joint the value of the rivet is less than the tensile strength of the plate and hence must be taken in account. But in the butt joint commonly used the shear exceeds the plate value. Therefore, we need only find a section in the outer row of rivets to give us the desired efficiency. Suppose we want an 86 per cent. joint, the outer row is the weakest section at the net plate, as the shearing value is high. If

$$\frac{P - D}{P} = \text{efficiency of plate}$$

then

$$\frac{\text{Diameter}}{1 - \text{efficiency}} = \text{pitch}$$

The diameter is 0.9375 and

$$\frac{0.9375}{1 - 0.86} = 6.696 \text{ inches}$$

Call it 6¾ inches as the nearest common fraction. Then,

$$\frac{6.75}{6.75 - 0.9375} = 86.1 \text{ per cent.}$$

The value of the solid plate is

$$6.75 \times 0.5 \times 56{,}000 = 189{,}000 \text{ pounds}$$

The shear of all the rivets is 243,560 pounds.

"This rule applies on a double, triple or quadruple joint provided, of course, ye use, within reason, the proper size rivet. The rivets in double shear will have a pitch either one-half or one-fourth of the outer row of rivets, dependin' on whether the joint is double, triple or quadruple, for by the pitch found by this rule is meant always the outer row. For instance, say ye want the ½-inch plate of 56,000 pounds tensile strength with a butt, quadruple-riveted joint with an efficiency of 94 per cent. Then,

$$\frac{0.9375}{1 - 0.94} = 15.625 \text{ inches}$$

for the outer row. The next row is 7.8125 inches and the inner row, the single pitch, is 3.90625 inches. In a double-riveted butt joint say we want an 80 per cent. efficiency. Then,

$$\frac{0.9375}{1 - 0.80} = 4.6875 \text{ inches}$$

the outer pitch, the inner being 2.34375 inches, or $4\frac{11}{16}$ inches and $2\frac{11}{32}$ inches.

"Another method is to find the pitch ratio an' multiply this by the diameter of the rivet hole. The formula, Duffy, is

$$\frac{1}{1 - \text{efficiency}} = \text{pitch ratio}$$

for any thickness of plate.

"Suppose an 80 per cent. joint is wanted. Then,

$$\frac{1}{1 - 0.80} = 5$$

and

$$0.9375 \times 5 = 4.6875 \text{ inches}$$

the desired pitch for this efficiency and this rivet hole in the outer row, or the double pitch. Mind you, Duffy, the double shear is greater than the tensile strength—and by finding the total shear an' comparing this with a pitch section of the solid plate you may design with any thickness of plate and any tensile strength, for any rivet the bull will drive. But, in shops not building Scotch marine bilers with heavy plate, they find it impracticable to drive, with a 100-ton bull, rivets much above 1¼ inches an' get a tight job. The marine shops require bulls up to 150 tons, an' ordinary shops stop at 100 tons. The rivet must fill the hole an' be allowed to shrink under pressure. True, a steel rivet don't swell when heated as an iron one did, an' in some shops the hole is but 1/32 inch smaller than the rivet instead of 1/16 inch. In this case it's easier to fill the hole."

"An' how about the distance between the pitch lines in a butt joint?" asked Duffy.

"Well," replied Doolin, "ye get good results by multiplying the pitch by 0.65 to get the distance between the rows in the inner rows of rivets in double shear. Mind that the plate edge should be planed square so that it butts solid together. This is important in allowing 1½ diameters from the edge of the plate to the first pitch line. For the other distances from pitch line to edge of plate, see you have the same allowance. For the rivets in single shear, lay out so the rivet head will clear the outer strap an' leave clearance for the die. Mind, in laying out the pitch by these methods 'tis better to have the diameter of rivet

$$T \times 2 - 1/16 \text{ inch}$$

an' the straps

$$T - 1/16 \text{ inch}$$

But, in ¼-inch plate make the straps ¼ inch, so they won't buckle and bulge when bull riveting. Indeed, it's a disputed argument among intelligent bilermakers about the thickness of the inner strap, as some claim it should be the thickness of the plate, owing to the stresses it must carry. Be that as it may, one thing I hold true, the straps should be absolutely true arcs of their respective circles in order that bending action will be eliminated. Another thing, Duffy, is that in practice the pitch of the rivets must be divided up so as to come out even in the given length of plate, else one section will be weaker than the rest. To do this it's best to measure the length and bring the odd pitch near the girth seam for, at this point, the shell is stiffened and strengthened by the hoop or girth-seam lap. In the girth seam the total lap should be three rivet-hole diameters. The gain in strength is then one diameter, or 33 per cent., at the girth as regards the cylinder, at this point.——An' there ye are, Duffy, in laying out butt-strap joints, the City Hall bunch won't have annything on ye if ye get this soaked into your system even if ye be only a sub for a Chink."

Energy Drop in Steam Turbines*

By E. Cardullo

The effect of fluid friction is to increase the total heat and the entropy of the steam as it flows through the turbine and to increase the proportion of power developed in the later stages. An empirical formula is proposed for estimating the quantity of power developed in each stage of a turbine.

There are three general methods open to the designer for determining the properties of steam during its passage through the turbine. He may make use of empirical equations giving the relation between the heat content, entropy and temperature or pressure of expanding steam, as was suggested by Doctor Steinmetz.† He may make use of Mollier's total heat-entropy diagram which gives the relation between the total heat, entropy, pressure and quality of steam. Or he may make use of a table like that of Professor Peabody's giving the relation between the temperature, entropy, total heat, quality and specific volume of steam. The last two methods are more simple and more accurate than the first one and are to be preferred.

Assume that a turbine is to be designed having n stages and that the diameters of the moving elements of each stage are the same. The heat drop per stage will be $\frac{1}{n}$ of the total heat drop. Were there no retransformation of work into heat, it would be necessary only to find from an entropy table or diagram the entropy and total heat of the steam as it enters the turbine, and the total heat, at the same entropy, of steam of the terminal pressure, to subtract the second quantity from the first in order to obtain the total heat drop, and then to divide this drop by the number of stages to obtain the heat drop per stage. The pressures in each stage would then be found by subtracting the heat drop per stage n times from the initial heat content and finding from the table or diagram the pressure of steam having the heat content so found, at the given entropy. This method may be illustrated by the following problem:

Assume that the initial steam pressure is 164.8 pounds per square inch and the final pressure is 1.005 pounds per square inch; that the steam is initially dry and saturated, and that the number of stages is two. From Professor Peabody's table, the initial entropy is found to be 1.56 and the initial heat content 1193.3 B.t.u. The heat content of steam of 1.56 entropy at the terminal pressure is 871.1 B.t.u. The difference between the initial and final heat content, or the heat drop, is 322.2 B.t.u. The heat drop per stage is one-half this or 161.1 B.t.u. The heat content of the steam entering the second stage is

$$1193.3 - 161.1 = 1032.2 \ B.t.u.$$

The pressure of steam having this heat content and the entropy 1.56 is 18.4 pounds, which would be the absolute pressure of the steam as it enters the steam chest of the second stage.

In the actual steam turbine, however, the quantity of heat transformed into work is 40 to 70 per cent. of the heat theoretically available for transformation by isentropic expansion. Most of the missing energy has been retransformed into heat by eddying, fluid friction, blade leakage, etc., and appears in the steam, increasing its entropy. Assume that in actual practice 60 per cent. of the energy theoretically developed in the first stage of this turbine, or 96 B.t.u., would be transferred to the rotating member, and about 40 per cent., or 64.5 B.t.u., would be retransformed into heat, making the heat content of the steam entering the second stage,

$$1193.3 - 96.6 = 1096.7 \ B.t.u.$$

This would give for the entropy of the steam at the pressure of 18.4 pounds, the value 1.655. The heat content of steam of 1.655 entropy and 1.005 pounds pressure is 925 B.t.u., which gives for the heat drop in the second stage

$$1096.7 - 925 = 171.1 \ B.t.u.$$

This is more than 6 per cent. greater than the heat drop assumed for the first stage. It is plain that in order to equalize the heat drop in the two stages, the pressure range in the first stage must be increased at the expense of that in the second stage.

It will be found by trial and adjustment that if the theoretical heat drop per stage, which may be designated by the symbol $\frac{\Delta H}{n}$, be multiplied by the empirical factor $(1 + K)$ the result will be the heat drop per stage which will give an actual equality in the quantity of energy developed in each stage. The value of K is found by the equation

$$K = 0.000[illegible] \left(\frac{n-1}{n}\right) \Delta H (1 - E)$$

where n is the number of stages, ΔH the total heat drop theoretically available by adiabatic expansion between the initial and terminal pressures, and E the probable thermal efficiency of the turbine. The value of E may be obtained from the equation

$$E = \frac{2545}{S \times \Delta H}$$

S being the probable steam consumption per horsepower-hour of the turbine.

In the case under consideration this efficiency has been assumed as 0.60, the heat drop as 322.2 B.t.u. and the number of stages to be two.

Substituting these values,

$$K = 0.000[illegible] \left(\frac{2-1}{2}\right) 322.2 (1 - 0.60)$$
$$= 0.0367$$

The probable heat drop per stage will therefore be

$$\frac{322.2}{2}(1 + 0.0367) = 167 \ B.t.u.$$

Allowing this drop in the first stage, the heat content after the first isentropic expansion will be

$$1193.3 - 167 = 1026.3 \ B.t.u.$$

From the entropy table, the pressure of the steam entering the second stage will be 16.86 pounds, since this is the pressure corresponding to the entropy 1.56 and the heat content 1026.3. Since the efficiency of the turbine is 60 per cent., the heat transformed into work is 60 per cent. of the theoretical heat drop and the heat transformed into work per stage is

$$\frac{\Delta H}{n} \times E = \frac{322.2}{2} \times 0.60 = 96.7 \ B.t.u.$$

Subtracting this quantity from the initial heat content, the heat content of the steam entering the second stage of the turbine is found to be

$$1193.3 - 96.7 = 1096.6 \ B.t.u.$$

Hence, the entropy of the steam entering the second stage is 1.663. Assuming the heat drop in the second stage to be the same as that in the first stage, the steam leaving the second set of nozzles will contain

$$1096.6 - 167 = 929.6 \ B.t.u.$$

The pressure of steam having 929.6 B.t.u. heat content at the entropy 1.663 is found to be 1.005 pounds, which gives a complete check on the work and shows the calculations to be correct.

If it is desired to find only the pressure of the steam as it enters each stage of the turbine, the following procedure may be employed: From the initial heat content of the steam H_1 subtract the quantity

$$\frac{\Delta H}{n}\left[1 + 0.000[illegible] \left(\frac{n-1}{n}\right) \Delta H (1 - E)\right] = h \qquad (1)$$

and write

$$H_1 - h = H_2 \qquad (2)$$

*Abstract of paper delivered at the spring meeting of the American Society of Mechanical Engineers.

†Proceedings, American Society of Mechanical Engineers, March, 19[illegible].

From the temperature-entropy table determine the pressure of steam of the initial entropy, having for its heat content H_2, which will be the pressure of the steam entering the second stage. Now subtract from H_2 the quantity

$$\frac{\Delta H}{n}\left[1 + 0.00056\left(\frac{n-3}{n}\right)\Delta H\,(1 - E)\right] = h_2 \qquad (3)$$

and obtain

$$H_2 - h_2 = H_3 \qquad (4)$$

The heat content, H_3, together with the initial entropy of the steam, will determine the pressure of the steam entering the third stage. The pressure of the steam entering the fourth, fifth, etc., stages is obtained in a similar manner except that the quantities $\frac{n-5}{n}$, $\frac{n-7}{n}$, etc., must be substituted for the quantity $\frac{n-1}{n}$ in (1) to obtain the quantities h_3, h_4, etc. When performing this operation in the case of any particular turbine, it will be found that the value of h is greater than $\frac{\Delta H}{n}$ for the $\frac{n}{2}$ high-pressure stages, and less than $\frac{\Delta H}{n}$ for the $\frac{n}{2}$ low-pressure stages.

Pressure Temperature Relations of Saturated Steam *

By L. S. Marks

Relations between the pressures and temperatures of saturated steam are accurately known for temperature ranges of 32 to 400 degrees Fahrenheit. Within this range the experimental values of Regnault and other investigators agree very closely with the recent work of Scheel and Heuse and of Holborn and Henning. At higher temperatures and pressures, however, there is no such agreement between the results of the different investigators. Of the later investigations within this higher range, the results of Holborn and Baumann appear to be the most authoritative. These covered a range between 400 degrees Fahrenheit and the critical temperature, indications pointing that the latter condition is reached at 706.3 degrees Fahrenheit with a corresponding pressure of 3200 pounds per square inch.

The measurement of vapor pressure may be by either the statical or the dynamical method. In the statical method the liquid and its vapor are maintained at a constant temperature and the corresponding pressure is measured. In the dynamical method the pressure is kept constant and the corresponding temperature is measured. The pressure is maintained by air or gas acting on top of the liquid, which is heated continuously, and the vapor which forms is condensed and returned by gravity.

The work by Holborn and Henning on saturation temperatures from 120 to 400 degrees Fahrenheit was by the dynamical method, and that of Holborn and Baumann by the statical method. As carried on by the latter investigators, water was contained in a steel vessel surrounded by a constant-temperature bath; absolute measurements of the pressure were obtained by means of a weighted rotating plunger; and the volume of water could be varied either continuously at an approximately uniform rate, or intermittently. It was noted that the water acted on the walls of the steel vessel and that after repeated heating to over 570 degrees, a small quantity of iron went into solution, the water becoming discolored upon standing exposed to the air.

*Abstract of a paper read at the spring meeting of the American Society of Mechanical Engineers.

TABLE 1. EXPERIMENTAL AND CALCULATED PRESSURES OF SATURATED STEAM FROM 400 DEGREES FAHRENHEIT TO THE CRITICAL TEMPERATURE

Temperatures, Degrees Fahrenheit	Pressures, Pounds per Square Inch			Deviation of Formula from Holborn and Baumann	
	Cailletet and Colardeau	Holborn and Baumann	By Formula	Pounds per Square Inch	Percentage
400	247.1	246.99	247.10	+0 11	0.044
410	276.4	276.34	276.47	+0.13	0.047

700		3080.4	3076.8	—3.6	—0.117
706.1		3200.0	3200.0	0	0

Table 1 gives the results of Holborn and Baumann as compared with those of Cailletet and Colardeau and those computed by the formula

$$\log. p = 10.15354 - 4873.71\,T^{-1} - 0.00405096\,T + 0.000001392964\,T^2$$

where p is the absolute saturation pressure corresponding to the absolute temperature T.

TABLE 2. EXPERIMENTAL AND CALCULATED PRESSURES OF SATURATED STEAM FROM 32 TO 400 DEGREES FAHRENHEIT

Temperatures, Degrees Fahrenheit	Pressure, Pounds per Square Inch		Deviations of Formula from Tabulated Values	
	From Marks & Davis' Steam Tables	By Formula	Pounds per Square Inch	Percentage
32	0.0886	0.088563	—0.000037	—0.042
50	0.1780	0.17765	—0.00035	—0.196
100	0.946	0.946	0	0
150	3.714	3.707	—0.007	—0.188
200	11.52	11.504	—0.016	—0.139
250	29.82	29.802	—0.018	—0.060
300	67.00	67.00	0	0
350	134.6	134.60	0	0
400	247.1	247.10	0	0

The agreement of the pressures calculated from this equation with the experimental results of Holborn and Baumann is very striking; from 400 to 650 degrees the difference is less than $\frac{1}{20}$ of 1 per cent., and from 650 degrees to the critical temperature the maximum difference is slightly over $\frac{1}{10}$ of 1 per cent.

Below 400 degrees Fahrenheit, the agreement of this equation with the experimental results is shown by Table 2. The experimental results are those of Holborn and Henning from 120 to 400 degrees Fahrenheit and of Regnault and other investigators for temperatures below 120 degrees. The differences are very small, as expressed in pounds per square inch, but amount to nearly $\frac{1}{5}$ of 1 per cent. in some cases. This, however, is not greater than the variations among the best experimental values in this part of the temperature range.

According to a recent French patent, an aluminum solder may be made by first making a fusible alloy—which will melt in boiling water—of three parts of tin, eight parts of bismuth, and five parts of lead. The solder itself is then made by taking ten parts of the fusible alloy, 300 parts of zinc and five parts of aluminum. This is said to make a strong solder. A softer one is made by taking 160 parts of the fusible alloy, 80 parts of zinc, 25 parts of aluminum. and 80 parts of tin.

An Old Time Tide Mill

When an engineer uses Slade's mustard or other seasonings for his meat at dinner, he does not stop to think that the power to grind out these delicacies was furnished by an old-time tide mill. In 1800 the legislature passed a bill which permitted the damming of the under the mill. Recently one of the wheels required renewing, and upon looking up the records it was found that it had been in operation for a period of 25 years before the action of the salt water had deteriorated it. The cost of repairs and renewal amounts to practically nothing.

The original spice mill was bought in

FIG. 1. SLADE'S TIDE MILL, SHOWING WATER FLOWING FROM THE WHEELS AT LOW TIDE

Snake river, which runs through the towns of Chelsea and Revere. The mill building burned down twice. The present structure and a view of the tide wheels and the water escaping from them to the river are shown in Fig. 1.

The tide wheels are four in number and generate a total of 100 horsepower. One wheel is 40 inches in diameter, and three are 54 inches in diameter. These wheels are operated six hours on each tide, and a day and night crew are kept at work. When the mill is not in operation, the men are taking care of the material which has been ground; thus there is no loss of time on the part of the workmen.

In the dam a raceway has been provided, at one end of which two gates are hung, to swing from one end, so that as the tide comes in through the raceway the flow automatically opens these gates, which remain open until the turn of the tide, when the flow of water swings them closed. The average flow of tide at this point is about 10 feet, but it is not necessary for the tide on the sea side of the gates to fall below the level of the wheels before the mill can be put into operation. The mill, therefore, can be operated as soon as there is a sufficient difference in head of the water on the two sides of the dam.

The flow of water is controlled by ordinary flat gates which allow water to flow from the pond side of the dam through four penstocks to the turbine waterwheels.

Fig. 2 shows two of the waterwheels 1847 by two Slade brothers, and they were one of the pioneer companies to introduce ground spice to the trade. This mill is now the property of the D. & L. Slade Company, Revere, Mass.

Water Jacket Deductions

By Frank Richards

Some interesting facts were recently brought out in a report by A. Hoffman regarding a test of a compound steam and two-stage compressor at the shops of the Ingersoll-Rand Company. This compressor had 20- and 38-inch steam cylinders, 32¼- and 20¼-inch air cylinders and a common stroke of 30 inches, the capacity being 2000 cubic feet of free air per minute.

Much of the material in the report is in the nature of "company data," but through the courtesy of the company, I am able to give extracts concerning the water jacket and the method of accounting for the heat thereby abstracted. What follows is taken almost verbatim from the report.

"It is well known from the principles of thermodynamics that the foot-pounds of work done in the air cylinder during any period of time is equal to the product of the increase in temperature produced by compressing the air, the weight of the air, the specific heat of the air and Joule's equivalent (778). In making up the heat balance this was found to check closely with the results found in practice."

"The work done in the cylinder must be equal to the heat given to the air-cylinder water jacket plus the heat contained in the air after leaving the cylinder, above the temperature of the intake air. Therefore, the heat given to the jacket is 2070 B.t.u. per minute, which is equivalent to 48.8 horsepower. The heat contained in the air above the intake temperature of 77 degrees is 8320 B.t.u. per minute, and this is equivalent to 196.3 horsepower. The total B.t.u. is the sum of these two quantities, or 10,390 B.t.u. which is equivalent to 245 horsepower. Theoretically, this total should represent the actual horsepower indicated in the low-pressure air cylinder, and it was found that this horsepower was 243, the difference being only 2.1 horsepower. A greater difference than this might be expected because the actual amount of air was figured from the vol-

FIG. 2. NEAR VIEW OF TWO OF THE WATER WHEELS

umetric efficiency of the indicator card, which, of course, was not absolutely correct."

"There was also a discrepancy due to the radiation of the outside air to the water jacket, but this was very slight, as was shown by the fact that the temperature of the water leaving the jacket before the compressor was started was the same as the temperature of the cold water in the main."

"It was at first thought that there was something wrong regarding these results, as they showed about 20 per cent. of the total indicated work in the cylinder to be given up to the jacket water; according to this considerably better than isothermal compression should be obtained, which, of course, would be impossible. The explanation is as follows."

"Very little heat is given to the water jacket while the air is compressed, because the compression begins at a low temperature, and the maximum temperature is not reached until the end of compression, and while at the maximum temperature, the piston is traveling very fast and there is not much chance for heat to be given up. After the discharge valves open, however, a great deal of heat is given to the jackets because during this period the air is at its maximum temperature and it also comes in intimate contact with the jacket of the cylinder head in passing out through the valves; in addition to this, the piston is traveling at a comparatively slow speed toward the end of the stroke. Some heat is also given to the jacket while the air is passing out through the discharge passage."

"This explanation is sufficient to account for the large amount of heat given to the jacket, and it shows that jackets really do more good than is usually supposed. Of course, heat given to the cylinder jacket while the air is discharging does not reduce the work in the cylinder but merely lowers the temperature of the air and raises the temperature of the jacket water."

Inertia Effects and Shaft Couplings

By H. J. Smith

The various factors entering into the choice of a suitable clutch are considered and a table giving horsepower ratings and equivalent shaft diameters is presented.

The influence of inertia in the starting of heavy masses into motion is well understood in installations using electric power. An electric motor under such conditions will show disturbances at the commutator, and the abnormal current consumption can be plainly noted at the switchboard meters. Special methods of winding field and armature coils, together with the introduction of resistance or controlling devices, are made to enable the motor to pick up the load of a trolley car, elevator, or other heavy starting loads. Such installations of motors, when of sufficient magnitude, are well studied, the data are reasonably exact and the results satisfactory. But with the occasional installation, where the data are not definite, the possibility of poor operative results insures a careful investigation and a recommendation from the builder of the motor.

In ordinary power-transmission work, either by belt, rope, gear, shaft or clutch drive, little thought is usually given to inertia. Horsepower capacities of driven machines are either assumed or obtained from the catalogs of machine manufacturers. These are roughly taken as a basis, to which may be added some additional values dictated by experience, or, as ofttimes happens, simply an extra haphazard allowance to increase the factor of safety.

In general, to engineers and those conversant with power-transmission machinery, belts, ropes, gears and shafting are easily figured for a given duty because the strength of material is well known, and with a proper choice of cross-section a factor of safety can be taken which will be ample for even extraordinary overloads. Speed merely increased the capacities of any of these transmission members, and so long as the most efficient speeds are maintained or the safe limits not exceeded, speed is not a disturbing factor in the calculations. If the transmitting machinery is to start with the engine or motor, the inertia loading will be overcome gradually, provided the limits of safety of the material are not exceeded by the stresses developed. If there is no breakage or slippage, then as the speed increases the inertia stresses decrease, until at the regular speed all parts are under the least stress. The duty thereafter imposed on the parts varies only according to subsequent work performed.

Horsepower Ratings and Equivalent Shaft Diameters

Horsepower at 100 R.p.m.	Equivalent Shaft Diameters
9	$1\frac{3}{16}$
12	$1\frac{15}{16}$
15	$2\frac{3}{16}$
20	$2\frac{7}{16}$
27	$2\frac{11}{16}$
35	$2\frac{15}{16}$
45	$3\frac{3}{16}$
60	$3\frac{7}{16}$
75	$3\frac{11}{16}$
90	$3\frac{15}{16}$
110	$4\frac{3}{16}$
140	$4\frac{11}{16}$
175	$4\frac{15}{16}$
230	$5\frac{1}{2}$
350	6
480	7
625	$7\frac{1}{2}$
875	$8\frac{1}{2}$
1300	10

While these calculations are relatively simple and reasonably effective for the transmission machinery mentioned, there are no such reliable formulas in the choice of a friction-shaft coupling. The latter is a great convenience not only because of the flexibility attained in the system whereby a part (or parts) may be operated at will but because it stands between the work to be done and the engine, waterwheel or motor, and relieves the latter from heavy starting stresses. A gas engine in power-transmission work must either be under a very light inertia load at starting or be started with no load at all. With most gas engines a clutch coupling is desirable. The waterwheel receives a full draft of water from the steam, and the motor its increased current from the generator. All that is required of either are strength and endurance to meet the shock or strains of starting and carrying loads to their ultimate capacity with continuous motion; variations of load are met by governing devices.

In the transmission of energy through a friction-clutch coupling, there is no automatic device to meet overload conditions. The clutch must rely on a fixed pressure which can only be regulated when the mechanism is at rest, while every time it is engaged it losses some of this pressure through wear at the friction surfaces and thereby has its capacity reduced; yet to operate successfully the clutch coupling is expected to practically take care of itself, and to be always reliable and not the cause of shutdown.

In the usual application of a friction-clutch coupling the power end of the transmission machinery has already been brought up to normal speed and is operating under the governor, and ready for any load within maximum limits. The load end is at rest. The friction-clutch coupling must then stand the brunt of the starting load. Half of it at this moment is at speed while the other half is at rest. The full shock, therefore, of starting a great mass at rest into motion, overcoming the total friction of rest, the distortion of parts, and often in addition a part or even the whole of the maximum load resistance, is required of the friction-clutch coupling. The whole work must be accomplished by the friction surfaces of the clutch which can only be under partial clamping pressure to allow a constant slip until both members of the clutch coupling are at the same speed. This slip, which may be of short duration for light inertia loads or extend over a considerable period of time in starting heavy loads, is the one indefinite factor in any calculation involving friction-clutch couplings. While under pressure a slip of the friction surfaces (which in power-transmission mechanism are usually hard dry maple on cast iron) produces abrasion and heat which rapidly remove the wood in proportion to the amount of work done and to the length of time the slippage continues. If either or both are very great, then it is quite possible that the wood surface may be so worn away that the clutch, while able to start the mass into motion, may fail to bring it up to speed, or if it does, may slip when a later loading is placed upon it. Unlike other mentioned power-transmission members, the question of sufficient strength to transmit a given horsepower is not the main consideration. A clutch can be made large and strong enough in its parts to do any stated work; but it must also have the prime requisites of large friction surfaces to resist wear and an easy means of renewing or readjusting the friction surfaces. The pertinent questions then in determining the size of a friction-clutch coupling are:

First, the normal running load.

Second, starting inertia load.

Third, the speed of either member of the clutch coupling at the time of engagement.

Fourth, the number of engagements in a given time.

Fifth, the diameter of the shaft (or shafts) on which the coupling or either of its members is mounted.

Considering these headings in brief detail it is fairly easy to fix on the normal running load of a machine, although its capacity to consume power is often underrated. The total power for more than one machine is not exactly proportional to their number, but is something less, depending upon the inertia stored up in the revolving parts of the machines and transmission machinery. This inertia, or flywheel effect, equalizes the fluctuation of delivered power, and therefore is of direct assistance to a clutch coupling when in motion.

In starting, however, the flywheel effect is entirely potential or even negative and resists the action of the clutch coupling to set the mass in motion. If this resistance is slight, then the clutch can be engaged in a minimum time and there will be very little wear of the friction surfaces. If the resistance is more severe, then the time of clutch engagement is protracted, the wear is great and the necessity for frequent adjustment of friction surfaces is essential. If the resistance to starting is absolute, then the duration of clutch engagement is simply limited by the total loss of clamping pressure of the friction surfaces occasioned by the actual burning of the wood shoes.

From the last paragraph it is obvious that in the choice of a proper clutch coupling the number of engagements is an important factor, and directly proportional to the severity of the service.

Recognizing the fact that the size of shaft chosen is an index to the character of the work done, manufacturers of clutch couplings have given an "equivalent shaft" rating to each size of clutch listed, based on a standard of 100 revolutions a minute and a reasonable factor of safety for both. While this approximate proportioning does fairly well in practice, it must not be assumed that the clutch is really of equivalent strength with the shaft under all conditions. A homogeneous steel shaft has a greater factor of safety in its ability to resist torsion than the cast-iron clutch, while the latter, because of its inelasticity, is still less capable of withstanding shock. Therefore the "equivalent shaft" rating of cast-iron clutch couplings is simply a convenient guide to prevent underestimating the size of the clutch coupling. There are usually more reasons to make the clutch larger and very few to make the size of clutch coupling smaller than in the accompanying table.

The ratings of clutches when based on actual prony-brake tests at a speed of 100 revolutions per minute show a considerable factor of safety as far as actual strength is concerned but the factor of endurance without readjustment is much less. Within usual limits of speed each clutch can easily start its rated load from rest with a sufficient factor of endurance. In practice the ordinary requirements for starting capacity are less than for the working-load capacity, but there are very many installations in which the inertia load at starting exceeds the rated capacity of the clutch. A clogging of machines, gears that bottom, abnormally tight belts, the attempt to too quickly accelerate heavy masses, produce extraordinary strains and decrease the endurance of the clutch.

The installation that gives trouble sometimes results from insufficient information in the hands of the clutch builder, but more often follows inaccurate deductions of the purchaser on catalog ratings, speed inertia effects and price. Poor judgment may be some excuse, but to deliberately place too small a mechanism because of its cheapness is the poorest of all excuses for an unsatisfactory installation.

As a concrete example of very severe inertia loading consider the following application of a clutch coupling.

A 400-horsepower gas engine is belted to a 5 $\frac{7}{16}$-inch jack shaft and drives the latter 450 revolutions per minute. The 4 $\frac{15}{16}$-inch mill shaft extended along the line of the jack shaft and had to be connected by a cutoff friction-clutch coupling so that the gas engine could be started light and the mill afterward started by means of the friction coupling. The character of the load was severe, and consisted principally of a battery of large attrition mills. These mills, on account of their construction, high speed and liability in service to be in a more or less clogged condition in starting, offer inertia-loading conditions almost impossible to calculate. Therefore, the first step was to predicate the size of the clutch coupling on the diameter of the driven shaft already fixed by the experience of the mill man. From the table, a 175-horsepower clutch coupling is the minimum size, but a larger size is preferable on account of the shock load and the larger friction surfaces. However, even a 175-horsepower clutch coupling could not be used because of the peripheral speed (4950 feet) of its friction surfaces exceeding the maximum safe speed of 3600 feet per minute (beyond this speed, wood friction surfaces char rapidly when the clutch is engaged), and secondarily because the outer periphery of the clutch exceeded the safe speed limit of cast iron—a mile a minute. For these reasons a 140-horsepower clutch was chosen which reduced the friction-surface peripheral speed to 4500 feet per minute.

The severe conditions in this installation point the moral of inertia loading. The 140-horsepower clutch (rated at 100 revolutions per minute), which appears large enough in view of the speed of 450 revolutions per minute, actually handled the running load without the least symptom of trouble, but the heavy inertia load at starting, aggravated by the high speed of the driving-clutch member, wore the wood shoes so fast that the assistance of a mill hand pulling on the belts was necessary to start the mill and at the same time to keep the friction surfaces in good condition for subsequent loads without constant readjustment. A slower speed of mill shaft, if chosen in the first place, would have allowed the choice of a clutch of ample size for the work with a peripheral speed well within safe limits for wear of friction surfaces.

A locomotive was run into the roundhouse after its first trip since having been overhauled and new flues put into the boiler. The foreman asked the darkey fireman how it steamed, and how much pressure he was able to keep on it. The darkey replied: "Ah don't know jes how much steam Ah had on 'er, but Ah sho did keep da' needle pintin' mos' towa'ds th' [illegible]."

Electrical Department

Especially conducted to be of interest and service to the men in charge of the electrical equipment

Air Cooled Choke Coils

It is sometimes convenient to mount choke coils on ceilings so that the insulating-coil supports hang pendent and at other times it is preferable to arrange them so that the coil rests on the supports, as shown in the engraving. The new Westinghouse choke coil, which this engraving illustrates, can be mounted either way, because the insulating "petticoat" columns can be removed and inverted on the supporting rods.

The choke coil consists of an aluminum rod bent into a helix of about 15 inches diameter and containing about 30 turns. Bracing clamps are provided to give mechanical strength to the helix. The aluminum rod used is of sufficient cross-section to safely carry 200 amperes.

Air-cooled Choke Coil

Each of the two insulating columns is made up of porcelain insulators which, except the end pieces, are interchangeable. The number of insulators used in the column depends on the voltage of the circuit in which the coil is to be used. For floor mounting, the parts are arranged as shown here.

These choke coils are intended principally for the protection of transformers and should not be used for generators. Where greater reactance than is afforded by a single coil is desired for the higher voltage circuits, it is recommended that two or more coils be connected in series.

Factors in Good Service on Transmission Systems*

By M. Hilgen

Absolutely uninterrupted service from a transmission system is impossible. Good and commercially acceptable service can be obtained, however, from any system which is properly designed, constructed and operated. For maintaining continuity of service more can be done before the system is constructed than at any time thereafter.

The most important factors in securing good service are insulation, mechanical strength, general design of the system and methods of operation.

Insulation

Probably more line shutdowns have been produced by insulator failures than by any other cause. The general reason is that, although other engineering structures are ordinarily built with factors of safety ranging from 4 to 10, insulators, for some unaccountable reason, have been considered adequate if they had a factor of safety of 2 or possibly 2½, notwithstanding the fact that the stresses which insulators are called upon to stand are probably more variable and uncertain than those encountered by most other structures. The higher the line voltage the less the factor of safety can be. For a 100,000-volt system a factor of safety of 3 under unfavorable conditions (with the insulator wet all over) gives excellent results. For 50,000 volts the factor of safety should be 4 and for 20,000 or 30,000 volts I believe a factor of safety of 5 is about right. The reason for this is that insulators rarely fail due to the normal voltage of the system, but rather to abnormal voltages caused by lightning and power surges; these abnormal voltages are greater in proportion to the normal voltage for a low-tension than for a high-tension system.

*Extracts from a communication presented at the New York convention of the National Electric Light Association.

To obtain a proper factor of safety for a 50,000- or 60,000-volt system with pin insulators is difficult; for a 100,000-volt system it is practically impossible. This fact led to the design of the suspension insulator, the introduction of which marked an important advance in high-voltage line construction. For voltages of 20,000 and above, no other insulator should be used.

Mechanical Strength

For straight construction in level country, the stresses to which a line will be subjected can be predetermined with a reasonable degree of accuracy and proper factors of safety allowed. For extra long spans or sharp angles the stresses can also be determined in advance and special pole structures or towers can be constructed to meet the conditions.

Where a line traverses rough and mountainous country for many miles, however, and no two spans are of the same length and no two towers or poles are of the same hight, each span and tower should theoretically be treated as a special case, which is obviously impossible; general rules must be formulated for the construction of the line as a whole. Towers or poles must be selected which are sufficiently strong to stand in the most unfavorable places and these guyed, when necessary, as an extra precaution.

If wire larger than No. 6 Brown & Sharpe gage is used it should be stranded. For No. 4 a three-strand wire gives excellent results, the strands being so large that no individual wire is liable to be broken by abrasion. For sizes of from No. 2 to No. 0000, seven-strand wire should be used. Six-strand wire with a hemp center exposes more surface to wind and ice, is less flexible and tends to crush out of shape in the wire clamps.

Hard-drawn copper wire should not be drawn too hard with the idea of getting great tensile strength. Wire having an ultimate strength of 45,000 to 50,000 pounds per square inch and an elastic limit of 26,000 pounds per square inch is strong enough. Stronger and harder wire than this is liable to become nicked or scratched in stringing or injured by the wire clamps so that the actual strength of the wire when erected will be less than the actual strength of a softer wire.

Wire clamps for suspension insulators should be connected to the insulator by a hinge joint located as near as possible to the wire so that there will be little tendency to turn the body of the clamp and bend the wire when the insulator pulls in a direction other than perpendicular to the wire.

The insulators should be hung so that they can swing freely in any direction. If the connecting device does not allow perfect freedom of motion it is liable to be broken.

General Design of System

Transmission lines feeding an important load center should be in duplicate or triplicate. If they come from the same power plant they should preferably follow different routes. If this is impracticable on account of the extra cost of right-of-way and patrol, the different lines should at least be mounted on separate towers or poles, spaced far enough apart to prevent the possibility of one line interfering with another.

For convenience in locating trouble, all lines should be sectionalized by means of outdoor air-break switches, located about twenty miles apart and at patrolmen's headquarters if possible. Two long duplicate lines should be provided also with a cross-over switching station at the middle of the line with the switches so arranged that one-half of either line may be cut out and the remaining section continued in operation. This switching station may be an outdoor affair with air-break switches, or if the charging current of half of one line cannot be broken by air-break switches, oil-break switches may be used and installed indoors or out.

If the load center is supplied by two or more separate and independent plants the conditions are better, because the chances of two independent supply systems being out of commission at the same time are remote.

In any case where two or more lines supply power to the same point, the incoming lines should be controlled by reverse-current relays. The greater the number of incoming lines the better the relays will work. Grounds rather than short-circuits between wires cause the great majority of line troubles. On a Y-connected system with a grounded neutral, any other ground causes a short-circuit and takes a considerable amount of power. For this reason reverse-current relays are of greater service on a Y-connected system than on a delta-connected system. On a very extensive delta-connected system, however, one having large line capacity, a grounded wire will take a heavy current and this current, on account of the resistance of the ground and the resistance of the wire, will represent true power. A very large system with an extended network and many plants will work equally well whether Y- or delta connected.

Trouble from lightning can be guarded against by high insulation, one or more overhead ground wires and electrolytic arresters; these represent the highest development yet attained in lightning arrester construction. The ground wires should be of ample section and grounded at every support.

Operation and Supervision

In the operation of a transmission system eternal vigilance is the price of continuous service. No amount of automatic apparatus can take the place of good operators.

New operators should first be placed in the smaller and less important stations or substations of the system; as they prove their ability and as vacancies occur, they should be transferred to the larger and more important stations. Under this plan the men have always something to look forward to and do not lose interest in their work. Only the best men get to be operators in the more important stations, and the men in the larger stations have necessarily had considerable experience and are well acquainted not only with the operation of their own station but with the switching connections and method of operation of several of the other stations of the system.

In very large systems all operations should be controlled by one man, called the "load despatcher." He should preferably be located at the principal load center and be in communication with all stations through a private telephone system as well as the public systems where one is available. In smaller systems the load despatcher may also be the operator in charge of one of the large stations.

The frequency with which a line should be patrolled depends upon the importance of the line and its liability to failure. An old wooden-pole line with pin insulators may have to be patrolled every other day if it supplies power to an important load center. A well constructed steel-tower line may need to be patrolled only once a week or less.

Certain parts of a line may need closer attention than others, notably those in mountainous country and swamps. Unimportant branch lines may be patrolled once a month, or perhaps not at all. A branch line to a small power plant is less important than a branch line to a small substation.

Patrolmen should carry portable telephones and report their location to the load despatcher at regular intervals. The record of the movements of the patrolmen can conveniently be kept by the load despatcher on a "patrol sheet." This is a continuous roll of cross-section paper with a time scale on the base and a vertical distance scale. For convenience, all the stations, patrol houses and other landmarks are shown on the sheet according to their relative location along the line. The progress of each patrolman on the line is then noted by dots on the chart through which a curve is drawn, just as progress of a train is shown on a railroad-train sheet.

Patrolmen are too prone to think that their one object in life should be to cover a section of line at stated intervals and as expeditiously as possible. High-speed patrol is about as good as no patrol at all. In one case it was discovered that a certain patrolman had purchased a motor cycle and was patrolling his section of line at 30 to 40 miles per hour, following the adjacent highways rather than the line.

A slow and thorough examination of a line once a month with a sharp lookout to discover preliminary signs of weakness, such as loosening tie wires, cracked insulators, loose bolts in towers, broken wires in a strand, uneven sags in spans, settling of tower footings, loosening of guy wires, etc., will do more good than a high-speed inspection daily.

On a large system a general line inspector should be employed whose duty it is to inspect all lines, going from one to another at indefinite intervals and reporting all signs of weakness and making reports as to work of patrolmen and recommendations as to repairs, reconstruction and other necessary matters.

CORRESPONDENCE

Interpole Motor Characteristics

Referring to the discussion of Messrs. Williamson and Dean regarding interpole motors, appearing in the issue of May

Electric Motor Speed Curves

23, I beg to take issue with both gentlemen as to some of their statements. Mr. Williamson's statements that the interpole winding adds no torque or counter electromotive force and that the speed curves of the shunt-wound motor and interpole motor are very similar, are incorrect. Although the interpole winding is added primarily to improve commutation and not with any idea of changing the speed, it does affect the counter electromotive force by tending to oppose the main field and this tends to increase the speed of the motor.

The speed curve of a shunt-wound motor always droops as the load increases. With an interpole winding the speed curve will not droop so much; it may rise and in some cases the speed may become dangerous when load is put on. For this reason it is the practice of motor builders to take a speed-characteristic test on all interpole motors. Motors having a rising speed curve are not passed for shipment until the trouble, due to too powerful an interpole field, is remedied, usually by shunting part of the current around the interpole winding.

I believe that Mr. Dean is right in saying that the trouble was due to wrong connection of the series winding, and I think if Mr. Wilbraham had reversed the series winding, leaving the interpole winding connected as at first, he would have had no trouble from sparking. From my own experience and from inquiries which I have made, I should say that a motor with a variable-speed ratio of more than 3 to 1 and with a differential compound winding is poorly designed and likely to run away when load is put on, as at the high speed the weakened shunt field would be easily overcome by the series field.

I can hardly agree with Mr. Dean's broad statement that "it is primarily an error to buy a compound-wound interpole motor" as there are undoubtedly cases where a differentially connected series field winding is desirable and safe for a constant-speed motor and there are other cases where a cumulative connection, giving a decided droop to the speed curve, is very desirable. Such cases, however, should usually be referred to the designing engineer.

The accompanying chart showing characteristic speed curves will help to explain my statements.

Central Station Service vs. Isolated Plant Operation

I have been very much interested in the various items appearing in POWER regarding the relative cost of isolated-plant operation and central-station power. Mr. Rushmore's article in the May 23 issue, to which I have referred in detail elsewhere in this issue, is but one example of the incompleteness of many of the reports made by the isolated-plant operators. On page 819 of the May 23 number, for example, A. P. Hyde states that his plant is producing electrical energy for 1.06 cents per kilowatt-hour and gives comparative coal and load data for three months of the year. If he gave a complete year's operation an intelligent comparison could be made, but the comparison as given is so incomplete as to be of little value.

Reliable and complete data of this kind would be of very great general interest and value. I believe that under certain conditions the isolated plant can produce its own power, heat and light at a lower figure than the total cost to the plant would be if taking central-station power and making low-pressure steam for heat. Under other conditions the reverse will be true. As these conditions of operation undoubtedly affect the result to such a very great extent, unusual care must be taken in accepting data, even when in complete form, and no snap judgment should be reached until the conditions have been thoroughly analyzed.

I should like to see the discussion of the relative value of the central-station service and the isolated-plant service continued even more thoroughly and in greater detail than it has been, but I would suggest that care be taken to see that no data are published which are not reliable and which do not consider all the elements of cost entering into the production of power.

Ass't Mech. Engr., Rochester Ry. and Light Company.

Rochester, N. Y.

Parallel Operation of Alternators Driven by Waterwheels

I wish to submit to practical readers of POWER a problem that has recently occasioned considerable study on my part.

We have a 200-kilowatt 2300-volt three-phase alternator of the revolving-field type coupled to a hydraulic turbine, the speed of which is controlled by a Woodward governor. The exciter is belt-driven from the main shaft of the alternator.

On the switchboard there are three ammeters, one in each lead of the generator, and a voltmeter which can be connected across any two leads. There are also a voltmeter and ammeter for the exciter as well as a field rheostat and a field switch with discharge resistance.

This unit supplies current for both power and lights and it is quite up to its capacity. In order to increase the output it is proposed to install generators to be driven by two smaller waterwheels at adjacent water sites. There have been ordered one 60-kilowatt unit to be placed about a mile from the largest installation and a 36-kilowatt machine to be located a mile farther down stream.

The question at issue is this: Is it necessary to supply the small units with governors or will the one on the 200-kilowatt outfit be sufficient? We desire the two new units to work at maximum capacity constantly and thus relieve the large unit of a substantial portion of its load. What additional instruments will it be necessary or desirable to place on the 200-kilowatt switchboard and what are necessary at each of the two small power houses?

What is the proper sequence of operations in throwing either of the smaller machines on the line when either or both the others are in operation? And, in reverse order, how may one unit be shut down without disturbing the other two?

H. T. DEAN.

Boston, Mass.

Starting Large Motor Generators

Sometimes it is found that a large motor-generator consisting of an interpole generator driven by a synchronous motor, when started from the direct-current side, takes excessive starting current. In such a case, if the generator is compound wound the best way to reduce the starting current is to reverse the connections of the series field winding so that the machine will operate as a compound motor, increasing the field excitation and thereby the starting torque per ampere of armature current. A double-pole double-throw switch can be easily connected in the series field circuit for this purpose.

Sheet Steel Magnetized by Rolling?

Can any reader explain why sheet steel becomes magnetized while passing through the rolls? In the rolling mill, cold water is run over the rolls while the billet is "roughed down" and also during the subsequent passes which reduce the metal to its final thickness. After the sheet is passed through the "flattener" it is cut up, and some of it is magnetized and other parts are not. We have never detected any magnetism in steel that has been rolled without the use of water on the rolls.

I will appreciate any suggestions as to the cause of the magnetization.

A. R. COFFMAN.

Scottdale, Penn.

A new method of coating various substances with metals, the invention of a Swiss engineer, consists in reducing molten tin, zinc, copper, lead, aluminum, or other metal or alloy to a state of pulverization by pressure of an inert gas —nitrogen or hydrogen—and in that state driving it against the surface to be covered from a flexible tube with a tip like that of a large vaporizer for handling liquids.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Some Instructive Indicator Diagrams

By J. C. Parmely

The accompanying diagrams were taken from a horizontal single-cylinder single-

Fig. 1. Normal Stop Diagram

acting gas engine working on the four-stroke cycle and show very plainly the effect of changing the point of ignition on light loads. The cylinder is 18½ inches bore and the stroke is 27 inches. The engine is rated at 100 horsepower and

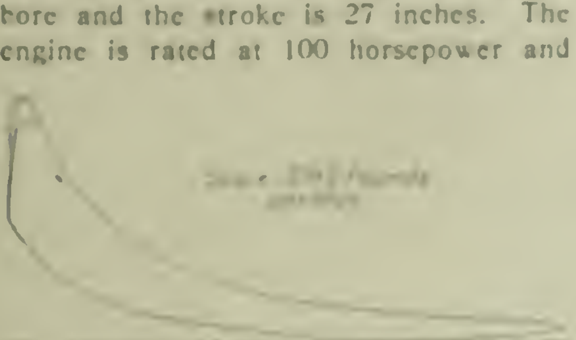

Fig. 2. Heavy Load

runs at 190 revolutions per minute at full load. The compression is 180 pounds per square inch. The engine is governed by throttling the mixture entering the cylinder, which is accomplished by a butterfly valve in the passage between the mixing valve and cylinder, controlled directly by governor.

The first three diagrams show the operation of the engine under normal conditions. Fig. 1 is a stop diagram taken with

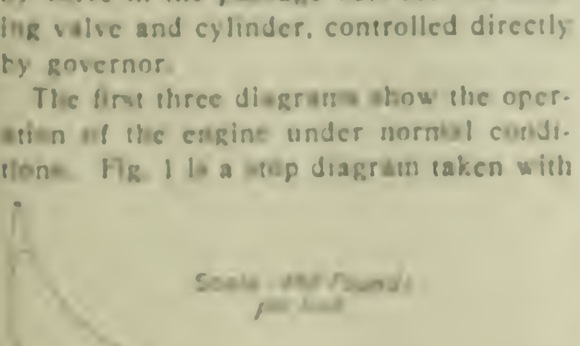

Fig. 3. Full Load

a 10-pound spring and it shows that the valves are adjusted properly, with the possible exception of the exhaust valve, which appears to close a trifle early. The rise of pressure from *a* to *b*, however, is very small, being slightly over one pound, and may reasonably be disregarded. The horizontal portion of the first part of the suction stroke, *c* to *d*, is probably due to the inertia of the incoming gases.

Fig. 2 shows a diagram taken, with a spring having a true scale of 187.2 pounds per inch*, when the engine was carrying a very heavy load. The explosion pressure on this diagram is about 370 pounds per square inch and the pressure at the opening of the exhaust valve is about 23 pounds per square inch and the diagram figures out 136.4 indicated horsepower. This engine frequently carries a load of 80 kilowatts for an hour or more.

Fig. 4. Light Load; Settings Unchanged

Fig. 3 shows a diagram taken with a spring having a scale of 240 pounds per inch.* This diagram was taken at a time when the engine was showing very slight signs of preignition, a slight thump being heard. This is indicated on the diagram by the excessive explosion pressure of one of the cycles, which is approximately 450 pounds per square inch.

The next diagram, Fig. 4, shows the effect of a light load. The load at the switchboard was 17.22 kilowatts and the indicated horsepower was 38.7, giving a combined efficiency of 59.6 per cent. for the engine, belt transmission and dynamo. This diagram was taken with a 120-pound spring* and shows a mean effective pressure of 21.0 pounds per square inch. It will be noted that the compression on this diagram is only about 140 pounds per square inch; this was doubtless due to the throttling action of the governor on the light load. The absence of pressure rise after ignition will also be noted. This is probably due to the fact that only a small amount of mixture is admitted by the governor. The action of the governor is also illustrated in this diagram by the variation of the expansion line.

The three remaining diagrams were taken when the load upon the engine was very light, to show the effect of changing the point of ignition upon the operation of the engine. These diagrams were all taken with a 120-pound spring and under conditions of steady load with gas of a fairly good quality. The temperature of

Fig. 5. Very Light Load

the jacket-water discharge was comparatively low at this time.

Fig. 5 is very similar to Fig. 4 in that there is no rise of pressure due to combustion. The ignition setting was 25 degrees ahead of dead center for both of these diagrams. The small triangular area

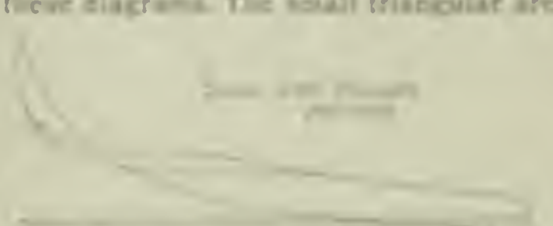

Fig. 6. Retarded Ignition

at the top of Fig. 5 was undoubtedly due to the fact that during one of the cycles shown by this diagram the mixture in the cylinder was poor and did not burn readily. This allowed the pressure to drop immediately after the ignition, causing the lower expansion line to be drawn. On light loads, occurrences similar to this are very common.

Fig. 6 was taken with the igniter retarded as far as possible from the normal

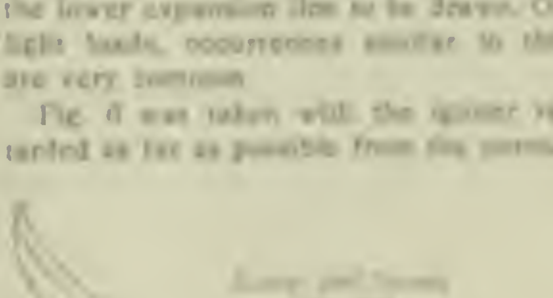

Fig. 7. Light Load; Extra Advance

operating position, which was about 25 degrees ahead of the dead center. According to the diagram, the ignition actually occurred slightly beyond the dead center and I think the igniter was set about 10 degrees past the center. The loop in the diagram is peculiar and is probably due to the cooling influence of

*The scales of all of the diagrams as printed here are twice the actual spring scales.—Ed.

the jacket water, decreasing the volume of the gas until the moment when ignition occurred.

Immediately after taking this diagram the spark was advanced ahead of the normal operating position to 30 degrees early. The engine did not run steadily at this point but speeded up and slowed down alternately. Fig. 7 shows this effect in the different areas of the two cycles which were recorded.

LETTERS

Corrosion of Water Cooled Exhaust Pipe

In Mr. Wild's letter under the above heading in the May 9 number, he does not say whether or not the exhaust pipe

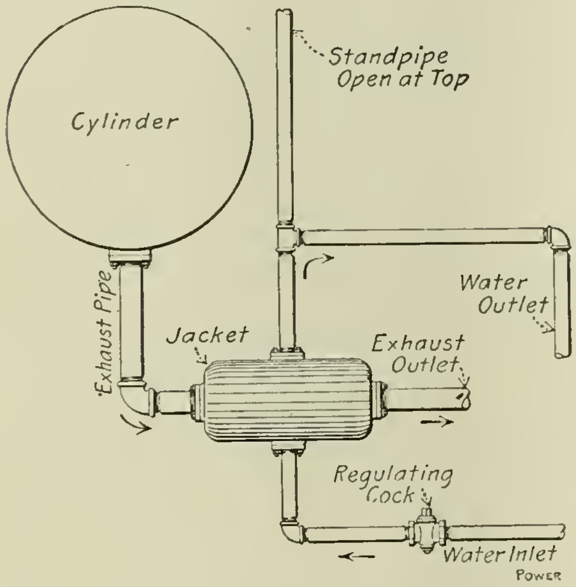

Fig. 1. Water Jacketed Exhaust Pipe

and muffler are drained to remove the water of condensation formed when the engine is not running. If the acid liquid cannot be readily discharged it is sure to eat rapidly through the metal. In any case, care should be taken to adjust the water feed to the exhaust pipe so that no excess of water is admitted; only enough should be allowed to pass to insure the water all being converted into steam. If the engine runs on a constant load, this should not be difficult of attainment, but if the load is variable, it will probably be found impracticable to vary the water supply accordingly and in this case the minimum amount of water feed will probably pay best in the long run.

A good way to cool the gases is to water-jacket the exhaust pipe, as shown diagrammatically in Fig. 1, if the water is available. It will probably be found cheaper and more satisfactory to have a short water-jacketed section cast with flanges at each end of it than to have a jacket fitted to the existing pipe, although I have seen the latter method applied with success. In multicylinder exhaust manifolds the piping may be arranged as in Fig. 2, with or without the standpipe, according to necessity.

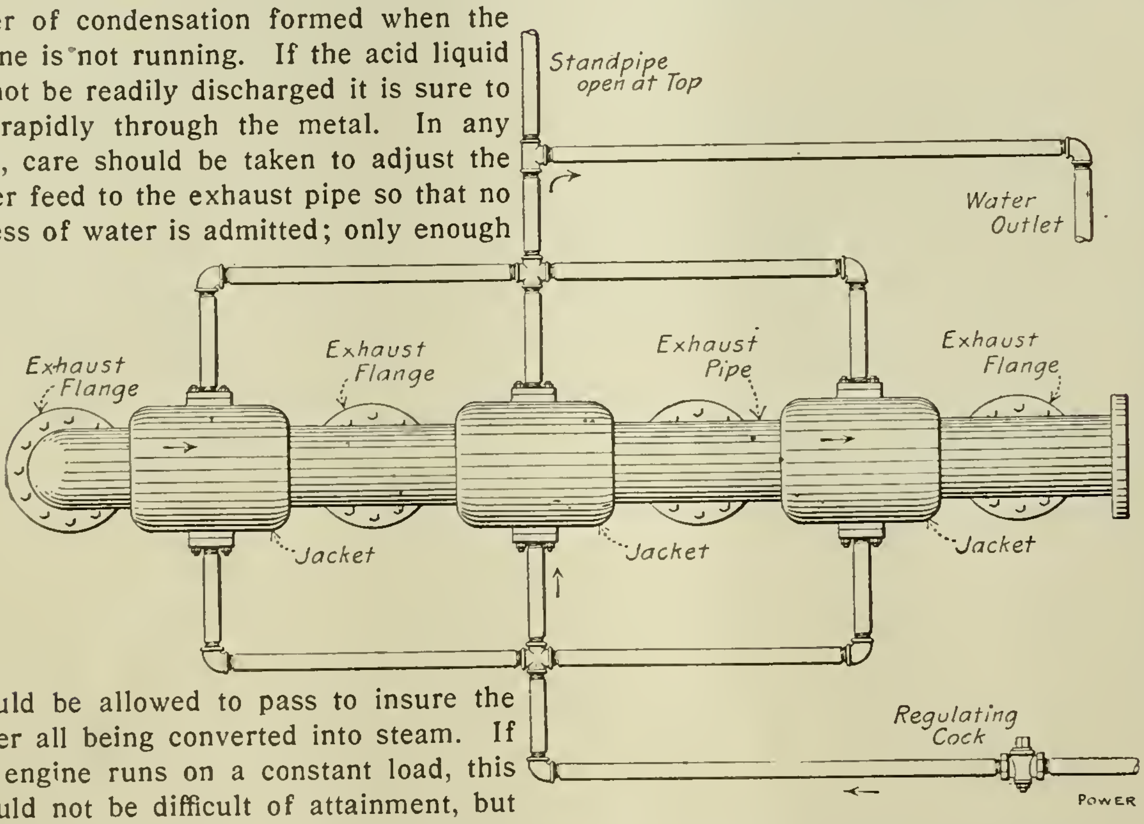

Fig. 2. Arrangement of Piping for Multicylinder Exhaust Manifolds

Another way to cool the gases and secure efficient muffling, usually adopted primarily for the latter purpose, is to provide a series of iron chambers to allow for the continuous expansion of the gases.

Manchester, Eng.

Mr. Rushmore's Operating Costs

In the issue of May 23, on page 812, appeared "A Comparison of Actual Gas Power and Central Station Figures," by Samuel W. Rushmore. I cannot agree with some of the general deductions reached by Mr. Rushmore, which seem to be more or less in line with the arithmetical errors which he has made. He gives the total cost as quoted by the central station as $555 per month and states that it would be necessary to use $125 worth of gas per month; this makes a total of $680, or 3.4 cents per kilowatt-hour. Mr. Rushmore figures this at 3.9 cents per kilowatt-hour, an error of ½ cent per kilowatt-hour. Mr. Rushmore includes no charges for repairs, cooling water or ash removal, and makes a very general assumption in regard to the fixed charges.

Apparently the standby losses included are only the night losses during the working days of the week; in other words, the standby costs from Saturday noon to the following Monday morning are not included.

The cost of the plant will be approximately as follows:

Producers, 400-horsepower at $12	$4,800
Engines and auxiliaries, 240-horsepower at $45	10,800
Foundations, settings, piping, etc., for producers and engines, 400-horsepower at $12	4,800
Building, 400-horsepower at $12	4,800
Total	$25,200

In a gas-engine plant of this character it is conservative to figure depreciation at 8 per cent., interest at 5 per cent., taxes and insurance at 2 per cent. and profit on investment at 7 per cent., making total fixed charges of 22 per cent., or $5544 per year. It is unnecessary to refer to the items on interest and insurance and taxes, as these are conservative. A plant owner would also hardly consider investing $25,000 in any branch of his business unless he expected to make some profit on the investment and 7 per cent. is a very conservative figure.

From a number of tests on operating plants, three cubic feet of cooling water per kilowatt-hour is a good average figure. During the six-day test referred to by Mr. Rushmore he would probably use 15,280 cubic feet of water, which, at 90 cents per 1000 cubic feet, comes to $14.75.

The corrected operating costs will then be:

Coal, 15,218 pounds	$21.50
Cylinder oil	3.00
Engine oil	1.25
Kerosene	0.20
Waste	0.80
Labor	33.00
Cooling water	14.75
Total	$74.50

Kilowatt-hours generated, 5094; operating cost per kilowatt-hour, 1.463 cents; fixed charges per week, $106.50; fixed charges per kilowatt-hour, 2.09 cents.

Mr. Rushmore has also figured the cost of central-station power for a rated capacity of 350 horsepower, whereas the power delivered by his gas engine was only 180 horsepower. Neither has he made any allowance for emergency service or breakdown service. A number of instances have come to my notice of gas-engine plants installed within the last few years where the emergency service has been very expensive, in spite of the efforts of capable operating engineers and a large amount of time devoted to the matter by the plant owners. To quote the words of the owner of a 240-horsepower gas-engine installation: "Our electricity did not cost us very much when we had it, but it cost us a whole lot more when we did not have it, and each time the wheels stopped going around the central-station service looked more attractive than ever, so we have sold the plant, and you can see how the factory is running."

If Mr. Rushmore's plant were located in Rochester, we could give him a rate based on his six-day plant test very much lower than 3.6 cents per kilowatt-hour. I am afraid he is leaving out many of the items entering into the total cost of his power when he makes the statement that it is not costing over one cent per kilowatt-hour. If he were considering his operating charges alone, and making no charges for repairs, or ash removal, or overtime on the part of the plant operators, and crediting the operating cost for the week, as shown above, with $30 for purchased gas, his net cost per week would be $44.50, or 0.874 of a cent per kilowatt-hour. The fixed charges on top of this makes a total of 2.964 cents per kilowatt-hour, instead of "not much over 1 cent per kilowatt-hour" as stated by Mr. Rushmore.

R. D. De Wolf,
Ass't Mech. Engr., Rochester Ry. and Light Company.
Rochester, N. Y.

Mr. De Wolf's criticism of my figure of 0.39 cent per kilowatt-hour is correct; I find I divided the total cost by the previous month's meter record of only 17,500 kilowatt-hours.

Mr. De Wolf is wrong in saying that I included no charge for repairs; I stated that our repairs and adjustments for a period of two years had not exceeded $10 per engine every sixty days.

I made no charge for cooling water because we have our own water supply and the engine consumption is a small part of our total pumpage. The coal handling and ash removal are included in the wages of the producer man; the coal is dumped directly from the railway trestle into the producer charging car, and contractors filling in land call for and remove the ashes free of charge.

I clearly stated that as we would not dismantle the gas-power plant should we adopt central-station service, therefore I did not include the otherwise important items of interest, depreciation or amortization.

I neglected to state that the central-station figures were based on the installation of a 150-horsepower alternating-current motor coupled to a direct-current generator, and were not based on the full use of the 350 horsepower total rating of our motors, although the two engines used in the test totaled 240 brake horsepower. Repairs, depreciation, interest, etc., on a motor-generator would wipe out any item I may have overlooked in present cost.

Although these two engines have been in constant service without any serious shutdown since first installed, one more than four and the other nearly two years ago, we have an additional 75-horsepower reserve gas engine and a 100-horsepower steam plant which we operate during the heating season.

We have no central-station breakdown service, yet, with the two Körting engines alone in service, our machinery has operated during the last three years with no more interruption than suffered by other shops in this district supplied by the central station.

I was a pioneer in the adoption of producer gas more than eight years ago. I have been through all the harrowing experiences and my present plant investment is probably twice as great as would be required today for equal results. Still, if I were now to make a fresh start in this locality, I would unhesitatingly install gas equipment and with the full expectation of producing power at less than half the central-station figures.

Of course, I regret that I am unable to hook on to Mr. De Wolf's busbars at Rochester, for nearly everyone knows that in that favored city central-station power is much cheaper than in most other localities.

Samuel W. Rushmore.
Plainfield, N. J.

Gas Production from Crude Oil

Reading E. C. Jones' paper presented at the San Francisco meeting of the American Society of Mechanical Engineers and printed in Power for May 2, I was somewhat surprised to note that Mr. Jones went to the expense of compressing air to 35 or 40 pounds pressure for the injection of the oil and to assist in the partial combustion of the oil in his experiments with an oil gas generator. We find it unnecessary, but prefer to use steam, as the energy to atomize the oil with it practically costs us nothing and it adds stability and volume to the generated gas. It also cuts down the nitrogen content away below Mr. Jones' figure of 70 per cent. An economizer in our exhaust gases gives us all the energy required for atomizing, and in this way heat that would otherwise be lost is utilized.

Of course, we get more hydrogen in the gas by using the steam, but I do not consider that a disadvantage. H. F. Smith, of the Smith Gas Power Company, stated in a paper read last year before the National Gas and Gasolene Engine Trades Association that he had never known of a single authentic case of preignition due to the presence of hydrogen; he had personally observed the operation of an engine on which the compression was run up experimentally to as high as 220 pounds per square inch, while supplied with gas containing 27 per cent. of free hydrogen, without any sign of preignition.

Our experience agrees with Mr. Smith's. We are now distributing to several thousand consumers illuminating gas under pressure, by means of pumps driven by gas engines running on crude-oil gas in the production of which we use steam as the atomizing agent and there is no preignition; neither is there any deposit on the cylinder wall or inlet valves. The spark plug has been in use two months at a time and on being examined has been returned for further service.

Joseph J. Nix.
Los Angeles, Cal.

Recovering Used Oil

Draining the oil channels of gas-engine beds and other means of keeping oil from flying in all directions seem to be ignored by most builders, more especially in the smaller types of engines. Though there have been feeble attempts in this direction, the results are not very satisfactory. The difficulty is increased in the vertical multi-cylinder engines using the splash system of oiling. The editorial paragraph in a recent issue of Power hits the nail on the head exactly in saying that splash lubrication is in the same class as hot-tube ignition.

I have handled several makes of gas engines and have failed to find one that could be kept clean of surplus oil any length of time. The only economical method is to use the oil over again by collecting the drips and circulating the oil through a filter. For example, if the excess oil of a single-cylinder horizontal engine were collected and filtered, the surplus from the new oil fed to the piston would provide a continuous supply for the bearings.

If gas-engine operators would figure up their oil bills, then collect all of the surplus oil and filter it, they would find that the filter had paid for itself by the time the first barrel was used.

There are various ways in which oil can go to waste. Usually the piston and the crank disks are not covered properly and the draft created by the motion of the piston will throw the oil on the flywheels. In a great many cases there is no provision for draining the channels around the base of the engine and it is a difficult task to drill and tap it for pipes if the channel is divided up by foundation-bolt bosses. In such a case, a neat job can be made with a sheet-iron trough extended along the edge of the channel supported by clips made of sheet iron. The clips should flare up at the edges and three or four strands of candlewick can be laid on the clips so that oil will drain from the channel by capillary attraction.

If the oil has a tendency to work out of the bearing along the shaft, a good plan is to make a spring wiper and fasten it to the engine beneath the shaft so it will drain into the channel.

While these simple suggestions are crude, they are effective in practice.

This Engineer Made Good

While working in a colliery as a ventilating-fan engineer, a young man was sent to the power house to take the place of one of the engineers. He was not skilled in running electrical machinery or steam turbines, but started in to do his best.

There were two 100-kilowatt turbine sets, the bearings of which were being melted out at the rate of three or four a week and costing the company $15 for each bearing. Vanes were also broken and the shafts were sprung.

He first cleaned the dirty oil cups that oiled the bearings. As a result, during the first month only three bearings seized, but not seriously, and they were scraped and put back. He refused to take heavy oil the storekeeper gave out and by using a lighter grade reduced his oil consumption from 12 to 7½ gallons a week.

One of the centrifugal condenser pumps refused to pick up after being shut down. It was packed and repacked by half a dozen different men, but was not improved.

The young engineer, having concluded that a porous casting caused the trouble, gave the casting one coat of quick-drying iron oxide and two coats of shellac.

When the engine-room force came on at 6 a.m. the pump was working well and the trouble ceased.

A few weeks later the lights went out from loss of vacuum and low steam pressure. The regular engineer struggled along with a 15-inch vacuum and the voltage was reduced from 500 to 420. It was believed that the plant would not work under 120 pounds steam pressure.

When the regular engineer went off duty the young man noticed that the feed pump was running overfast, and that the condenser pump was running too slow. He speeded it up and got a 27-inch vacuum. As the pump had a peculiar sound he concluded that it was not getting enough water. A boy was sent to the canal to clean the strainer which was found to be covered with a mass of weeds. The result was that the feed pump was slowed down, the voltage was back to normal and the machines carried their loads with ease.

This experience goes to prove that it pays to always be on the alert and find out the why of things about the plant.

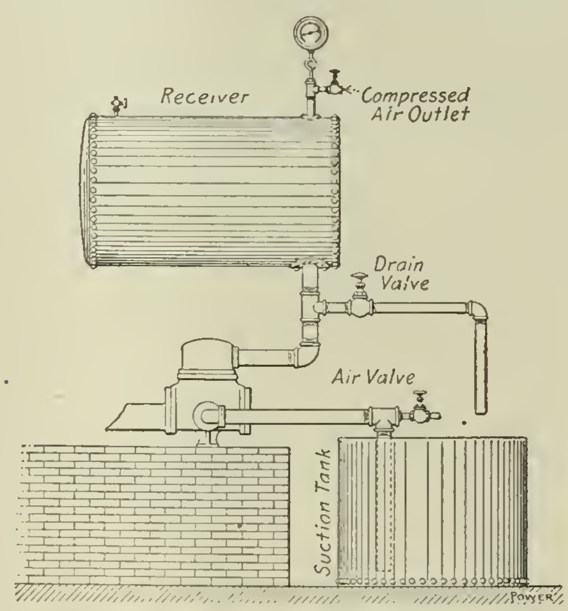
Toledo, O.

Pump Used Compressed Air

Some time ago I was employed in a plant where iron barrels were occasionally tested, an air pressure of 10 or 12 pounds per square inch being necessary. The foreman said he had thought of using a small duplex pump, but he could not pump over 4 pounds of air pressure. I told him I could get all the pressure he needed and, to prove my argument, devised the scheme shown in the accompanying drawing.

The barrel to be tested is first connected by a hose to the open-air outlet



PIPING FROM PUMP TO TANKS

valve on the receiver. The drain valve is closed. The pump is then slowly started and when primed the air valve on the suction line is opened just enough to prevent the pump from entirely "losing its water." By proper regulation of this air valve the pump will take in a large volume of air with each stroke and just enough water to keep the plungers and valves fairly well sealed. When a pressure of 8 or 10 pounds is reached the air valve on the suction line is closed, the pump takes water and the receiver is nearly filled. This forces the air out of the receiver into the barrel being tested and increases the pressure at the same time.

Should more pressure be desired the air-outlet valve is closed and the receiver is drained into the suction tank. The small valve shown on top of the receiver admits air when the receiver is being drained. The operation mentioned is then repeated.

Incidentally it is not the most economical way of compressing air.

Filing Engineering Articles

One of the inconveniences in filing magazine clippings is that of having two or more articles, on different subjects and desired for filing, printed on one sheet. This precludes the collecting of all articles on one subject under a single head. The easiest plan would be to purchase as many copies as there are articles desired; but, unfortunately, few men can afford this.

The envelop system has several disadvantages: It is bulky and much time is expended in getting a clipping out of its envelop, which if used frequently is soon destroyed.

Clippings laid flat between covers and held in place as in a book are preserved with the least wear and tear. A very convenient file for this purpose is that commonly known as a loose-leaf grip file. This consists of a piece of tough manila paper, folded to form a cover. To this is securely fixed a flexible metal cup with two needles, over which the papers to be filed are placed after being perforated with a punch supplied for the purpose. The needles are then bent down and outward, the locks secured, and the filing is complete. The files, which take up only the room of the papers themselves, have expanding backs to accommodate the growth of the contents; each file holds about 300 papers.

These files are made in several sizes, but I find the 12x9-inch size the most convenient.

It is not always advisable to cut away the reading matter surrounding an article; some of these pages should be left intact and the reading matter not required crossed out. These marked pages may then be used as a background upon which to paste small clippings.

The files should have a complete and reliable index, the card index being the most suitable for this purpose. This requires blank cards on which to record the articles, a set of alphabetical guide cards, for locating the index card on which any article has been recorded, and a box in which to keep the cards.

To illustrate the use of the system, assume that it is being started with one file (marked *A*), and it is desired to file the article entitled "Condensers for Steam Engines and Turbines," by Frank Foster, printed in POWER for December, 1906. Having cut it out of the magazine, punched and filed it, and numbered the pages 1, 2, 3, 4, etc., the next step is to index the clipping. This will require four cards as follows:

ARTICLE: Condensers for Steam Engines and Turbines.
AUTHOR: Frank Foster, POWER, December, 1906.
FILE: A. PAGES: 1-4.

ARTICLE: Engines and Turbines, Condensers for Steam.
AUTHOR: Frank Foster, POWER, December, 1906.
FILE: A. PAGES: 1-4.

ARTICLE: Steam Engines and Turbines, Condensers for.
AUTHOR: Frank Foster, POWER, December, 1906.
FILE: A. PAGES: 1-4.

ARTICLE: Turbines, Condensers for Steam Engines and.
AUTHOR: Frank Foster, POWER, December, 1906.
FILE: A. PAGES: 1-4.

The titles ARTICLE, AUTHOR, FILE and PAGES on the cards should be made easily distinguishable from the rest of the record, such as underlining, the use of a different colored ink or by the use of a rubber stamp. All that remains then is locating these four cards in their alphabetical order under their respective guide cards, *C*, *E*, *S* and *T*, in the index case.

The initial cost of such a system is 78 cents.

Youngstown, O.

Sump System for Oil Seepage

For some years the waters in northern California, principally the Sacramento river and its tributaries, have been polluted by seepage of fuel oil from the many industrial plants in the valley.

The Southern Pacific Railroad has been an especially large loser, and, with the view of operation economy, has, after repeated experiments, apparently solved the problem by the installation of a simple sump system at the shops.

Along the bank of the river, opposite the shops, a trench was dug for about 450 feet. In excavating, various strata of oil were exhibited, an accumulation of many years' waste, which percolated through the soil and emerged into the stream from the bedrock. The company constructed a system of seven sumps to engage the oil which, whenever conditions warrant, is skimmed from the surface of the water. For temporary experiment these sumps have been constructed of sacks of sand, but the method has proved so successful that concrete tanks will be built to act as a positive catch basin for all seepage.

To give an idea of the enormous loss of oil from this plant the company within a single week reclaimed fully 350 gallons by its skimming process. At the reduced cost of petroleum to the railroad, this amount is almost sufficient to pay for any cost of installation.

Thin Fires

My method of obtaining economical results in the boiler room is to carry the furnace fire just thick enough to cover the grates, and to fire light and often. This gives the coal a chance to burn. I admit enough air through the fire-door baffle plates to get proper combustion.

The firemen keep the ashpit doors so adjusted that there will be an opening into the ashpit just one-fifth of the area of the flue space for the admission of air. I find this to be a very good method of regulating the air, and it saves fuel.

W. T. HUNN.

Bellefontaine, O.

Clogged Condenser Gage Pipe

Recently I had charge of a cross-compound engine and a jet condenser pump. One day as I stood looking at the vacuum gage the pointer dropped to zero and rested on the pin. The pump was working normally and the engine kept on running as if nothing had happened.

Then I said to myself, "The pump is working all right, and there is a good vacuum in the engine cylinder or the engine would let me know it very quickly. The trouble must be between the condenser and the gage."

I took down the 1¼-inch gage pipe, which was about 3 feet long, and found that it was full of mud and slime. I cleaned it and put it back; as a result I got 26 inches of vacuum on the gage.

The condensing water was taken from the north branch of the Hoosac river, which after a rain is dirty. Shortly after, I went to a larger plant. Three months later my old superintendent asked me to go down to the mill with him and look over the condenser as he could get no vacuum and the mill had been shut down. I went to the plant and found the engineer and two pipers who had inspected the piping from condenser to the engine for leaks. They found everything in good condition at the water end of the condenser pump but there was no vacuum.

I told the engineer that the superintendent had asked me to come in and help out if I could and that sometimes two heads were better than one.

We started the pump and it ran as nicely as any pump could and the quick start and slow ending of the stroke showed that it was producing a good vacuum in the condenser. The pointer on the vacuum gage never moved, however. I told the engineer that he would find the trouble in the 1¼-inch pipe between the gage and condenser.

When he took the pipe down he found it full of slime and mud. After it was cleaned out and replaced he had 23 inches of vacuum showing on the gage with the engines standing still.

The trouble was found and overcome in ten minutes by one who had had experience in that line. This incident goes to prove that to retain a competent engineer he must be paid what he is worth to his employer and outside assistance would not then be necessary.

JAMES MITCHELL.

North Adams, Mass.

Line Shaft Repair

An accident occurred in the plant in which I am employed when the main driving shaft carrying a heavy shed

BREAK IN THE LINE SHAFT AND THE REPAIRS

twisted off almost flush with the flange coupling *A*, as shown. The shaft was 4½ inches in diameter, but had been turned down to 3 inches where it fitted in the coupling. To take this shaft out would have meant shutting down the tire making departments for the rest of the week, as the next shift would have had to come off all the ropes unspliced, as well as taking off the driving pulleys for the other room.

The repair job was begun by taking out the section of shaft *B*, on which were two flange couplings and to which the coupling on the broken piece was bolted.

The flanges were removed from this shaft, and the flange *C* was then pressed on a longer section of shaft *D*, which came up to the point where the shaft had twisted off.

A compound rest was then taken from a lathe and rigged up on a staging alongside the shaft and that part of the tapered shaft at *E* was turned down to a diameter of 3 inches.

This turning was done during working hours, with the other room running at full speed, the shaft making 270 revolutions per minute.

A keyseat was cut at night in the broken shaft with a portable keyseating machine, and the two shafts were then connected by a box coupling, as shown in the lower view.

New Bedford, Mass.

Corliss Valve Setting

Methods of setting the valves of a Corliss engine have often been described, but nothing has been said that would be

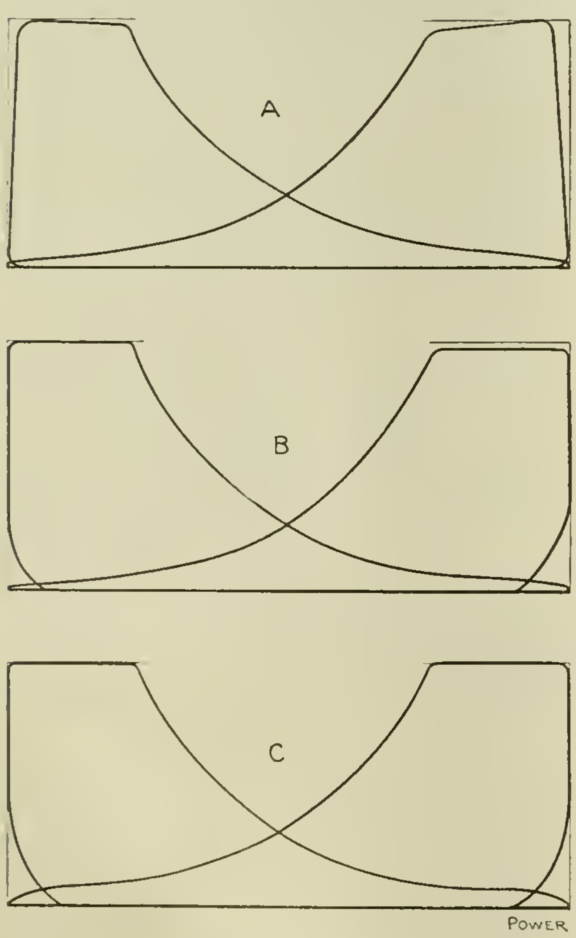

FIG. 1. DIAGRAMS TAKEN FROM THE ENGINE

of service to the average engineer if, after having set the valves according to laid-down rules, factory marks or blueprints furnished by the manufacturer, the engine would not work satisfactorily. In my experience factory marks and blueprints have often been disregarded and the valves set to suit the indicator as well as to obtain smooth running.

One engine, of the heavy-duty type, 38x40-inch cylinder, was direct connected to two double-acting 20x40-inch ammonia compressors, working against 160 to 180 pounds discharge pressure. The indicator showed an initial pressure of 110 pounds per square inch. The steam valves were of the slotted type, that is, live and exhaust steam traveled through the valve instead of over it. The directions for setting these valves were as follows:

Set the steam valve with $\frac{1}{2}$-inch lap, exhaust valve $\frac{1}{8}$ inch lap and give the steam valve $\frac{1}{16}$ inch lead. The blueprint showed the amount of travel for each valve and length of rods from the wrist-plate to the bell crank. After the valves were all set according to directions and the eccentric fastened, the engine was turned by hand to the opposite center and the lead adjusted to suit the $\frac{1}{16}$-inch mark which, of course, altered the lap slightly. The engine was started up, and if one ever heard a bad running machine this one was it. An indicator was attached and a diagram produced, as shown in diagram *A*.

I stopped the engine and examined the diagram. The thump occurred after the piston had traveled 2 inches from either end, and I wondered why the thump was not at the beginning of the stroke. If it was due to lack of compression, the thump would have happened before it reached the end of the stroke; if it were due to too much lead, it would have happened at the beginning of the stroke; but coming when the piston was 2 inches from either end, when the steam valve was nearly open, I will admit I was puzzled.

I reasoned that the thump was due to concussion by having full steam pressure admitted to the cylinder too late, as the indicator showed. I advanced the eccentric slightly and the thump lessened, and advancing the eccentric a little more the thump ceased, but the exhaust valves rattled slightly. I took another indicator diagram and *B* was the result.

I had followed the marks on the valves and cylinder, also the blueprints and instructions of the builder and I had no compression, even after altering, so to get the shaft, bearings, crank and crosshead running quietly, I started to lengthen the reach rods on the exhaust valves until both valves had $\frac{3}{8}$-inch lap. Then, to get both ends alike, I lengthened one rod until one exhaust valve had $\frac{7}{16}$ inch lap, obtaining diagram *C*.

This adjustment produced a smooth-running engine, but the speed could not be changed more than 10 revolutions per minute, and in this plant the ice machine should run at 25 as well as at 70 revolutions per minute. The regulating arm on which the weight hung for changing the speed was changed from its original shape to look like that shown in Fig. 2. Then a weight of equal size was put on each side. This arrangement worked all right at speeds from 38 to 50 revolutions per minute. I next attached a spring, as shown. This spring attachment solved the problem and the engine

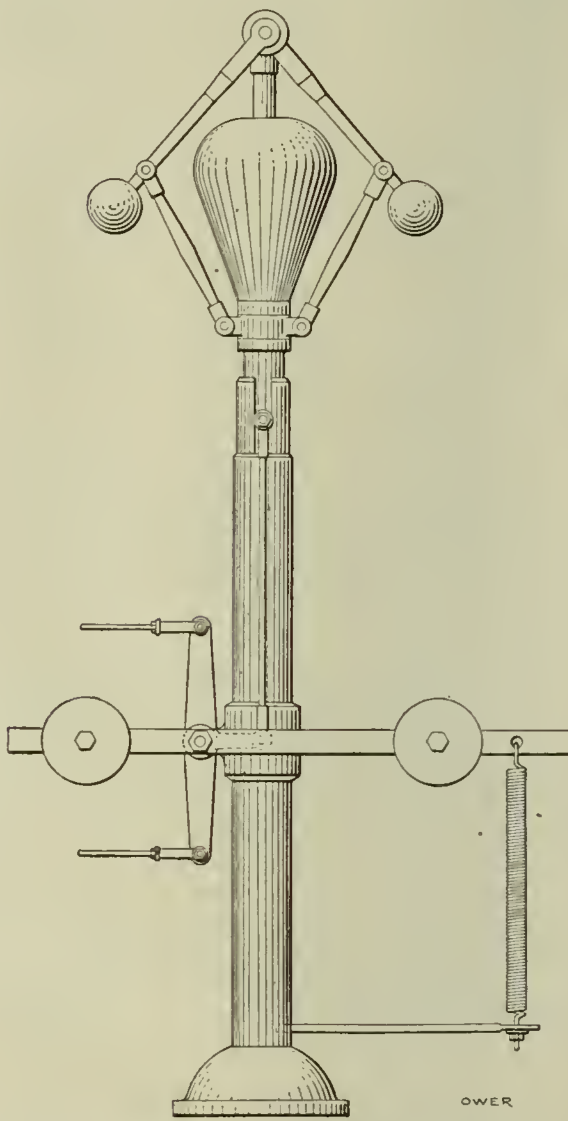

FIG. 2. SPRING ATTACHED TO THE GOVERNOR ARM

can be run from 10 to 50 revolutions per minute, with the throttle wide open and with a steady cutoff.

W. NOEYES.

Kansas City, Mo.

Reinforced Crank Pin Brasses

The crank-pin box on a small steam engine gave trouble by heating. On examination it was found that the brasses were so lightly made that under heavy loads they would spring. There was a center rib on each against which the rod end and adjusting wedge bore, and metal on each side of this rib was left very thin. As a consequence this rib was forced against the crank pin, causing the center of the brasses to wear faster than the outer ends.

The cavity on each side of the rib was cleaned, turned and then filled with hard babbitt metal. This gave a full bearing for the rod end and adjusting wedge. After making this change the box gave no further trouble.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Size of Turbine Exhaust Pipes

William Kent says that my formula, given in POWER of March 28, appears to be defective insofar as it does not include the length of the pipe and the allowable drop in pressure between the condenser and the turbine.

As to the length, I will be pleased to consider suggestions for making the area of the pipe vary with variation in the length if I am shown that this is necessary or desirable. My present opinion is that the length affects the desirable area very little if at all.

Consider an exhaust pipe 10 feet long and of any reasonable sectional area. This pipe costs a certain sum of money, and the space it occupies may cost something. If we were to reduce the sectional area of the pipe, we would reduce the cost.

The friction of the pipe causes the vacuum at the exhaust end of the turbine to be less than the vacuum at the condenser and the difference in the vacuum will depend on the area of the pipe. The pressure required at the turbine is, say, P. To obtain this pressure, a lower pressure, say, P_1, must be maintained at the condenser; and the difference in pressure, or $P - P_1$, depends on the area of the exhaust pipe.

If we were to reduce the area, we would increase $P - P_1$; and, therefore, to maintain P constant, we should require to reduce P_1 and this would involve increased initial cost of condensing plant, or increased running charges, or both. What is required is to determine the diameter of pipe at which the rate of reduction in cost of pipe with reduction in area will just equal the rate of increase in cost of condensing plant with reduction in area.

We have been considering a pipe 10 feet long but, if one only 5 feet long is taken, the variation in cost of pipe with reduction in area would be just half, while the increase in cost of the condensing plant would also just be half, so that the best area for the 5-foot pipe would be exactly the same as the best area for the 10-foot pipe. It therefore appears that the length of the pipe does not require to be taken into account.

As regards Mr. Kent's other objection to my formula, namely, that it does not include the allowable drop in pressure, it would, I consider, be foolish for anyone to state an allowable drop of pressure without considering the cost of obtaining this. The formula is intended to determine the area which will give the drop of pressure which is best in any case. The drop will, of course, be very much greater for a long pipe than a short one. For a short pipe the drop ought to be very small because it can be kept small at a trifling cost. For a pipe twenty times as long, it would be unreasonable to limit the drop to the same amount, as this could only be accomplished by multiplying the sectional area of the pipe many times and the cost would be enormously increased.

As regards the exponent 0.4 of the factor f in my formula, most formulas for the flow of fluids through pipes of circular section make the friction vary as the square of the volume of fluid passing a given point in the pipe every minute, and also make the friction vary as the fifth power of the diameter of the pipe. With nonelastic fluids weight may be, and often is, substituted for volume in the formula. If F denotes the friction, B the volume and d the diameter

$$F \propto \frac{B^2}{d^5}$$

For convenience later on, let A denote the internal sectional area of the pipe, then

$$F \propto \frac{B^2}{A^{2.5}}$$

If v denotes the velocity of the fluid

$$B \propto vA$$

Therefore

$$F \propto \frac{v^2}{A^{0.5}}$$

That is, for constant velocity the friction varies inversely as the square root of the sectional area. Presumably the reason is that the ratio of superficial area of the pipe per foot length to sectional area varies inversely as the square root of the latter, and the friction increases with the superficial area. Therefore, for pipes of dissimilar but equal sections, we can take the friction to vary as the superficial area per foot length, or simply as the internal periphery.

If f denotes the periphery in feet of a figure of the shape of the cross-section of the pipe or duct and of an area of one square foot, then for all pipes of one square foot sectional area

$$F \propto f$$

and for all pipes whatever

$$F \propto \frac{B^2 f}{A^{2.5}}$$

Therefore, for equal friction

$$A^{2.5} \propto B^2 f$$

or

$$A \propto B^{0.8} f^{0.4}$$

In my formula W (the total weight of steam per hour) is employed for convenience instead of B.

R. M. NEILSON.

Glasgow, Scotland.

Did Not Hook On

I submit the following answers to the questions of S. E. Mead as given in the May 23 number, page 814, regarding the diagram from a Corliss engine which did not hook up.

"Why does the diagram from that end include any area?"

Because the movement of the piston changes the pressure of the contents of that end of the cylinder by alternately compressing and expanding it.

"Why does not the expansion line follow back upon the same line as the compression?"

The expansion line drops down below the compression line because at the beginning of this stroke both the steam and the exhaust valve at this end of the cylinder are closed, and as the piston starts away the contents of the clearance space expand, thus losing pressure very rapidly at first, and then gradually until at about half stroke, after which point it runs nearly parallel with the line of zero pressure. Then when the exhaust valve opens it raises slightly to meet the line of lowest pressure attained by the condenser.

In explanation of this diagram I would say that it is directly opposite to the ordinary steam-engine diagram in that the expansion curve is the lower line which approaches nearest the line of absolute vacuum, and the compression curve is the upper line or the one nearest the atmospheric line. In this the diagram is very similar to the diagram of an air compressor.

The compression starts in a line very nearly straight and parallel to the atmospheric line for more than half stroke

This is because the exhaust valve is open and the piston moves against the lowest vacuum attained. Then as the exhaust valve closes, this charge of low-pressure steam is compressed, thus raising the pressure highest at the end of the stroke.

In answer to Mr. Mead's last question, I would say that the expansion line cannot be lowered as it represents the very best possible vacuum attainable with his engine.

CHARLES F. CLARK.

Hartwick, N. Y.

Boilers Foam

In the May 23 number, J. M. Stewart asks for opinions about his foaming boilers. I have had the same trouble with domeless boilers connected to hoisting engines, and have noticed that sometimes they do not furnish dry steam even on more regular service.

I believe that something serving the purpose of a dome is necessary on a horizontal tubular boiler, but I would not want a dome connected in the usual way, as it greatly weakens the shell to cut out the area necessary for the rivet holes and steam passage.

I would prefer a horizontal drum connected to one end to the boiler by a thimble and flange joint, and at the other end resting freely on a support made by riveting thimbles of the proper length to the shell of the boiler and drum.

A drum connected in this way will cause some loss from radiation but if it is properly covered the loss will be small and the extra steam space is a great gain to a boiler connected to a hoisting engine.

Mr. Stewart's trouble might be in his feed water, but if he will boil samples of it in an open vessel, he will be able to tell by its behavior if such is the fact.

H. L. TURNER.

Bartlesville, Okla.

Receiver Pressure

L. Johnson, in the May 16 issue, asserts that the most economical receiver pressure is that which causes the governor to revolve in the highest plane, basing his conclusion on the fallacy that the earlier the cutoff in the high-pressure cylinder the smaller the steam consumption. The fact is, early cutoff in the high-pressure cylinder does not necessarily mean less steam consumption, and furthermore it is possible with no change of cutoff to vary the steam consumption within considerable limits, say 10 per cent., simply by changing the receiver pressure.

The steam in the cylinder at cutoff is made up of two parts, a small amount left in the cylinder at the closing of the exhaust valve, and a larger amount which flows in from the chest while the admission valve is open. These two volumes of steam mingle in the cylinder, but they can be kept separate for purposes of reasoning. The steam left in the cylinder at compression is sometimes called cushion steam. Its volume is constant but its weight is variable depending on the density, which in turn varies with the receiver pressure. With high receiver pressure the cushion steam may be 15 per cent. of the steam at cutoff, while with low receiver pressure it may be as low as 5 per cent. These figures are based on 5 per cent. clearance and one-quarter cutoff and are to be regarded as approximate values for average conditions.

The steam consumption is measured by the steam that comes in from the chest and joins with the cushion steam to make the volume present at cutoff. Calling the weight of steam at cutoff 100 and the cushion steam 5, the balance, or steam consumption, is 95 corresponding to low receiver pressure. Calling the steam at cutoff 100 and the cushion steam 15, the steam consumption is 85 for a high receiver pressure. In this case the steam consumption is changed 10 per cent. by variation in the cushion steam, brought about by alterations in the receiver pressure and not by a change of cutoff in the high-pressure cylinder.

Experience tends to confirm the truth of the foregoing reasoning. A good illustration is to be found in some forms of pumping engines having no governor, where the high-pressure cutoff can be set by hand. Under these conditions with a steady load, if the receiver pressure is lowered the engine gains in speed, showing that it is using more steam and doing more work. If the receiver pressure is raised the engine loses speed, showing that it is using less steam and doing less work.

The simple rule quoted by Mr. Johnson is sure to lead to too low a receiver pressure and hence to poor economy. There is reason to fear that many engineers are following it, not knowing the unsound basis on which it rests. A final argument against the rule may have weight with those who do not follow the theoretical reasoning. It is that, in all trials of compound engines where the steam is measured and the best performance is desired, the highest economy is obtained with a receiver pressure giving but little drop in pressure at the end of the expansion in the high-pressure cylinder.

E. H. LOCKWOOD.

New Haven, Conn.

Who Is Responsible?

After a man has worked for you for six months or a year and shown you that he possesses the ordinary amount of brains, then when the water column becomes clogged, instead of getting word to you, unscrews the plug in the column tee and rams a rod through into the boiler, cleaning out the obstruction and also—well, you can imagine the rest; who is responsible? I know men to whom you can talk and explain till you are blue in the face and they will say "yes, yes, I know," and yet by only the fraction of a minute did I save one of them from the disastrous results of taking the top from a check valve before he had closed the globe valve in front of it. However, is there a man in the business who cannot point to some fool thing he has done at some time or other.

C. A. SCOTT.

Wales, Wis.

Relative Size of Compound and Simple Engine Cylinders

In POWER for April 25, C. E. R. asks, "What would be the comparative diameter of the low-pressure cylinder of a compound engine to develop the same horsepower as a simple engine at the same speed and steam pressure?"

The answer to the question begins with the remark: "If the work done is to be the same in both cases, the number of expansions must be the same." This is equivalent to saying that all steam engines of the same power, speed and steam pressure have the same number of expansions, which, of course, is erroneous.

The reply then continues: "Consequently, with the same initial and terminal pressures, the diameter of the low-pressure cylinder of the compound must be equal to the diameter of the single cylinder of the simple engine." This is approximately true, barring the terminal drop in the high-pressure cylinder and other losses. The question must have been misunderstood. One of the main reasons for compounding is to increase the number of expansions without shortening the cutoff beyond the economical limit, and the terminal pressure in the low-pressure cylinder of a compound may be, and practically always is, considerably lower than that of a simple engine working between the same pressure limits.

As an example, assume a simple noncondensing engine of 500 indicated horsepower, with 140 pounds absolute initial pressure, 16 pounds absolute back pressure; a clearance of 5 per cent. and compression at nine-tenths of the stroke. Cutoff at one-fourth stroke is common for the rated load of such an engine. Then with a diagram factor of 0.85 and a piston speed of 750 feet per minute, the cylinder is 22 inches in diameter. A compound, noncondensing engine of the same power and piston speed, with the same pressure limits, clearance, compression and diagram factor, but with a terminal pressure of 20 pounds absolute, would have for the diameter of the high- and low-pressure cylinders respectively, 17 and 29 inches. Or, using Tribes tables with a still lower terminal pressure, the cylinders would be 18 and 30 inches in diameter.

Twin engines are sometimes converted into compounds by replacing one of the cylinders by a low-pressure cylinder, the size of which depends on whether a condenser is used; but in all cases it is larger than the cylinder it replaces.

William E. Ninde.

Syracuse, N. Y.

Water in Oil

R. C. Monteagle recently made a statement about water in fuel oil putting out a fire and overflowing from the furnace onto the fire-room floor. In externally fired boilers there is danger of such an accident only when starting the fire and the brick is cold. It is then necessary to watch the burner closely, as the flame may go out and allow oil to flow into the furnace. If the torch is applied there will be, of course, an explosion, as the combustion chamber and tubes will be filled with oil vapor. After the oil has been burning for some time, water may put the fire out, but the oil will instantly ignite, as the brickwork is at a white heat. There is usually some water in fuel oil, but not enough to interfere with the operation of the fire.

Norborne, Mo. Andrew Blair, Jr.

Cooling Hot Bearings

In regard to the cooling of hot bearings, I would like to submit my cure which has never failed and which works quicker than anything I have tried.

Mix half and half by volume No. 6 Keystone grease and ammonia and feed through the oiler as fast as possible by drops. If No. 6 grease is not available, common engine oil will do, but it will have to be stirred almost continuously.

Theodore L. Darling.

Pascoag, R. I.

Antifriction Metals

In the May 16 number of Power, Charles H. Taylor has a letter on the so called antifriction metals which was of unusual interest to me, especially the part in which he states that the general composition for a nonfriction metal should be 76 parts lead to 24 parts antimony. I cannot understand how Mr. Taylor is going to make this metal stand up under all conditions. It is not to be expected that a bearing running at a fair speed, and with little or no shock, will need the same quality of babbitt as a bearing which is operating under severe conditions. I believe if Mr. Taylor would modify his composition to the proportions of not over 20 parts antimony to 80 parts lead he would have a bearing metal that for light high-speed service will be found to give very satisfactory results.

A composition that has given good service under trying conditions is one composed of 5 per cent. copper, 8 per cent. antimony and 87 per cent. tin. Ordinarily this composition is almost prohibitive on account of the cost, and if allowed to run loose for any length of time it will certainly fracture. If it is kept tight on the journal at all times, that is, just free enough to run, it will be found to be all right.

Another composition that will give very satisfactory results when the shock is not too great consists of 20 per cent. tin, 15 per cent. zinc and 65 per cent. lead. It will improve the wearing quality if the metal is covered with a coat of fine charcoal during the time it is in the melting state.

I. B. Green.

New York City.

The Institute of Operating Engineers

There has been considerable criticism of the Institute of Operating Engineers, but if I fully understand the working of the organization it is certainly worthy and along the right lines. No one has anything to say against the homemade engineer. He is usually a good kind, and this association will only help him to be better. I see no need in his feeling that anyone is working a scheme to manufacture engineers to take his place. The homemade engineer who will be alert and look out for his duties and the welfare of his plant need not fear such an association. In fact he might easily better himself by joining the order.

The association presents an opportunity for progress to those who are willing to study and are reaching upward for the rung on the top of the ladder. Pushing ahead is no disgrace, and those who are contented might well allow progressive engineers this privilege. The Institute of Operating Engineers is the center of a good movement and if some engineers do not appreciate it and fail to join, there is no occasion to retard the movement.

C. R. McGahey.

Baltimore, Md.

Vacuum Cleaner

S. G. Rose, in the May 2 number, asks how to remove the dust from floors, ceilings, etc., without sweeping. He practically answers his question when he makes inquiry about a vacuum cleaner. I would advise him not to attempt making a homemade affair, when vacuum-cleaning outfits at small cost can be bought ready for use.

It is a well known fact that dust causes much damage to generators and other appliances and it is a common sight to see an attendant around working at generators and motors trying to dislodge the dust with a bellows or a stream of air from a compressor. A brush fitted to a long handle which is hollow and this handle fitted in turn to the vacuum hose will soon remove all dust from the high spots. A regular vacuum broom attached to the hose will be all right for the floor. The principal items necessary are a dust-settling chamber, a brush or cleaner by which the dust is collected and directed into the hose and an exhaust blower.

Scale in Feed Pipe

In a recent issue an engineer stated that he had a great deal of trouble with scale in the feed pipe of his boilers. In two different plants with which I have been connected we had the same trouble with the internal feed pipes of Heine and of Babcock & Wilcox boilers. The water was taken from the same river and contained a great deal of scale-forming matter which was mostly carbonates and sulphates of calcium.

In one plant the external feed pipes were made of brass and gave no trouble, but the feed pipes inside the boiler were of iron and became plugged up solid in a very short time. The iron pipes were finally replaced by brass pipes of the same size, and there was no further trouble from scale.

In the other plant the external pipes were of iron and after a short length of time became pitted full of holes from 3/16 to 1/2 inch in diameter, while the internal pipes of the same material became closed up with scale. As there are two internal pipes in the Babcock & Wilcox boiler we renewed one with iron and the other with brass. In a few weeks the iron pipe was plugged up and the brass pipe remained clear. It was then decided to use brass in all of the boilers, which, as far as I know, never gave any further trouble.

An 8-inch high-pressure brass pipe was considered too expensive for the main feed line, so we used extra-heavy steel pipe, and it is doing fairly well.

I have never been able to find out why the scale did not adhere to the brass pipe as it did to the iron pipe, but in this case brass pipe solved a very dangerous as well as troublesome problem. I would suggest that the engineer above referred to try brass pipes in one boiler and note the results, which will give him an idea as to whether or not this will solve his difficulty.

J. Case.

Hyattsville, Md.

I am interested in several letters under the above title and think there is quite a little to be learned. I do not agree with Mr. Jahnke as to his two-pipe system, especially the one connected to the blowoff pipe. Combinations usually mean complications. The following system is better than any other which I have seen or heard of:

It is unnecessary to have two separate feed lines to a boiler, but take care of the one. Always enter the feed pipe somewhere on the top of a return-tubular boiler, as it is perfectly accessible, both inside and outside. If hot or warm water is used all the time, it is unnecessary to have a long pipe inside, as it is apt to cause more trouble than it is worth. Run the pipe down to the flues, then use an elbow and a horizontal piece of pipe not over 3 feet long. To avoid depositing the impurities which the heaters and purifiers have failed to collect, on the flues or sheets, fasten a pipe of not less than 3 inches diameter to the flues so that the feed pipe will discharge into it, carrying in with the discharge a quantity of the boiler water. The impurities will collect inside of the large pipe and may be easily removed on cleaning day with a hose or hammer. Let the feed pipe enter the large pipe only a couple of inches; the large pipe should be not less than 4 feet long. If a pipe above 4 inches in diameter is used, place the collector pipe at an angle so that the water will take a spiral course through it.

Boiler Design

Having read with interest "Desirable Improvements in Boilers," on page 761 of the May 16 number, it would seem that the correctness of the title in every particular might be questioned when viewed in the light of practical experience in boiler operation. Mr. Dean has adopted an old form of longitudinal joint which he believes is best for boiler work. It has overcome one disadvantage in the former style of joint he recommended in reducing the pitch of the rivets along the calking edge, for this must have been a disadvantage in manufacture even when using heavy butt straps.

While it is hard to see any real advantage in Mr. Dean's new selection of joint over the kind of butt-strapped joint in common use in the United States, it would be interesting to know if such a form of joint really shows under test the calculated strength he gives it. The committee of research on riveted joints of the Institute of Mechanical Engineers found that to obtain the full strength of a double-riveted lap joint it was required that the two rows of rivets be sufficiently separated to prevent the joint breaking zigzag, and making sure that the joint would break straight across; the net section of metal measured zigzag should be 30 to 35 per cent. in excess of that measured along the seam. While Mr. Dean's joint omits the figures to determine whether the zigzag distance is what is required or not, it appears to the eye as if he had neglected to consider this fact in designing his joint, and that he had bunched the rivets too nearly together girthwise.

Mr. Dean's attack on the Manning boiler seems entirely unwarranted; it is true that the ogee flange as originally designed was very thin and of such shape that all the movement due to pressure was concentrated along one line around the flange. A few of the flanges of this design cracked in service, but after the thickness was increased and its form changed none have failed; therefore, his remarks on this score do not apply at all to the Manning boiler as now constructed. Anyone of experience can take direct issue with Mr. Dean when he says that the Manning boiler is unquestionably dangerous. It is only dangerous in the sense that any steam generator is dangerous, and it is far safer than the average boiler. Mr. Dean speaks of the behavior of the ogee flange on a destructive test of this type of boiler, and he doubtless refers to the test made at the Bigelow plant last summer. The writer had the pleasure of witnessing this test and he distinctly remembers that the center of the ogee flange rose only about ¼ inch under a pressure of 700 pounds, while at 450 pounds the movement was not measurable. As a check on this the overall length of the boiler did not change until after a pressure of 400 pounds was reached, and it amounted to less than ⅜ inch at 700 pounds.

As boilers of any type are rarely operated for general purposes at pressures exceeding 200 pounds, I think Mr. Dean is drawing entirely on his imagination when he asserts that the explosion at the Amoskeag mills was caused by pressure on the ogee flange. I am ignorant of any facts that will establish his claim, and the long record of the Manning boiler with a minimum of accidents absolutely refutes his statements implying that this boiler has inherent structural weakness as constructed today.

If Mr. Dean was versed in practical boilermaking he would hardly suggest a coned sheet in place of the ogee flange, for any boilermaker can tell him of the difficulties encountered by the introduction of such a shape. While Mr. Dean's intentions are good in advising that many more tubes than customary may be put in horizontal tubular boilers, I think he is considerably exceeding good practice in this direction. It is a well known fact that a large body of water directly over the fire is desirable in this type of boiler, aside from the need of room sufficient to permit ready access below the tubes. With the number of tubes he recommends for the different-sized boilers, the required space would not be available at this point. The water line in his layouts would also be considerably higher than practice has demonstrated to be required for good service. With a 1-inch space between tubes it is difficult to clean a scaled tube sheet, and reducing this distance by 25 per cent. would certainly make it much more difficult, besides weakening the bridging between tubes. I hardly think many engineers will agree with Mr. Dean that his suggestion along this line can be considered an improvement in boiler design.

New Haven, Conn.

How to Condense Steam

In answer to E. G. Eldred's question, "How to condense steam," I think the best plan is to take a barrel that will hold water, fix an overflow to it and let the water enter through a pipe at the bottom of the barrel. Then make a coil of ½-inch or ¾-inch pipe of a few turns that will go in the barrel easily. Put the bottom end of the coil through the side of the barrel with lock nuts and connect the top to the steam pipe.

I have tried this method and considerable steam can be condensed in a short time. If the water is allowed to drip a few inches through the air it will get some air in it and help the taste of it.

Decatur, Ill.

Oil Fuel for Steam Boilers

In the May 16 number Mr. Collins says that in burning oil a boiler can be brought up to 150 pounds steam pressure from cold water in less than half an hour if necessary. This may be possible, but it is certainly not the right thing to do. In an externally fired boiler it will take half an hour to get the furnace hot enough for economical combustion. In my experience with burning oil I have found that it takes from two to four hours to get up steam to working pressure from cold water. I do not agree with his statement that 35 per cent. more capacity can be obtained with fuel oil than when burning high-grade coal. This, at least, has not been my experience.

POWER

Accidents and Education

There are two movements in which the engineer is either consciously or unconsciously interested, for they touch his vocation in vital points. These movements are industrial education and the prevention of industrial accidents.

By industrial education is meant that vocational training which gives the worker a knowledge of the principles underlying his trade or calling as well as the definite and complete manual skill which marks the difference between the master workman and the unreasoning routine drudge. The growing importance of the work of the engineer in the industries of production, transportation and distribution is beginning to be recognized by the general public and by those directly interested, and this recognition manifests itself in attention given to license and inspection legislation and in the establishing of schools, classes and lectureships in universities and other institutions for the purposes of giving practical instruction in steam-power plant operation.

It is plain that the engineer is, or should be, interested in this as it tends to put within easier reach than ever before the systematic education needed to advance him in that intimate knowledge of his vocation that makes for success.

This relates directly to the prevention of accidents in an industry that is as wide as the continent. Steam boilers under pressure are no safer in the care of incompetent operators than is dynamite in the hands of children.

Knowledge of the expansive force of steam, of the potential energy of a mass of highly heated water in a boiler and of the inherent weakness of certain forms of construction—with the ability to calculate the strength of materials and joints and the effects of the repeated distortions of the shell of the lap seam—reduces the hazard of this form of construction and discourages its installation.

With every engineer familiar with the weakness of this type of joint and with the courage that comes with knowledge opposing the making and installing of such apparatus and the operation of that already installed, one class of industrial accidents will be materially reduced.

These are subjects which should not be lightly dropped; on the contrary, they should be weighed with careful judgment if the great body of engineers desires to place the vocation of steam-engine operation in the position, in the estimation of the public, to which it is entitled by its importance.

It is a calling that confers dignity on its followers who give to it the best that is in them.

The New York Edison Company's Advertisement

The question of the isolated plant versus the central station is becoming a burning one the country over. Engines are replaced by motors, engineers by switch-pulling janitors, and every small plant shut down or precluded by central-station service means losses of sales of engines, boilers, pumps, heaters and auxiliaries in connection with, and of oil, packing and all sorts of supplies continuously. There is therefore little sympathy for the central station among operating engineers and manufacturers of material used in isolated plants. The following letter, recently received, is a manifestation of this lack of sympathy:

> New York City, June 14th, 1911.
> To the Hill Publishing Co.,
> New York City.
> Gentlemen:—
> I, as well as the business people who use your paper for advertising, also the steam engineers of the city of New York, believe that it is harmful and detrimental to publish advertisements of the New York Edison Company, a company that is absolutely taking the bread from many engineers and firemen, as well as our business from us the manufacturers.
> If in the next number of POWER you have another advertisement of the New York Edison Company, the matter will be taken up by all the engineers' locals of this city and other States as well as the manufacturers, asking them not to take POWER, and declaring the same a paper that is against the engineer and manufacturer. Every engineer will be asked to cast out POWER from his engine room as an enemy.
> It is the duty of your paper to help the engineer to fight and make resistance against the usurpations of the New York Edison Company, which is a monopoly and detrimental to all. Why not from this date start an article, and help the engineers who are your friends, with an article "The Little Engineer vs. The Big Engineer" (the Big Engineer is the New York Edison Company). If you do all of this it will help you to [illegible] them [illegible].
> Yours very truly,
> C. A. of K.

We have received numerous other admonitions by mail, telephone and word-of-mouth against the continued publication of this advertisement.

There are two separate, distinct departments in POWER. Into the advertising pages anybody may come at the regular rate, and say anything that is not libelous or indecent and is in the line of power-plant practice. On the other hand, nobody can buy at any price any space or utterance in the reading columns. What POWER says editorially is based upon the best information obtainable, and inspired by the ambition to offer the best in the way of analysis, suggestion and observation which its editors with their facilities and in the light of this information can produce. It is by these utterances and not by what appears in its advertising columns that the attitude of a paper should be judged. And what has been the editorial attitude of POWER upon the central-station question? Have you read the "Foreword," October 25, 1910; "Central Station versus Factory Plant," February 14, 1911, and March 21; "The Cost of Power," "Interest and Sinking Fund," March 21; "Will an Isolated Plant Pay?", "The Marginal Principle," March 28; "The Central Station versus Isolated Plant," April 18; "The Central Station Could Not Meet His Figures," April 25; "Isolated Power Plant Makes a Good Showing," May 9; "The Cost of Industrial Power," May 30; "Foreword," June 6; "Central Station Failure," June 20, and the "Central Station Viewpoint," June 20. These are only a part of the references which might have been given, but a reading of the above articles will show the stand we have taken on this subject.

We take it that even the members of the I. A. of E. (we regret that we do not know what the initials stand for) recognize that there are places where the central-station service can be used to advantage, and that their organized opposition to the extension of that service applies to situations where power can be produced cheaper than the central station can legitimately supply it. In opposing the aggressions of the central station beyond its legitimate field; in opposing rate discrimination and subterfuge whereby additional load is taken on at less than the cost would be if charged with its proportion of the fixed charges, as are the services of the small consumer; in exposing the sophistries of the solicitor whose gentle job it is to convince a customer that he can make money by buying current for more than he can make it, the engineers and manufacturers of the whole country—for the question is not a local one—will find POWER with them all the time, and if our unknown correspondent has anything which will help in the process we shall be glad to see it.

Peat as gathered contains a large percentage of moisture. To dry it by exposure to the sun and air takes a long time, and to dry it artificially takes a good deal of heat. An attempt has been made at Emden, Germany, to utilize this heat by drying the peat in a closed vessel under pressure, the steam driven off being available for power and other purposes.

Engineering Graduates

Once more the season of college commencements is at hand and hundreds of young men are about to start on an engineering career. The increasing popularity of the engineering courses, as compared with the older professions, gives rise to the remark so often heard: "The field is being overcrowded." Some will contend that such overcrowding is sure to result in fewer opportunities for advancement and lower salaries, while others will argue that there is always room for good men in any field.

Among the large number graduated every year there are undoubtedly many that fail to make good. This, however, is usually attributable to one of two causes: either the individual has not the qualities that make for success, in which case he would have failed in any other line of work, or he has chosen engineering without seriously consulting his natural inclinations. In this connection, it may be said that fully fifty per cent. of the students when entering college do not really know what line of work they want to make their life's vocation. A course is often chosen because it appears popular, its name is attractive, or some friend has had success in that particular line.

A factor responsible for this condition is the age at which the average student enters upon a technical course. If those who intend taking up engineering would spend two or three years, after leaving high school, in shops or construction work before entering college, they would soon find wherein their inclinations lie; they would get more out of their college course, and would be better prepared to attack practical engineering problems after graduation.

It would appear then that some are doomed to failure through causes independent of the supply and demand; but to offset this the demand for technically trained men has greatly increased during the past few years.

Very often the mistake is made of expecting too much of the technical graduate, and much misunderstanding and criticism of the whole educational system result.

Inefficient Equipment

Economy is the watchword in the power plant where the management and the engineers are wide awake. In others, economy is a meaningless term, and extravagance takes its place.

Most men will have the hole in their pocket sewed up as soon as it is discovered, for fear that a few cents may be lost, but these same men, if owners of a steam plant, will contentedly watch a fireman shovel dollars into a boiler furnace and make no effort to save any of them. A growl will be heard when the amount of the yearly coal bill is ascertained, but beyond "jumping on" the fireman no effort is made to detect and remedy the cause of excessive coal consumption.

Power plants of less than five-hundred horsepower contain engines, pumps, heaters and other power-plant apparatus which are wasteful in the extreme. But the engine turns the wheels, the pump manages to keep water in the boiler and the heater warms the water a trifle above its normal temperature, all of which seems to satisfy those "higher up."

For years the feed water in a certain electric-light plant was sent to the boilers by means of an injector, the water passing through a heater which had become so foul with scale that the water entering the boilers received practically no additional heat above that imparted to it in passing through the injector.

In another small steam plant an old cylinder heater, about ten feet long, lies on the floor alongside the engine. It is inefficient and, although it does take the chill from the water, much of the heat in the exhaust steam that could be utilized if a proper heater were used escapes to the atmosphere.

These two instances illustrate the manner in which the operating costs of a steam plant can run above normal when apparently everything is all right. But if the men who were financially interested in these plants had taken the trouble to look into the matter of feed-water temperatures, as obtained under the conditions found, and compared them with the temperatures obtained in other plants, their eyes would have been opened to the waste of heat and coal.

Thousands of people are ailing more or less—few are physically whole—but they do not know it. When they do, a doctor is consulted in order that the trouble may be removed.

It is the same with steam plants. Few are operating under economical conditions in every particular, and many are "real sick." Their case is not diagnosed, and their ailment is allowed to grow worse day by day.

When power-plant owners and engineers look upon a steam plant as a source of expense, as not producing a finished product, and make up their minds that it can be operated efficiently, the central station will loom less prominently before the engineer's vision and the owner will have the satisfaction of knowing that he can produce power in his own plant cheaper than he can purchase it elsewhere.

The Institute of Operating Engineers has the support and indorsement of able and clear-thinking men. If you are an operating engineer or hope ever to be one it might be worth your while to investigate it. The secretary's office is in the Engineering Societies building, New York City. He answers questions.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Flywheel Proportions

I have a side-crank engine 11½x16 inches which is direct coupled to a fan and which I wish to reinstall to drive a laundry requiring 45 horsepower. The engine is designed to run at 120 revolutions per minute but can be adjusted to run faster. The steam pressure is 75 pounds.

I have two wheels 66 inches in diameter, 15-inch face, weighing about 1300 pounds, and would like if possible to use one or both of them. I have applied several formulas found in handbooks and none of them agree within several thousand pounds. The speed variation is not important and it would be possible to run the engine at a higher speed than stated to permit a lighter wheel.

L. C. R.

Flywheel formulas vary according to the conditions under which the wheel is to be used, and which must be known before the proper one can be selected. A flywheel suitable for a plain slide-valve engine driving a stone crusher might be only quarter heavy enough for a Corliss engine of the same power in an electric-lighting plant. For a plain slide-valve engine doing ordinary work, use the formula

$$W = 350{,}000 \frac{d^2 S}{D^2 R^2}$$

in which

- d = Diameter of the cylinder in inches;
- S = Stroke of the piston in inches;
- D = Diameter of the wheel in feet;
- R = Number of revolutions per minute;
- W = Weight of the wheel in pounds.

Substituting the numerical values in the equation it reads

$$\frac{11.5^2 \times 16}{5.5^2 \times 120^2} \times 350{,}000 = 1700 \text{ pounds}$$

the weight required in a flywheel 66 inches in diameter. If the wheels weigh 1300 pounds each, both will fill the bill very nicely or a slight increase in the number of revolutions will make one suitable.

Constant-current Transformer Working

How can I tell when a constant-current transformer is overloaded? Why do the secondary windings break down if left on open circuit?

T. F.

If it regulates properly, a constant-current transformer cannot be overloaded in the secondary windings because the secondary current remains practically constant at all loads. The primary winding can be overloaded by increasing the resistance in the secondary circuit a good deal beyond that for which it was intended; this will cause the current in the primary winding to increase beyond the rated current. When the secondary circuit is opened, an excessive potential is induced in the secondary winding because the transformer automatically increases the secondary e.m.f. as the secondary resistance increases, in order to keep the current constant. The excessive e.m.f. caused by opening the secondary circuit breaks down the insulation.

Effect of Low Shaft

What effect, if any, will a shaft 11/16 inch low from a line drawn through the center of the cylinder and guides have on a simple engine running over?

J. M. P.

On the out stroke the crank pin would travel over more than one-half of the crank-pin circle while on the return stroke it would travel over less than one-half of the circle. The effect would not be appreciable, or even measurable by any ordinary methods.

Motor Balancer Functions

When two machines with coupled shafts are used to balance a three-wire direct-current circuit, do both work as motors or as dynamos, or is one a motor and the other a dynamo?

A. H. J.

With an unbalanced system, one machine acts as a motor and the other as a dynamo. Which is which depends on the load conditions; the armature connected to the lightly loaded side of the system runs as a motor and the other one as a dynamo, these functions changing automatically as the unbalancing changes. When the two sides of the system are equally loaded, both machines run as motors.

Bad Speed Regulation

A 250-kilowatt and a 125-kilowatt generator driven by separate engines run in parallel without difficulty but when the large machine is cut out, leaving the smaller one to carry the load, the voltage drops from 125 to about 75 or 80 volts for a few moments and then comes up to normal. When the small machine is disconnected from the load, its voltage runs up beyond the range of the voltmeter. What is the cause and how can it be removed?

W. H. L.

The cause is a sticky governor on the small engine. It seems evident that it is a shaft governor and the bar does not swing freely on the pivot pin. The remedy is obvious.

Constant-current Transformers

Why are constant-current transformers used to connect a circuit of arc lamps to a primary alternating-current circuit? Could not 30 or 35 inclosed arcs requiring 65 volts each be connected in series directly across a 2300-volt primary circuit without using a transformer?

W. H. K.

For two reasons: First, in order to put any desired number of lamps in one circuit regardless of the voltage of the main supply circuit; second, in order to obtain regulation of the arc-lamp current. Thirty-four 65-volt lamps could be supplied directly from the 2300-volt circuit if the current would remain constant through the arcs, but by interposing a transformer any number of lamps can be supplied in a single circuit and the current will be kept practically constant by the transformer, no matter whether the lamps regulate accurately or not or whether they are all burning or some of them are cut out.

Direct-current Motor on Alternating-current Circuit

What changes in connections are necessary to make a shunt-wound direct-current fan motor work on an alternating-current circuit of the same voltage?

K. E. T.

Changing the connections will not produce the desired result. If the motor will not run on the alternating-current circuit as it is, which is very probable, it will have to be rewound. Instructions for rewinding cannot be given without complete knowledge as to the dimensions and magnetic character of all parts of the magnetic circuit of the machine.

Refrigeration Department

Principles and operation of ice making and refrigerating plant and machinery

Double Pipe vs. Atmospheric Condensers

By R. P. Kehoe

The popular favor with which the double-pipe type of condenser was accepted, was not due to increased efficiency nor cheaper first cost, but because it was something new and it looked nice. The water was not visible; no pan was necessary; and the condensers could be placed anywhere in a building. Furthermore, the water enters at one end and the ammonia at the other, introducing the countercurrent principle and thus promising extraordinary results.

It was these facts which gave the chief impetus to the sale of double-pipe condensers, and while there is no question about their advantages under a few favorable conditions, it is usually a mistake to adopt them on account of the disadvantages which are herein pointed out.

Faults of Double-pipe Condensers

One of the worst features of this type is its inability to handle river water that is not absolutely free from vegetable matter or sewage. If only a small percentage of such impurities are contained in the water they will quickly collect in the fittings and pipes, causing a rapid decrease in efficiency and final stoppage if the pipes are not frequently cleaned.

A formation of the same thickness of scale on the atmospheric condenser and in the double-pipe condenser is more serious in the latter case. The scale in the atmospheric condenser gathers on the outer surface of the pipe and consequently increases the cooling surface, while the scale in a double-pipe condenser forms on the inner surface of the water pipe and decreases the cooling surface. Furthermore, less scale is required to form a certain thickness of deposit on the inner surface than on the outer surface of a pipe. The decrease of the transverse area of the water pipe from scale in a double-pipe condenser requires an increase in power to circulate a given quantity of water through it, or else if more power is not available, the quantity of cooling water is decreased. In an open-air ammonia condenser cooling water simply overflows the slotted-pipe gutter, and whether the scale is heavy or light on the pipes, the free flow of water either to the distributing gutter or over the condensing surface is not affected.

With the atmospheric condenser any deposit on the pipes is quickly perceived and may be readily scraped off, even while the condenser is in operation, whereas the double-pipe type must be discontinued from service while it is being cleaned.

In a cooling tower advantage is taken of the reduction in temperature resulting from the evaporation of some of the water to be cooled by a natural or forced air current. The more the evaporation the greater is the amount of heat carried off in this way. This principle is employed in an atmospheric condenser and figures largely in its high efficiency. This advantage is lost in the double-pipe type.

Also, in view of the great affinity of anhydrous ammonia for water, a leak in a double-pipe condenser may remain undiscovered for a long time.

During a recent winter, the engineer of a large brewery failed to drain all the water from a battery of double-pipe condensers when the plant was idle, and the water froze, resulting in many split pipes and fittings, and making it necessary to practically rebuild the condensers.

This type of condenser is usually placed inside the building, while atmospheric condensers are installed outside. In this respect, the latter naturally secure an advantage from the cooling effect during cold weather which is almost entirely lost by the former.

The efficiency of the double-pipe type can be maintained only by forcing the condensing water through the pipes at a fairly rapid rate, and due to the friction in the pipes a large amount of power is required for this purpose.

First Cost

The comparative first cost of the two types f.o.b. cars at the factory is approximately as follows:

	Atmospheric Type	Double-pipe Type
Diameter of pipes, inches	2	1½ and 2
Number of pipes in hight of standard condensers	24	12
Length in feet	20	18
Square feet of cooling surface	300	80
Approximate cost of one condenser	$150	$150
Cost per square toot	$0.50	$1.87

From these figures it will be seen that the first cost of the double-pipe condenser is nearly four times the cost of the atmospheric style per square foot of cooling surface.

The number and size of sections of both types usually furnished for each 100 tons refrigerating capacity per 24 hours are as follows:

	Atmospheric Type	Double-pipe Type
Number of sections	8	8
Number of pipes in hight	24	12
Length in feet	20	18
Total cooling surface, square feet	2400	640
Total cost	$1200	$1200

Comparative Efficiency

In spite of the many faults previously mentioned, the double-pipe condenser has a high efficiency when operated under favorable conditions, such as good water, clean pipes and a high velocity of the condensing water. Good water, however, is available only in certain places; clean pipes are seldom found except in new plants and the velocity is naturally limited by a reasonable amount of power for pumping and the use of a reasonable amount of condensing water.

Giving the double-tube type the benefit of the most favorable conditions in practical operation, the comparative efficiency of the two types expressed in the number of B.t.u. exchanged per square foot of cooling surface per hour is as follows: Atmospheric, 60 B.t.u. per degree difference; double pipe, 100 B.t.u. per degree difference, with cooling water flowing at 250 feet per minute.

This greater efficiency makes it possible to use about 40 per cent. less surface but this is offset by the fact that the cost per square foot is increased nearly 300 per cent. Furthermore, in the average plant this efficiency would not be maintained because the tubes are not kept clean enough.

Advantages of Double-pipe Condensers

In small plants up to 10 or 15 tons capacity it is often advantageous to use double-pipe condensers. They are small and compact, can be located close to the machine and, in view of the saving of connections and a condenser pan, are cheaper than the atmospheric style. Furthermore, when using city water that must be paid for, its merit is apparent, as no dirt is accumulated and the water consumption can be reduced to a minimum. It also has a field where the water is used again for other purposes.

After fairly summing up the advantages and disadvantages it is apparent that double-pipe condensers are not the best type to adopt in the usual refrigerating or ice-making plant except under special conditions. The practical faults alone should be sufficient to condemn them especially in ice plants, where all the apparatus is subjected to rough usage and where great cleanliness is not often practised. The simplest and most accessible apparatus should be preferred and while open-air condensers are not as pretty to look at, their simplicity is unquestionable.

There are several designs of the latter type which will be discussed.

Atmospheric Types

The cheapest design of condenser is that in which the hot ammonia gas is led into the highest pipe in each stand and the liquid drawn off from the lowest pipe. It is also the least efficient not only per square foot of surface but in the head pressure maintained. The term "cheapest design," however, must not be misunderstood; it merely refers to the cost per square foot of cooling surface.

One of the most important considerations in the efficiency of a condenser is the head pressure. A few pounds difference in this pressure against which the compressor must work may mean hundreds of dollars every year either saved or thrown away. The heat transmission per square foot affects only the first cost and a few dollars more or less in the initial expense is not as vital as a loss that might go on year after year through high head pressure.

The pressure in a condenser is consistent with the temperature at which the ammonia begins to liquefy. The object, therefore, in an efficient design is to make this temperature as low as possible. With the type in which the gas enters the top pipe the condensing water is at first heated by the absorption of the superheat in the hot gas coming direct from the compressor. It is only after this heat has been removed that the ammonia can be brought down to the point of liquefaction, but then the temperature of the water has risen considerably and the ammonia must liquefy at a relatively high temperature. The result is a higher pressure than would be attained if the initial temperature of the water had been brought to bear on the ammonia at the point of liquefaction.

Another type of condenser is constructed with the gas entering the lowest pipe, from where it ascends through four pipes and then passes through a standpipe to the highest pipe. The ammonia then proceeds downward and the liquid is led off from the fifth pipe from the bottom. The theory upon which this condenser is based is that the four lower pipes (called the forecooler) will remove all the superheat and bring the gas very nearly to the point of liquefaction before it enters the top pipe, where the gas encounters the coldest water and then begins to liquefy at the lowest possible temperature. The practical faults of this type are that the four lower pipes, or the forecooler, cannot be depended upon to just remove the superheat.

Consider the difference in the amount of gas to be condensed according to the capacity developed; the difference in the temperature of the condensing water during all seasons of the year; and the variations in superheat of the gas in every plant. As these upset the theory unquestionably, it might be well to inquire into the result.

If all the superheat is not removed, the balance must be taken out after the gas has risen to the top pipe, and the same fault then exists to some extent as when the gas enters directly into this pipe from the compressor. The operation is much worse, however, if the conditions produce liquid in these lower pipes, which remains pocketed and interferes with the flow of gas until conditions change and it is regasified. To partly obviate this fault some designs provide a small connection from the lower pipes or precooler to drain off the liquid which may form. This special drain pipe is connected to the liquid main.

Reverting to the first principle of this design, it was the object of the precooler to deliver the gas to the top pipe at or near the point of liquefaction, so that it would liquefy at the lowest possible temperature. The introduction of the special liquid drain admits the fault of liquid forming in the lower pipes where the water is at the highest temperature. As a result, this liquid must govern the head pressure because liquefaction takes place here at the highest temperature. Therefore, the primary object of the design is entirely lost, as the head pressure corresponds with the temperature of the water leaving the condenser and not with the initial temperature. Under these conditions the precooler condenser will not do as well as the concurrent condenser.

Countercurrent Atmospheric Condensers

As already pointed out, the double-pipe condenser owes its efficiency entirely to the fact that it is countercurrent in principle and can bring the temperature of the liquefying ammonia as nearly as possible to the initial temperature of the water. A countercurrent atmospheric condenser will therefore offer the same efficiency as the double-pipe type without the practical faults of the latter.

The countercurrent open-air condenser is arranged with the gas entering the lowest pipe and the liquid leaving through several drains at various levels. The superheat is removed in the lower pipes as in the precooler type and as the gas ascends it encounters the effect of colder and colder water. There is no space wasted by the accumulating liquid, which flows off as fast as it forms.

Such a condenser will meet every condition and can always be depended upon to give the best results. It never should be over 18 pipes in hight, as more than this are superfluous on account of the efficiency of the countercurrent effect. In fact the hight may be less. If the initial temperature of the water is high, it will be an advantage to make the stands only 12 or 14 pipes high and provide a greater number. More water is used if this is done, but the head pressure is lower because of the greater amount of work accomplished by the water.

Not long ago an experiment along these lines was attempted by the chief engineer of a large brewery. The plant was equipped with several countercurrent atmospheric condensers, each 24 pipes in hight; 12 pipes were removed from every stand and the condenser pressure was found to be exactly the same. Later on the pipes which were removed were reerected in the form of additional stands and as soon as these new stands were put in operation the pressure dropped from 10 to 20 pounds.

A comparative test of the concurrent atmospheric condenser, with the gas entering the top pipe, and the countercurrent type, just described, will show that the latter can produce the same head pressure with nearly 20 per cent. less condensing water. If the same amount of condensing water is used, the head pressure will be reduced 10 pounds.

Hence, the countercurrent style will afford greater economy under all conditions. If water is scarce it can produce good results with a smaller quantity and if there is plenty of water available, it will reduce the head pressure and cut down the coal bill.

Yet it will be found that many of the large packing houses throughout the country use the open-air condenser of concurrent design almost exclusively. Some of these plants have one hundred or more condensers, all with the gas entering the top pipe, using more water and maintaining a higher head pressure than necessary. The only reason for this is that the operators have become accustomed to this style and do not like to change.

A recent patent describes a direct method for the production of ammonia by the passage of a mixture of hydrogen and nitrogen over finely divided osmium or uranium, or other similar catalytic material. The operation is conducted under about 1000 pounds pressure, and the ammonia is separated from the uncombined gases by cold.

Cutting Packing Over a Wooden Mandrel

In the April 25 issue selling section, I read with interest the talk on packing, by "Old Bill," of the Thermoid Rubber Company's advertisement. The wooden mandrel is all right and there should be several in every engine room, one for each machine, as the mandrel saves time and money.

In the plant in which I am working we have two ammonia piston rods of different sizes; one is 1/16 inch smaller than the other. I got a mandrel made

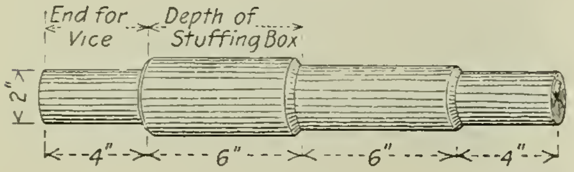

Fig 1

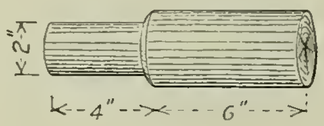

Fig. 2

out of hardwood, like the accompanying Fig. 1, for the ammonia piston rods and one like Fig. 2 for the steam piston rod.

The smaller ends of the mandrel shown in Fig. 1 will serve to put in the vise, and also the small end of Fig. 2. The enlarged parts may be as long as the stuffing boxes are deep. The diameter is to be 1/32 inch less than the diameter of the piston rod, so that there will be some space between the ends of the ring, when it is cut and placed over the rod. When the packing is warmed up, expansion will bring the ends together. In case the packing fits tight in the stuffing box, the space between the ends should be a little more.

The mandrel may be marked, for example, "No. 1 Machine; depth of stuffing box, 8 inches; nine rings of ¾-inch spiral." When cutting the packing, put the mandrel in the vise, take a thin wire nail and fasten the end of the spiral packing to one end of the mandrel, wind the former around the mandrel until it is all covered and fasten it with another nail at the end of the last ring. The packing may be cut straight across or on a slant.

For pumps the mandrel is very handy. It may be made to suit the size of the plunger, piston rod and valve stem. When packing the plunger with duck packing, more space must be allowed between the ends, and the follower plate should not be screwed up too high. The mandrel can be made in a short time by any engineer who has a lathe and knows how to use it.

Air in Ice Water System

It is my opinion that Mr. Johnson's suggestion to prevent air in his ice-water system will not remedy the trouble. On account of the hight of the building, say 100 to 110 feet, and the design of the piping system, air will be drawn into the piping under certain conditions of operation. No means is provided to rid the system of this air and it is churned around in the centrifugal pump with the water, causing the latter to become milky. My suggestions would be: First, to get rid of the centrifugal pump and put in a triplex pump. Second, to discharge the cold water into a tank as high above the main on the tenth floor as possible and feed the system from this tank. A float should be provided in this tank to regulate the supply of fresh water taken in from the supply tank. The cold-water supply tank should be made flat like a pan and insulated. This will give a large disengaging surface for the air.

Opening an Ammonia Joint

At a certain plant my assistant engineer was instructed to break an ammonia joint. It was necessary to take out an ell and replace it with a tee and flanged valve so as to extend the coils in the cooling rooms. He claimed that the coils had been thoroughly pumped out.

I gave him a helper and he took all of the bolts out of the flanged ell and was prying the joint apart with a small bar, when it let go with a loud explosion and a shower of oil and muddy substances. A yell from the engineer followed and the next thing I knew he was all in a heap on the floor, choking with ammonia. I grabbed him and made for the open door.

The room was full of the fumes of ammonia and a hissing sound denoted a serious leak. I rushed for the valves in the engine room to isolate that coil and found one valve partly open. None of us was ever able to account for that open valve. My assistant had mistaken the valves and pumped out the wrong coil.

I started the machine and pumped some of the ammonia from the coil into the system, but soon stopped as I did not want to get air into the system.

As the engineer's lips, eyes and tongue were badly burned by the ammonia, he was taught a lesson which he will not forget.

The moral is, never remove all of the bolts on a joint at one time, but loosen them all a little and break the joint gently; then in case of a serious loss of ammonia, the bolts can be tightened up with safety and an investigation made.

Clearance in Compressors

In designing ammonia compressors it has been the practice of most of the manufacturers to cut down compressor clearance to the smallest possible degree in order to obtain what is commonly believed to be the maximum capacity per cubic foot of compressor displacement. Several other factors, however, should be considered in this connection which tend to militate against the successful working of a compressor under the above conditions. Prominent among these are safety of operation and the superheating of suction gas as it enters the compressor.

Dwelshauvers-Dery has demonstrated that the cylinder walls of a compressor have a very considerable thermal influence upon the working medium, which influence depends in amount on the conditions of operation and not upon the size of the compressor. It is a well known fact that, although clearance reduces the apparent volumetric efficiency, the horsepower necessary to compress 1 cubic foot of gas in a compressor with reasonable clearance remains the same as in a compressor without clearance. The reason for this is that the cylinder walls of a no-clearance compressor will superheat the gas more, and thereby reduce the capacity to a greater extent, than will a compressor with clearance reduce the apparent capacity. It is the effect of cylinder superheating which must be fully understood before the proper size of the clearance can be determined upon in the design of a compressor.

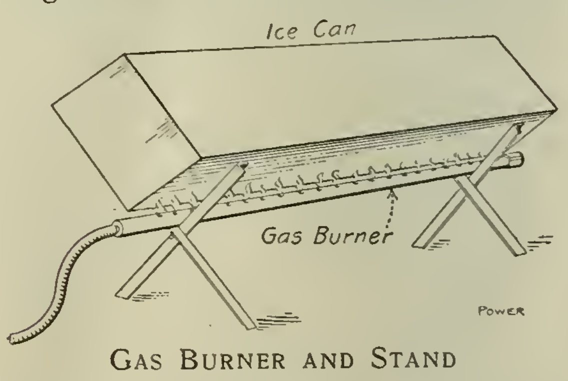
Temporary Can Repair Kink

The following method was employed by an ingenious engineer to solder leaky cams. It is inexpensive and has prolonged the lives of cans as much as two



Gas Burner and Stand

years. The materials used are an equal mixture of turpentiine and beeswax.

To apply this mixture a gas burner made from a 1-inch pipe the same length as the can to be repaired is used. The pipe is perforated with small holes and mounted on a rack which is also built to hold a can in such a position that the corner will be directly over the jets. The mixture is poured in hot so that it will penertate the smallest crevices.

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

Improved Flow Meters

The General Electric Company, Schenectady, N. Y., has developed several types of flow meter of approved design and high efficiency. These include both the recording and indicating types, the former making a continuous graphic record of the rate of flow and the latter giving readings of instantaneous values of the same. The unit of measurement varies with the commodity measured, being pounds per hour for steam, cubic feet per minute for air and gas and gallons per minute for water.

The recording water-flow meter, shown in Fig. 1, comprises a nozzle plug for screwing into the pipe at the point where the flow is to be measured, thus being exposed to the pressure of the water, a meter element which measures the pressure set up in the nozzle plug and a recording mechanism which makes a graphic record of the rate of flow.

The nozzle plug, shown in Fig. 2, has two sets of orifices: the leading set, located parallel to its axis extending across the main and facing the direction of flow, and the trailing set, consisting of three holes located on the opposite side of the plug near the middle and at right angles to its axis. The two sets of orifices open into separate longitudinal chambers leading to the outer end of the plug. The nozzle plug is arranged for use on either vertical or horizontal mains and its introduction is said to cause no appreciable drop in static pressure even at very high rates of flow.

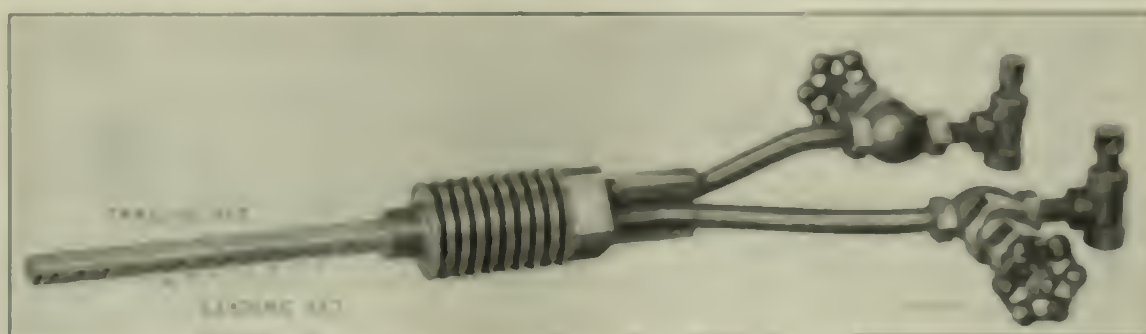

FIG. 2. NOZZLE PLUG AND PIPING FOR WATER-FLOW METER

When the plug is inserted in the main, the water impinging against the orifices of the leading set develops therein a pressure equal to the static pressure plus a pressure due to the velocity head, while the pressure set up in the orifices of the trailing set is equal to the static pressure minus the pressure due to the velocity head, thus causing different pressures in the longitudinal chambers leading to the outer end of the plug. The different pressures are communicated to the meter through pipes attached to the outer end of the plug and connected to flexible steel tubing placed within the meter case.

The meter element consists of two vertical cups or hollow cylinders connected at the bottom by a tube. The U-tube thus formed is filled with mercury to about half the hight of the vertical cups and the whole arrangement is supported and is free to move about a set of knife edges like an accurately constructed balance.

The different pressures in the two sets of orifices in the nozzle plug cause the mercury to rise in the left-hand cup and to fall a corresponding amount in the right-hand cup until the unbalanced mercurial column exactly balances the difference in pressure. This action causes the beam carrying the cups to descend on the left-hand side of the knife edges until the moment of the weights on the right-hand side exactly balances the moment caused by the displacement of the mercury into the left-hand cup. The motion of the beam is multiplied by means of levers and actuates the recording pen, the movement of the latter being proportional to the amount of mercury displaced.

The chart carrying the recording paper is driven by an eight-day clock. The paper is calibrated to record the flow in gallons per minute and the rate of flow may be read at any instant, or the average rate determined for any given length of time.

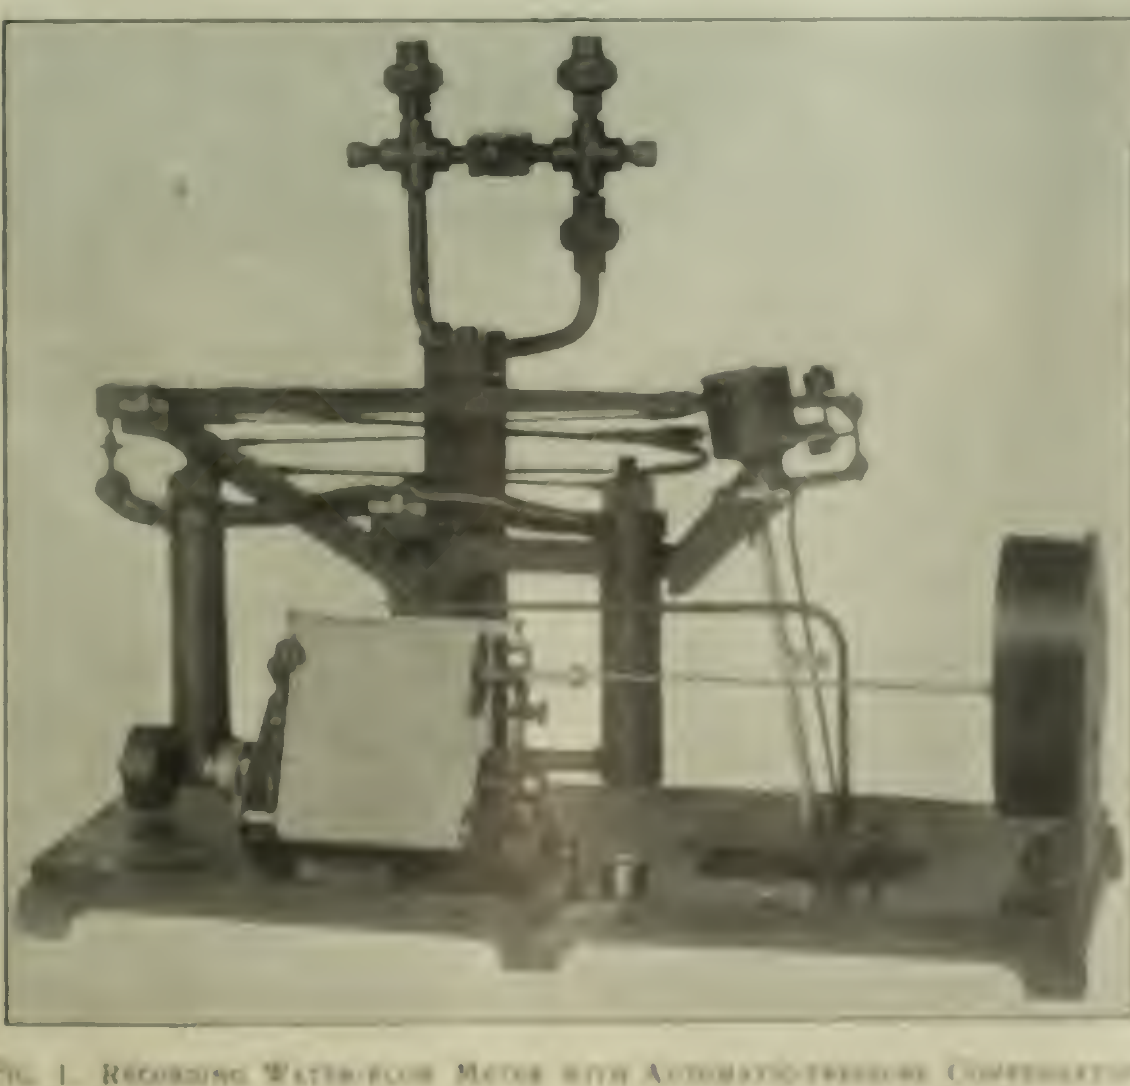

FIG. 1. RECORDING WATER-FLOW METER WITH AUTOMATIC-PRESSURE COMPENSATION

The standard paper furnished is calibrated for a rate of feed of 3 inches per hour, but paper for feeding at a rate of 1 inch or 6 inches per hour can be supplied if desired. The meter is equipped with a spring-operated reroll device capable of holding one complete roll of paper.

Although the meter is calibrated to record the rate of flow in gallons per minute at 39.1 degrees Fahrenheit, suitable means are provided for readily setting it for different temperatures, pipe diameters and rates of flow. In order to measure the flow under normal conditions in any number of different pipes, it is only necessary to use nozzle plugs of sufficient length to extend across the pipes and record paper of suitable calibration range.

This meter is useful for ascertaining the output of pumping plants, the total amount of water consumed by a municipality or the amount distributed to different sections thereof, the input to water turbines and their loss of efficiency, the amount of water consumed in manufacturing processes, the amount of feed water delivered to boilers, the amount of

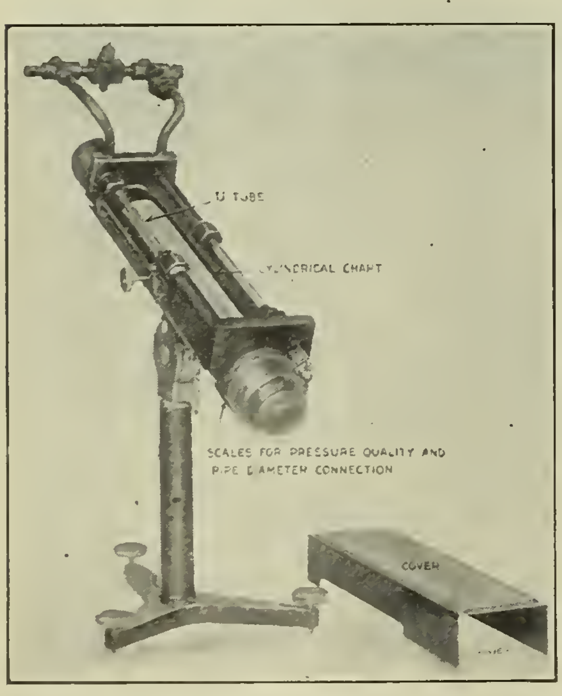

Fig. 3. Indicating Steam-flow Meter, Showing Scales

cooling water used in condensers, the slippage in pumps due to leaky plunger packing or worn-out valves, and for discovering losses due to leaks in water mains.

The recording air-flow meter, suitable also for measuring steam and gas, operates on the same principle as the recording water-flow meter and is practically similar in all details of construction.

The indicating steam-flow meter, shown in Fig. 3, is designed for testing work and other purposes, such as locating trouble due to leaks, determining efficiency of boilers, etc., where accurate, instantaneous readings of the rate of flow are desirable.

This type of meter operates on the same principle and employs the same type of nozzle plug as the recording meter, but differs considerably in details of construction. It can be readily adjusted for various rates of flow and indicates the instantaneous rate of flow in pounds per square inch of pipe cross-sectional area for steam, or in cubic feet of free air at 70 degrees Fahrenheit, for air.

An Oil Eliminator for 66-inch Exhaust Pipe

The accompanying illustration shows a steel shell oil eliminator of the right-angle type recently built by the Hoppes Manufacturing Company, of Springfield, O., for the Milwaukee Electric Railway and Light Company, Milwaukee, Wis.

This apparatus is designed to remove the oil and water from 385,000 pounds of exhaust steam per hour before it passes to and is used in the operation of two 7500-kilowatt low-pressure turbine units. It embodies all of the Hoppes principles of construction for this type of eliminator, having large internal areas for the free and unrestricted flow of the steam and being thoroughly equipped with intercepting troughs partly filled with water to catch and remove all entrainment. The cylindrical shell of this machine is 10 feet in diameter and 23 feet long and when in place will stand vertically. The exhaust steam from the reciprocating engines enters at the side near the top and the purified steam passes out at the bottom.

Some idea of the enormous capacity of this machine may be had from the fact that the exhaust inlet flange is 5 feet 6 inches in diameter, the eliminator being installed in an exhaust pipe line of like dimension. The large special tee at the bottom for connecting to the turbines is not shown in the photograph.

Large Oil Eliminator in Course of Shipment

Boiler Explosion at Alton, Ill.

By H. R. Rockwell

A serious accident recently occurred at the power plant of the Illinois Glass Company at Alton, Ill., in the shape of a rupture of a 66-inch by 18-foot horizontal tubular boiler. This boiler was one of a battery of four of the same class, all connected to one common 12-inch header. The shell plate was of ⅜-inch steel. The writer was unable to find any brand on the plate signifying its tensile strength, but from the appearance of the ruptured plate it seemed to be of first-class material. The longitudinal seams were of the double-strap butt type triple riveted and the boiler contained 54 four-inch tubes.

The boiler is composed of two 9-foot sheets. The front plate was split from end to end, and 43 rivets were sheared on the girth seam and 23 on the head. About one-third of the flues were pulled from the front head and several were jammed through the back head of the boiler, which was raised bodily from its setting and badly damaged a steel roof truss about 20 feet above it. One of the other three boilers was thrown out of its setting and the remaining two were twisted enough to break the 12 and 12 by 6-inch tees which connected them to the header.

Two men were seriously scalded and one of them has since died. The accident happened just at 6 a.m. as the night and day shifts were changing. This very probably accounts for no greater fatality.

The man who was in charge of the boilers claimed that about 15 minutes prior to the accident he blew down the boilers and walked along the front and blew out each water column. The water rose to its proper level in each boiler.

The writer had charge of the plant and upon his arrival, about one hour after the accident occurred, he found that the water-column connections on the exploded boiler were open and the blowoff valve was closed just as they should be.

My theory of the accident is that a large quantity of scale was precipitated from the shell and tubes of the boiler and settled on the lower sheet over the fire, which allowed the sheet to become overheated sufficiently to start the initial rupture. Some seem to think that the explosion was a case of no water, but the damage to the boiler was too great for me to think that there was not plenty of water in it at the time.

Water Works Association Convention

About five hundred delegates and guests attended the thirty-first annual convention of the American Water Works Association at Rochester, N. Y., June 6 to 9. At 10 o'clock on Tuesday morning, Mayor Edgarton gave a cordial welcome to the association in the banquet hall of the Powers hotel, to which John W. Alvord, president of the association, responded.

Some seventy manufacturers of waterworks appliances were represented with exhibits which covered stands and lined the corridor and sample rooms. After the routine business was despatched, the presentation of papers relating directly to water works was begun.

Pumping-station Management

Thomas McMillan read a paper on pumping-station management in which he traced the history of the Milwaukee, Wis., water works from 1872 down to the present, giving short descriptions of the additions made from time to time, coupled with statements of the cost of operation for each ten-year period. The methods followed in the purchase and handling of coal were minutely described, as were also the boilers and the details of their operation. He described the special arrangements in steam and water piping for facilitating repairs, feeding the boilers and for increasing the temperature of the feed water, the cost of the installation and the operation of the oiling system, the auxiliaries and appliances for making and handling repairs and the general manner in which the operating force was managed in the apportioning and arrangement of the work.

Panama Canal

Tuesday evening, Dabney H. Maury, one of the engineers appointed by President Taft from the American Engineering Society to make an investigation of conditions at the Panama canal, gave an illustrated lecture in which he spoke especially of the economy which is being practised in building the canal and of the sanitation methods instituted to make conditions such that the men employed are better fitted to work. He said that the canal will be finished much sooner than expected. On June 1, 1913, it will be practically complete, and on that date vessels of 20-foot draft will be able to pass through. These vessels will thoroughly test out the canal until January 1, 1915, when the formal opening to all vessels will be made.

Emergency Intakes

W. P. Mason, speaking on the above subject, said that when the water supply of a municipality is changed it is the common practice to allow the old connections to remain as an emergency supply. Such practice may reduce insurance rates, but it increases typhoid risks, and the question becomes, which is better to lose, a house by fire or a life from fever?

Numerous instances were cited where the use of an emergency intake in the case of fire was followed by an epidemic of typhoid because of the polluted water which was pumped into the regular water mains.

Steel and Cast-iron Water Pipes

This topic was discussed by Allen Hazen. When large steel plates became available their fitness for use in the manufacture of high-pressure water mains was investigated. Steel pipe 30 inches in diameter costs about two-thirds as much as cast-iron pipe of equal strength and is believed to be in most places equally lasting, while because it is malleable it is much more reliable in trenches where bending and deformation from settling or shifting are liable to occur.

With the hundreds of miles of steel pipe in service there is no record of a destructive failure, while a break in cast pipe is invariably destructive and the flow continues until the reservoir is empty or the water is shut off. Steel pipe has not been standardized, but the earlier installations were designed by able men who established good precedents.

Surrounding steel pipe with concrete adds to its stability and durability and increases its cost, but not to the extent that will equal cast iron.

Fire-line Meters

In this paper, by George Housted, attention is called to the fact that many if not all of the insurance companies object to all types of water meters except one in fire lines on the ground that they catch trash.

Question was raised as to whether the particular meter named was not also a trash catcher in that it allowed debris to pass into the branches of a sprinkler system and choke the smaller pipes.

It was suggested that with the current type of meter on a sprinkler system any matter that would choke the smaller pipes would be caught by the meter, and even though it stopped the rotation of the propeller blades it would still allow enough water to pass to extinguish an incipient fire, while with the favored meter the matter that would choke the sprinklers would pass the meter only to stop the flow where it was most needed. Citation was made of a specific case in which there was no meter in the line and the pipe leading to a single room was choked as soon as a few sprinklers opened, causing a property loss of about $40,000.

Hot-water Troubles

George C. Whipple read a paper on the troubles that come from rusty hot water, due to the corrosion of iron and steel service pipes, tanks and boilers. The list of natural waters which cause corrosion included nearly if not quite all not distinctly alkaline. No one remedy is suitable in all cases, but, where practicable, lime or soda ash and the use of appropriate materials in pipes and heaters is advised.

The Purification of Drinking Water

The above was the subject of a paper by John L. Leal. As about 70 per cent. of the weight of the human body is water the importance of wholesome water is evident. It should not contain either organic or inorganic matter enough to interfere with its inherent properties, nor should it carry specific germs of disease.

Rain water, when it reaches the earth, is already fouled by impurities taken from the air, and in soaking into the ground is still further polluted by bacteria and soluble matter in the upper layers of soil. Filtration, which purifies it to some degree, takes place as it passes through the pervious soil to some impenetrable stratum along which it flows until it reaches its lowest level, where it is held or finds its way to the surface at some point below the ground level. Such water is usually of a high degree of purity, though due to a loose, shallow soil and crevices, springs which are fed by what is practically surface water may supply water impregnated with typhoid germs.

Sedimentation, said [illegible], mechanical filtration with coagulation, aeration and sterilization or disinfection have all been successfully adopted as means of water purification.

Sedimentation is an old method practised in ancient Babylon and Egypt. Sand filtration dates from 1829. In mechanical filtration and coagulation, the water is usually first treated with sulphate of alumina and then filtered through gravel and sand.

There are upward of 600 plants of this type in operation in the United States, and there seems to be little doubt that it is the most suitable practical system for water purification.

Oxonation has never been practically tested on a large scale, and sterilization has had only a limited application, the first time it was ever used in a continuous process being at Boonton, N. J., in 1908. However, the sterilization process marks a great step in advance on account of cheapness, simplicity, efficiency and certainty.

Wisconsin N. A. S. E. Convention

Eleven years ago Milwaukee was the scene of the national convention of the National Association of Stationary Engineers. During those eleven years there has been wonderful progress in the growth of the organization and it was freely said by those who had attended the national meeting that the late State meeting held there June 8, 9 and 10 was larger and better in many ways.

H. J. Mistele, chairman of the local committee, presided at the opening exercises and introduced Mayor Emil Seidel, who delivered the address of welcome. The response was by State President A. A. Schroeder, of La Crosse, following which Fred W. Raven, national secretary, spoke on the "National Association of Stationary Engineers."

E. P. Gould, secretary of the Central States Exhibitors' Association, was also called on for a few remarks regarding the business end of convention work, and R. D. Tomlinson, of the Allis-Chalmers Company, who is a past national president of the organization, gave a short address.

Educational work was prominent during the convention. John W. Lane, editor of the *National Engineer,* in an address on the subject, gave many valuable suggestions for increasing the value of this department to the organization.

"Heat and Ventilation" was the subject of a lecture by B. J. Miller, of Milwaukee, some of the fundamental principles of this subject being taken up and explained in detail. Another lecture, that on the "Nonreturn Stop Valve," by E. P. Gould, of Chicago, contained a clear and concise statement of what this important piece of equipment should be and of some of the defects which are commonly found in its operation.

On Friday afternoon a visit was made to the plant of the Richardson-Phenix Company. The smoker given by the Central States Exhibitors' Association in the main dining room of the Plankington house on Saturday night was presided over by Royal D. Tomlinson, and proved a great success in promoting good fellowship and good cheer between the engineers and the supplymen.

On Sunday morning a baseball game between the engineers and supplymen was the principal event of interest; the game was won by the former by a score of 12 to 3.

Officers for the ensuing year were elected as follows: William Classman, of Milwaukee, president; Henry Holst, of La Crosse, vice-president; Robert Fenn, of Sheboygan, secretary; John Murphy, of Madison, treasurer; H. Breitbach, of Stevens Point, conductor, and Dan Dreger, of Manitowoc, doorkeeper. The place of next meeting will be decided by the State officers.

The Wisconsin Delegation at State Convention

Exhibitors at the convention were as follows: Allis-Chalmers Company, American Steam Gauge and Valve Manufacturing Company, J. Andrae & Sons Company, V. D. Anderson Company, Chase Brothers Company, Crandall Packing Company, George B. Carpenter Company, G. M. Davis Regulator Company, Dearborn Drug and Chemical Works, Garlock Packing Company, Greene, Tweed & Co., Philip Gross Hardware Company, Hawk-Eye Compound Company, Hills McCanna Company, Hoyer Metallic Packing Company, Jenkins Brothers, H. W. Johns-Manville Company, Keystone Lubricating Company, Lunkenheimer Company, Lyons Boiler Works, Mechanical Appliance Company, Milwaukee Factory Supplies Company, Michigan Lubricator Company, *National Engineer,* Osborne High-Pressure Joint and Valve Company, Perfection Heater and Purifier Company, William Powell Company, Power, *Practical Engineer,* Richardson-Phenix Company, Scott Valve Company, Fred Sprinkman & Son, Steam Appliance Company, Swift Fuel Company, Vilter Manufacturing Company, Wadhams Oil Company, Western Iron Stores Company, Wickes Boiler Company.

Identification of Power House Piping

The committee of the American Society of Mechanical Engineers on the identification of power-house piping recently turned in the following report:

In the main engine rooms of plants which are well lighted, and where the functions of the exposed pipes are obvious, all pipes shall be painted to conform to the color scheme of the room; and if it is desirable to distinguish pipe systems, colors shall be used only on flanges and on valve-fitting flanges.

In all other parts of the plant, such as boiler house, basements, etc., all pipes (exclusive of valves, flanges and fittings), except the fire system, shall be painted black, or some other single, plain, durable, inexpensive color.

All fire lines (suction and discharge), including pipe lines, valve flanges and fittings, shall be painted red throughout.

The edges of all flanges, fittings or valve flanges on pipe lines larger than 4 inches inside diameter, and the entire fittings, valves and flanges on lines 4 inches inside diameter and smaller, shall be painted the following distinguishing colors:

DISTINGUISHING COLORS TO BE USED ON VALVES, FLANGES AND FITTINGS ONLY

Steam division	High pressure—white Exhaust steam—buff
